Dr. Burnham, of Toronto, showed the instrument and explained its mechanism. He had brought it from London for a relative affected with persistent tic, which had resisted all modes of treatment, but had apparently been cured by the use of the percuteur. About one hundred and fifty percussions were made in the second. Dr. Granville had found it very beneficial in neuralgias and the lightning pains of tabes.

SOME POINTS IN CHRONIC BRIGHT'S DISEASE.

Dr. Osler, of Montreal, referred: 1. To the fact that so many cases of chronic Bright's disease were unsuspected, and the physician was first called to see the patient with one of the grave manifestations, cerebral or otherwise; cases were given in illustration. 2. To some peculiarities in the onset of the uræmic symptoms; two cases were given; one in which violent mania ushered in the uræmic attack in a man in whom no kidney trouble had previously been suspected, and a second, a woman in whom pronounced hysterical symptoms preceded an attack of uræmic coma. 3. To the occurrence of fatal uræmic symptoms at a very early stage of renal cirrhosis, while indeed, the coarse appearances of the kidneys were fairly normal. Two instances were given of sudden and fatal uræmic symptoms in men—apparently healthy— and the condition of the kidneys was such that they would have passed a superficial inspection, but on microscopical examination changes were found in the form of atrophy of some of the tufts and slight epithelial alterations.

Dr. Graham spoke of the great importance of the sphygmograph in the diagnosis of these cases, and referred a remarkable instance of chronic Bright's disease in which, with pronounced uræmic symptoms and finally death, the amount of urea was not reduced.

Surgical Section.

Dr. Tye, of Chatham, in the Chair.

Dr. Holmes, of Chatham, read an interesting paper on *Erosions of the Female Urethra*, which was discussed by Drs. Fulton and Sheard.

Dr. Hingston, of Montreal, showed to the Section a *note-book* which he had prepared *for ovarian and abdominal tumors*, and which he thought might be of some service.

Dr. Major, of Montreal, described the various *tumors* met with in *the naso-pharynx*, and the modes of removal. Several interesting specimens were shown.

Dr. Oldright read the notes of a case of *Fibro-myxoma of the Thigh*, and exhibited the specimen.

Dr. Poundfoot, of Montreal, read an article on *Color-Blindness*, and exhibited Thomson's instrument.

Public Health Section.

A meeting of the health officers and others interested in sanitary matters was held to discuss the proposed Sanitary Association. Dr. Sweetland, of Ottawa, was appointed Chairman, and Dr. Campbell, of Seaforth, Ont., Secretary.

Mr. Boxer, C.E., of Montreal, was invited to address the Section, and state what steps had been taken in the way of organization.

Dr. Oldwright moved, seconded by Dr. Robillard (Ottawa): "That in the opinion of this Section it is desirable that a Canadian Sanitary Association be formed for the purpose of assisting in the diffusion of information, and engaging in discussion regarding sanitary subjects, and to aid by its influence the various bodies which are or may be formed for introducing and carrying out sanitary measures among the people of the Dominion." Carried.

Mr. Boxer then presented the scheme which had been framed for the establishment of a Public Health Association for the Dominion, and after discussion the meeting adjourned.

The afternoon and evening were spent in an excursion among the Thousand Islands.

Friday, Sept. 7th, Third Day.

Morning Session—General Meeting.

After the reading of the minutes, on motion of the Secretary, the papers of Drs. Buller, Workman, Brouse, and Gardner were taken as read.

Dr. Saunders, of Kingston, called the attention of the members to a remarkable case of *Tumor of Bones of the Skull* in a child in one of the ante-rooms.

The Nominating Committe reported the following list of

OFFICERS FOR THE ENSUING YEAR:

President.—Dr. Sullivan, of Kingston, Ont.

Vice-Presidents.—*Ontario*, Dr. Thorburn, of Toronto; *Quebec*, Dr. Robillard, of Montreal; *New Brunswick*, Dr. Christie, of St. John; *Nova Scotia*, Dr. McDonald, of Londonderry; *Manitoba*, Dr. Lynch, of Winnipeg.

General Secretary.—Dr. Osler, of Montreal.

Treasurer.—Dr. Sheard, of Toronto.

Delegates were appointed to the American Medical and the American Public Health Associations.

Montreal was chosen as the *next place of meeting*, the date to be arranged by the President and Secretary in order to place it a few days before that of the British Association for the Advancement of Science, which meets in Montreal towards the end of August, 1884.

An invitation to meet in Winnipeg was received, but it was thought that in a year or two the means of communication would be better, and the members from the older Provinces could then get there with less inconvenience.

Dr. Bristol, of Napanee, and Dr. Thorburn, of Toronto, brought up the question of the *Standing of Militia Surgeons*, and moved a series of resolutions embodying changes which it was hoped the government would be able to effect.

The routine business was then transacted, after which the Association adjourned.

PHILADELPHIA ACADEMY OF SURGERY.

Stated Meeting, June 18, 1883.

The President, S. D. Gross, M.D., LL.D., D.C.L., in the Chair.

Dr. J. Ewing Mears presented a patient in whom

COLLES' FRACTURE OF THE RADIUS

had been very satisfactorily treated with the splint devised by Dr. Coover, of Harrisburg.

Mr. D., about six months ago, while walking along the street, near Broad and Chestnut, slipped on the ice, threw out his hand to protect himself, as is usual, and sustained a fracture of the radius just above the lower extremity. He told me he distinctly heard the bone snap. After the fall he rolled over on his back. A few minutes later he came to my office with a friend, and on examining the arm I found the usual well-marked symptoms of fracture at the lower extremity of the radius. The silver-forked deformity was very distinct. I also detected a luxation of inter-articular fibro-cartilage. Making extension and counter-extension with a good deal of force, I reduced the fracture, and thought that I had reduced the luxation of the cartilage, but I think that there is some evidence that it was not entirely reduced at that time. I then applied a temporary splint, and on the day following applied the splint which I now show, and which is, no doubt, familiar to the Fellows of the Academy.

I use this splint because it seems to especially fulfil the indications in fractures at this point. It is also very comfortable to the patient. In this it differs from the ordinary Bond splint, which is not a comfortable one. This splint is light, it is hollowed out for the reception of the ball of the hand, and it allows free movement of the fingers, which is important in these fractures.

On the second day I removed the splint and reapplied it. At the expiration of the first week, I began passive motion, guarding well the point of fracture. This was repeated twice a week during the entire progress of the treatment. I think to this is due, is great measure, the excellent movement which Mr. D. enjoys at this time.

The deformity is not very marked. He can flex and extend the hand freely and has also good lateral movement and pronation and supination.

Dr. Charles B. Nancrede exhibited a

FATTY TUMOR

which he had removed from beneath the aponeurosis of the occipito-frontalis muscle of a child, sixteen months old. The specimen is only interesting from the position in which it was found. It is nothing but a fatty tumor, but I question very much whether any of us have ever seen a fatty tumor in this position before. I know that there are at least two tumors that are said to have been removed from the same position, but whether they were under the aponeurosis or congenital, I cannot say. I removed this tumor, which was as large as a fist, this morning, from a child sixteen months old. It had been detected when the child was three months old, and therefore must have been congenital. It was then about the size of a bean, and rolled freely beneath the skin. When I saw it, it was just about the occipito-parietal portion of the skull. The bone was indented by it. From the fact that it was not a meningocele, that it was not a vascular growth, that it was congenital, that the skin moved freely over it, and that the exploring-needle showed that it contained no fluid, I thought it was fair to conclude that it was a dermoid tumor. I thought of fatty tumor, because it had been so diagnosed by Dr. Bennet, but I had never heard of a fatty tumor occupying this position. The operation showed it to be beneath the aponeurosis of the occipito-frontalis muscle, where no fatty tissue exists. A careful microscopical examination shows that it is a fatty tumor. I thought that possibly it might be myxomatous, but the microscope does not show it.

In the last edition of Gross's *Surgery* it is stated that Dr. S. W. Gross removed a tumor from this position. The patient was an adult, therefore I presume that it was not congenital and was not beneath the aponeurosis.

CORRESPONDENCE.

DISINFECTION.

To the Editor of The Medical News.

Sir: The "special article" on Cholera Disinfection, in your issue of September 1st, seems to me of sufficient importance and authority to justify me in pointing out certain errors which have crept into it. These errors are of a kind common enough in medicine, viz., statements, apparently probable by themselves, but not really based on definitely proven data. A disinfectant should not be recommended on theoretical grounds, but its application should depend on the results of actual and conclusive experiments to the point. We do not know as yet the nature of the cholera germ, however likely its existence appears. Hence, not knowing how difficult it is to destroy it, we should certainly make use only of those disinfectants which trial has shown to be the most destructive to micro-organisms. Otherwise we can but lull ourselves into a dangerous feeling of false security. This is equally true of disinfection in typhoid fever. For, while we yet lack absolute certainty as to the cause of this disease, we suspect, at least on just grounds, that the bacillus discovered by Eberth in the tissues represents the virus of typhoid fever. The bacillus is known to produce spores, and it is equally well known that in the state of spores micro-organisms offer by far the greatest resistance to antiseptic influences.

Of the disinfectants mentioned in the article, corrosive sublimate is decidedly the most reliable one according to all experiments. One part in five-thousand of fluid proves destructive at once to the most resistant spores. But, if substances are present which can unite chemically with the mercuric bichloride, and then convert it into mercuric combinations either insoluble or of less poisonous action upon bacteria, we require evidently a much larger proportion of the corrosive sublimate in the first place in order to get its disinfectant action. The alvine evacuations contain extractives, and in the case of rice-water discharges also mucus and albumen, so that a large proportion of the mercuric salt is practically wasted by entering into more or less inert combinations. How large a proportion of corrosive sublimate is required to get a disinfectant action upon the micro-organisms contained even in the healthy passages has never been determined by experiment. Perhaps the safest rule to go by for practical purposes, would be the directions given by Koch in the Report of the German Board of Health, who found that the presence of one part of *free ununited* corrosive sublimate in five-thousand parts of a solution is indicated by the amalgam formed on the surface of a polished piece of sheet copper in less than half an hour, which test fails when the mercury is in another state of chemical combination.

Quite different is the antiseptic power of chloride of zinc, so strongly recommended in the article. Koch found it harmless to spores in any concentration, while a one per cent. solution did not affect developed micrococci within sixteen hours' exposure. Bouvet sought a reason for its extensive surgical application in Germany in the fact that it renders an albuminous soil unfit for the development of bacteria, though it does not kill the latter. Sternberg required a two per cent. solution of chloride of zinc to destroy the micrococci of pus, though a half per cent. sufficed in the case of the septicæmia-micrococci. He does not mention any experiments with more resistant bacteria or spores. Hence, if the evacuations contain no spores, the proportion of chloride of zinc mentioned in the article might perhaps be barely sufficient for disinfection were not a part of it precipitated by uniting with organic substances, but if spores are present, which we must expect until the contrary is proven, this substance can be of no value whatever. Its power of arresting bacterial development while present in the mixture is of no account, for as soon as the evacuations are diluted with the contents of the cesspools or sewers, the percentage of chloride of zinc falls far below the proportion necessary to maintain this temporary antiseptic effect. The perfect disinfection of evacuations requires the absolute destruction of the contained germs before the material is thrown into the sewerage. On this account, carbolic acid cannot be trusted implicitly without an impracticable delay in time. For, while this agent destroys almost at once all developed micro-organisms, when present to the extent of two per cent., and probably even in a concentration of half to one per cent, it does not act upon spores in a five per cent. solution unless the exposure lasts longer than twenty-four hours. As regards the metallic sulphates, especially the iron copperas, I know of no investigations justifying their employment. On the other hand, Koch found them wholly inert with reference to spores, while Sternberg could not kill even the more vulnerable micrococci by an exposure of two hours to a sixteen per cent. solution of sulphate of iron.

The accurate experiments of Koch, Sternberg, and a few others, have shown that disinfection is not so easy a task as is usually supposed, even when we can immerse the material in the disinfectant fluid. Much more difficult even is aerial disinfection. Chlorine and bromine are certainly efficacious; but only when used in irrespirable quantities and with precautions requiring expert supervision. Sulphurous acid, on the other hand, has not proven reliable in the rigid tests made by Koch. In order to exert any effect at all, it must be present in such a proportion as to render it impossible to breath such air, and even under those conditions it did not penetrate well into the interior of thicker masses of material to be disinfected, while its effect on spores was very unsatisfactory. The employment of aerial disinfectants in an inefficient manner should certainly be discouraged, for the feeling of false security which it engenders, can but lead to the neglect of other precautions. The disinfection of the walls of rooms can be accomplished much more thoroughly by washing with antiseptic solutions, corrosive sublimate, chlorine and bromine water, or carbolic acid, when the wetting, moreover, of the dust adhering to the walls renders impossible the detachment of—living—particles by concussions or currents of air. For *wet* particles cannot be detached as readily as dry germs—if at all—from the surface to which they adhere, so as to become part of the floating matter in the air.

Lastly, allow me to supplement the "special article" by emphasizing the necessity of thorough ventilation, not alone with reference to its salutary effect upon the patient himself, but more so on account of the dilution of the aerial germs which it produces. Common medical experience, perhaps in typhus fever more than in any other disease, has shown that the danger of contagion increases in proportion as the air, breathed by the patient, is confined within walls. Though this may not apply in the case of diseases, the virus of which is confined to the more solid excreta, like cholera or typhoid, it is still best to insist at every fit occasion upon the utility, too much underrated by the profession and the laity, of thorough ventilation in the prophylaxis of contagious diseases.

H. GRADLE, M.D.

CHICAGO, September 1, 1883.

[The criticism of Dr. Gradle on our "Special Article" on disinfection, whether well founded or not, will serve to increase the interest, now too languid, on this important subject. He rightly states that only properly conducted experiments are of value; but he rashly assumes that our views were based on theoretical notions. Every agent referred to in the article in question has been the subject of numerous experiments. But Dr. Gradle appears to have no confidence in any observations not made on germs, and he seems doubtful of any experiments that do not have the stamp of Koch's laboratory. Admitting the existence of germs that are supposed to stand in a causative relation to certain diseases, must our disinfectants be limited to their destruction? Is not the fixation of organic matter, so that further changes, including the growth of minute organisms, cannot take place, a proper object of chemical disinfection? Dr. Gradle merely echoes the statements of our article when it is asserted that the most powerful aerial disinfectants are only effective, if at all, in an irrespirable quantity; but articles of a movable kind, unoccupied halls and rooms, can be saturated, so to speak, with chlorine and other gases. Dr. Gradle fears that the public will be lulled into a false security by the use of well-known and long-tried disinfectants that have not been shown to destroy spores—would he therefore discourage their employment? Until Koch follows the spores into the air, and discovers some gas which arrests their development whilst it does not harm the sick and their attendants, must we not utilize the agencies under our control? Will not the spores which resist chlorine, cease to grow when their pabulum is destroyed?—ED.]

THE ARREST OF HEMORRHAGE BY MEANS OF SURGICAL NEEDLES AND SILK LIGATURE.

To the Editor of THE MEDICAL NEWS.

SIR: The article of Dr. Allis in THE MEDICAL NEWS for September 1st on a special method for the arrest of hemorrhage during operations induces me to send for publication the details of the manner in which I have been controlling hemorrhage during operations for the last fifteen years. I have never seen Dr. Allis's forceps used, but I feel confident that they cannot be any more readily applied than the needles. With me it has for the last several years been a consideration to use as few instruments as possible. The various uses to which a single instrument can be put often enables a surgeon to dispense with quite a number of special ones, and if the experience of other country surgeons is similar to my own, one is saved the frequent vexatious annoyance of having the assistants hand the wrong instrument, which is almost certain to happen when one is most in a hurry, unless the assistants are extra well posted in the names of the legion of modern surgical appliances.

Before commencing an operation, if bleeding from small vessels is anticipated, I always thread a number of straight and curved needles with five or six inches of silk ligature, and lay them aside for use. As soon as hemorrhage becomes troublesome, an appropriate needle is selected, and being seized with a pair of Nicol's needle-holding forceps, the point is passed down and under the bleeding vessel, and brought out at a point opposite the point of entrance. The silk ligature is then passed by two or three figure-of-eight turns around both ends of the needle sufficiently tight to compress the bleeding vessel, and, at the last turn, the thread is pulled tightly under the end of the needle, and allowed to hang loose. When completing the dressing of the wound, the thread is unwound and needle withdrawn; if necessary, the artery can then be ligated or twisted. Respectfully yours,

H. OTIS HYATT, M.D.

KINGSTON, N C., September 6, 1883.

THE JOHNS HOPKINS UNIVERSITY.

To the Editor of THE MEDICAL NEWS:

SIR: From the number of editorial and other notes which have appeared in your valuable paper, it is evident that you take much interest in the future Johns Hopkins Medical School. But since that is not yet open, it may be interesting to look into what the other part of the University is doing for the advancement of medical education.

The faculty have recognized the fact that the collegiate education of one who intends studying medicine should be quite different from that of the future lawyer, classic scholar, divine or scientific specialist. They have therefore arranged a course of study, preliminary to medicine, which, being very practical, it would be well to glance at.

Chemistry and biology predominate. In chemistry, experimental lectures and recitations are given daily (for two years), on general chemistry (metals and nonmetals), organic chemistry and chemical philosophy. Besides, two years' work in the laboratory comprises a good course in the study of the elements, in chemical analysis (qualitative and quantitative), the preparation of various compounds, etc.

The course in biology consists of lectures on general biology (with laboratory work on typical individuals of plant and animal life), lectures and recitations on human and comparative osteology; lectures and laboratory work on the embryology of the chick, during the first year; and during the second year, lectures and laboratory work on physiology, histology, and mammalian anatomy.

The importance of these courses cannot be overrated.

Beside these there are one year courses in physics (experimental lectures, recitations, and laboratory work), in German, and in French; and elementary courses in history, English literature, and composition, and philosophy (ethics, logic, and psychology).

This plan is preëminently scientific, and it lays a good foundation in those sciences, which are at the basis of medicine. The great amount of laboratory work in different directions trains the student well in the *modus operandi*. How few are able to experiment "scientifically?"

Before closing let me add, that all who obtain the B.A. degree at the end of this course have at their matriculation, shown considerable familiarity with the classics and with mathematics.

It is very evident that this training prepares one excellently for the rational study of medicine.

Yours, H. F.

BALTIMORE, September 6, 1883.

NEWS ITEMS.

Yellow Fever at Pensacola.—During the past week there were thirteen deaths from yellow fever at the Pensacola Navy Yard. The latest telegrams now report all the cases as convalescing, and no new cases.

The cordon around the yard has been strictly maintained, and no cases have been reported outside of the naval reservation.

Yellow Fever at Havana.—There were eighteen deaths from yellow fever in Havana last week.

Cholera in Egypt.—The last reports from Alexandria state that numerous attacks of cholera still occur there, but that the average daily death-rate is reduced to four. The mortality in the provinces is stated also to be rapidly diminishing.

The total mortality from the beginning of the epidemic to the 15th of August is 21,524, and includes the residents of more than 200 towns and villages.

The responsibility for the unsanitary condition of Egypt is still unsettled. While Sir Edward Malet exonerates the Ministers from the charges of negligence brought against them on the ground of the utter incapacity of the Board of Health, the President of that Board and the Minister of the Interior are exchanging public congratulations on the zeal and success of their common efforts towards suppressing the cholera.

Dr. Schaffey Bey, who was despatched by the Egyptian Government to report on the origin of the cholera outbreak at Damietta, and whose opinion deserves thoughtful consideration, finds no history of importation from India, but he describes the existence in and about Damietta of precisely the same conditions which obtain in connection with the genesis of cholera in the Indian delta of the Ganges. Apart from local filth, he regards these conditions, however, as exceptional in the case of the Nile delta, and he describes how the special fouling of the water with the carcasses of animals which had died of bovine typhus, and how the orgies that prevailed during an eight days' fair which immediately preceded the outbreak, tended to favor the epidemic.

The French Cholera Commission has been most favorably received by the Egyptian authorities. M. Strauss, the chief of the commission, unhesitatingly pronounces the disease to be cholera.

The Commission has notified the French Government that the epidemic in Egypt is extinct.

M. Dumas, Perpetual Secretary of the Academies des Sciences, has received a telegram from M. Pasteur, under date of August 26th, stating that he had received that morning telegrams from the Cholera Commission in Egypt announcing some curious and novel observations.

Harvard Medical School.—The Medical Faculty of Harvard University will celebrate the centennial anniversary of the establishment of the school on October 17th. Dr. Oliver Wendell Holmes will deliver an oration, after which the new building recently erected for the college on Boylston Street will be dedicated.

The Ohio and Miami Medical Colleges.—Lectures were begun at these colleges, in the first week of September, according to the *Cincinnati Lancet and Clinic*, and the classes were from ten to fifteen per cent. larger than were ever before present at the opening of the session, and there are good prospects for a considerable increase over the large classes of former years.

Association for Diseases of the Respiratory Organs and Climatology.—A meeting for the purpose of organizing the national "Association for Diseases of the Respiratory Organs and Climatology" will be held in the parlors of the Academy of Medicine in New York on Tuesday, September 25th, at ten A.M.

Administration of Anæsthetics in Vienna.—The Vienna correspondent of the *Maryland Medical Journal* says that the administration of anæsthetics is conducted there in a way that "would make The Philadelphia Medical News turn purple with indignation. In some clinics pure chloroform is used, in others a mixture of chloroform three parts, ether one part, alcohol one part. The anæsthetic is poured upon a piece of flannel, which is stretched over a wire frame, which probably allows a sufficient admixture of atmospheric air, but no attention is paid to the position of the patient, the head and thorax being placed high or low according to the fancy of the operator, and it is no uncommon thing to see the administration being pushed with the patient in the upright position and vomiting. A few days ago I saw a boy suddenly become pale and pulseless, and it was only after the most vigorous artificial respiration, with galvanism, enveloping the legs with Esmarch's bandage, injections of ether, elevation of the lower limbs, forcible injection of cold water against the pericardium, and brisk flagellation that he was eventually restored to life."

Sir Spencer Wells.—It is announced that Sir Spencer Wells has been elected an Honorary Fellow of the Physico-Medical Society of Erlangen.

M. Verneuil will represent the Society of Surgery of Paris at the next International Medical Congress. M. Depres was invited to accept a commission, but he replied that he made it a rule never to attend "scientific fairs."

The French Cholera Commission.—M. Jules Aronssohn, Professor of Organic Chemistry at Paris, is charged with a scientific and medical mission in Egypt, where he will study cholera from an etiological point of view, while studying, at the same time, the physiological chemistry and therapeutical indications.

A Fatal Spider-bite.—Chancellor Carroll, of South Carolina, died on August 24th, at Cæsar's Head, from erysipelas following the bite of a spider. About a week before, this eminent jurist was walking in the woods about the famous mountain peak, and his face came in contact with a spider-web, which was suspended between two trees. The spider alighted on his chin, near the under lip, the Chancellor brushed it off with his hand, but was bitten by it in the mean time. He was attended in his illness by Dr. F. A. Miles, but after a week's suffering the distinguished jurist succumbed to the results of the spider-bite.

The Death of Louise Lateau, the stigmatica of Bois d'Haine, who attracted so much attention in medical circles a few years ago, is announced. This singular being was born on the 30th of January, 1850. She made her first communion at the age of 11 years, and began to earn her living as a seamstress at the age of 15. During the cholera visitation of 1866, she exhibited much devotion in attending to the wants of the pest-stricken. In 1867 she was attacked with a lingering malady, and received the last sacraments. She was, however, cured (miraculously, said her friends), but only for a short time. Early in 1868 she was said to have first experienced pain in the locality of the stigmata, and she again received the last sacraments. It is alleged, nevertheless, that she foretold her recovery, and on April 21st she appeared completely restored to health.

The first outward indication of the stigmata is said to have taken place on the 24th of April, 1868, when a wound in the side was visible, which healed the next day. On the 1st of May blood was reported to have issued from the upper surfaces of her feet as well as from her side, and she then confided the matter to M. le Curé. Seven days later the stigmata of the hands added themselves to the others, and M. le Curé advised her to apply to the physician of Fayt, who attempted to cure her. In the course of 1868 several evidences of ecstacy are said to have occurred, and on September 25, 1868, the crown of thorns first appeared. After this she ceased to sleep. Her alleged complete abstinence from all nourishment began on the 30th of March, 1871, and the wound on the shoulder appeared in the following April.

The case attracted great attention at the hands of medical men, physiologists, and psychologists, and numerous pamphlets appeared on the subject. Difficulties were interposed in the way of a thorough sifting of the case, but it was pronounced a gross imposture by many who had an opportunity of investigating it.

SALICYLIC ACID IN CANNED FRUITS AND VEGETABLES.—It being known that salicylic acid is used in foreign countries, to a considerable extent, as a preservative agent in articles of food, and that the quantity used frequently exceeds the amount allowed by law, MR. J. D. DENNY has recently examined twelve samples of different canned fruits, all of which were put up by American firms, in order to ascertain whether, and, if so, to what extent, that preservative is used in this country. After a thorough examination, he was unable to find any trace of salicylic acid.—*Physician and Surgeon*, Aug. 1883.

DROPPING THE TITLE OF HOMŒOPATHY.—The homœopaths do not seem zealous to adopt the suggestion of the advocates of the New York Code, that they should drop their distinctive title. *The New England Medical Gazette* (Homœopathic) says: "If, with success perched upon our banners, we trail them in the dust, if we surrender our home and deny our faith for the sake of membership in societies with which we cannot affiliate, and for consultations which we do not want, we shall indeed be traitors to our trust, and our names will rightly be 'a hissing and a byword to all coming generations.'"

RESECTION OF THE STOMACH.—This operation was performed on July 25th, by DR. F. SUPERNO, at the Pondidera Hospital. The operation lasted two hours and three-quarters. Twenty-four hours afterward the patient was in a good condition.

TREATMENT OF QUININE FALSIFIERS IN FRANCE.—HENRI CONSTANT LACOMBE has recently been tried before the Tribunal Correctioné, in Paris, for adulterating a large quantity of quinine which he had contracted to furnish to the Assistant Publique in monthly parcels. The parcels gradually became worse, and a box received in November, 1882, was found to contain a surface layer of quinine, the remainder consisting of a fraudulent mixture, and the box received later, while still intact and sealed with the contractor's seal, was similarly filled, about four-fifths of the contents being fraudulent. The accused pleaded that it was the result of an error on the part of his assistant that the quinine was adulterated.

The Tribunal gave judgment: "That the falsification having been committed in regard to an article which the accused knew was to be used for the diseases of patients entrusted to public charity, no extenuation could be admitted. Lacombe is, therefore, condemned to imprisonment for one year and to pay fifty francs penalty. And the court orders that this judgment shall be affixed to the number of twelve copies, one of which shall be attached during twenty-four hours to the door of Lacombe's warehouse, and that it shall be inserted in full, at Lacombe's expense, in twelve newspapers, and medical and pharmaceutical journals. Lacombe to pay the costs of the action."—*Quinologist*, September, 1883.

HEALTH IN MICHIGAN.—Reports to the State Board of Health for the week ending Sept. 1, 1883, indicate that typho-malarial fever and dysentery have increased, and that scarlet fever and remittent fever have decreased in area of prevalence.

Including reports by regular observers and by others, diphtheria was reported present during the week ending Sept. 1, and since, at seventeen places, scarlet fever at twelve places, and measles at five places.

OBITUARY RECORD.—The *Gazette Hebdomadaire* announces the death of DR. E. A. HOMOLLE, at the age of sixty-nine years. His name is connected with the discovery and therapeutic employment of digitaline, and he has long been known as an original worker in experimental therapeutics.

NOTES AND QUERIES.

BICARBONATE OF SODA IN ACUTE TONSILLITIS.

To the Editor of THE MEDICAL NEWS.

SIR: In your issue of August 25th, I noticed a communication from Dr. Vinke, of St. Charles, Mo., on the subject of Bicarbonate of Soda in Acute Tonsilitis. I have used this remedy myself during the past year, and desire to add my testimony as to its efficacy. In all cases of acute inflammation of the tonsils I have found relief to be prompt and lasting from a few applications of the soda. On first seeing the patient I apply the remedy myself, being careful to cover the entire surface of the inflamed glands with the medicine, which I do by any convenient method that I may have at hand. This is done in the presence of some member of the family, who is directed to make the application in like manner three times a day till recovery takes place A second visit is rarely necessary, nor are more than three applications usually required.

This remedy is simple; always at hand, and requires very little skill in its application, yet in a large majority of cases will be found exceedingly effective.

Respectfully yours,

JAMES ORR, M.D.

TERRELL, TEXAS, September 3, 1883.

OFFICIAL LIST OF CHANGES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM SEPTEMBER 3 TO SEPTEMBER 10, 1883.

SHUFELDT, ROBERT W., *Captain and Assistant Surgeon.*—Granted leave of absence for three months on surgeon's certificate of disability, with permission to leave the Department of the South.—*Par. 3, S. O. 204, A. G. O., September* 5, 1883.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

ORIGINAL ARTICLES.

FEVER NOTES.

BY RICHARD McSHERRY, M.D.,
PROFESSOR OF PRINCIPLES AND PRACTICE OF MEDICINE, UNIVERSITY OF MARYLAND.

IT is not many years since there was a lively discussion in regard to the unity, duality, or plurality of some of the essential fevers, which, to most students of the present day, seems to be finally settled against the advocates of unity. *Conclusum est,* they would say, leaving no rational basis for argument. But granted that the dualists or pluralists have the right of it, there is often room in the mind of the practitioner for "obstinate questionings" as to what category the fever under treatment may properly come. Fever is undoubtedly more or less protean in shapes, and one form may merge into another, as, *e. g.*, to-day remittent, and to-morrow yellow; but it has common characters enough to entitle it to consideration independently of its varieties.

A great American authority of the last century says: "I shall not attempt to give a definition of fever. It appears in so many different forms that a just view of it can only be given in a minute detail of all its symptoms and states." (B. Rush.)

The American Medical Association attempts pretty successfully what Rush declines, thus: "Fever, *febris*, an acute affection of the system, with increased heat and derangement of all the functions."

Fever is then a very unquestionable entity, and the family likewise is so marked in its varieties as not unfrequently to cause difficulties in diagnosis or nomenclature:

"*Facies non omnibus una, nec diversa tamen qualem debet esse sororum,*" and, until science makes the living body quite transparent, some allowance may be made for the doctor's occasionally confounding congestive remittent with yellow fever, typhus with typhoid, or typhoid with acute tuberculosis. Any one may merge into the other.

Diseases will often deviate from the types so clearly laid down in the text-books; in fact, a real typical case agreeing throughout with its classical description is something of a rarity.

I saw but the other day some eight or ten cases of measles, where the eruption was not only measly, but purplish. The visitation was among boys picked up from the streets, poor, homeless little vagrants, who were taken to a house of charity, where they were to be taught useful trades, reading and writing and the catechism. The attending physician, Dr. Goldsmith, reported out of twenty-one cases taken ten deaths, and more in prospect. There was absolute adynamia, with rapid prostration, red and dry tongue, congested fauces, temperature, when exceeding 105° F., always indicating a fatal result, which occurred notwithstanding the liberal use of quinine and whiskey. Who ever sees such measles in ordinary practice?

I thought there was here a remarkable resemblance to typhus which I had seen some years previously in the same institution. Dr. John Morris, who saw these cases, remarked to me on the following day, that their whole condition and aspect reminded him of the Irish typhus as he had seen it in the Dublin Hospitals. Now, this predominance of typh-symptoms was due to over-crowding aided by sewer-gas. Tents were immediately procured for the sick, and improvement was immediate.

Thus, modifying circumstances, as ochlesis, may give to every fever quite a change of type or form. Our once great authority, Rush, says, "There is but one fever," no matter what its source, cause, or development; "we might as well say that men are of different species because they are tall or short, or because some are long and others short-lived, as that fevers are of different species because they vary in their symptoms and duration." We need not accept such view to make the assertion that fever has certain unities never obliterated by its forms, and that some of these defy strict nosological arrangement. I have frequently had to treat continued fevers that did not correspond textually with any one of the three predominant forms, typhus, typhoid, or typho-malarial.

In 1879 I attended many cases of continued fever in this city, which had some peculiar characters, and of which I gave a brief verbal account at a meeting of the Baltimore Academy of Medicine. The reporter (*Maryland Medical Journal*), following my language pretty closely, says, "Dr. McSherry spoke of the so-called typho-malarial fever. It is not distinctly typhoid, nor typhus, nor malarial, though doubtless there is in it a malarial element. He should be disposed to call it 'typh-fever,' after Chambers. Quinine will not break it up. A remarkable feature about it is the disproportion in the pulse and temperature. For instance, in one case the temperature was 103° F. while the pulse was 80, and this relation continued for about three weeks. Once the pulse went up to 108, but the temperature then was 107° F. With such a temperature as this we should have a right to look for a pulse of about 160. The patient recovered. He had heard of a case in which the temperature rose to 109° F., with a fatal result. In the case of a medical student, æt. 24, when first seen the temperature was 102° F., the pulse 92; the next morning they were respectively 105° F. and 86. The highest pulse-beat at any time was 96, the temperature being at the same time 104.1° F. He read from a letter just received from Prof. Bartholow, of Philadelphia, in reply to some inquiry upon the subject. Prof. Bartholow said that he had seen many such cases in Cincinnati, and that the disease was there called typho-malarial fever. He had obtained the best results from the following:

"℞.—Tinct. iodin.,
Acid. carbolici, partes equales.
S.—Gtt. j–ji quartâ vel sextâ quaquâ horâ.

"Quinine, he says, does nothing more than reduce the pyrexia. When diarrhœa occurred he used liq. potass. arsenical. gtt. j and tinct. op. deod. gtt. ij-v every four hours.

"Dr. McSherry thought quinine was wantonly wasted under German authority," etc.

I will recur to the use or misuse of this potent agent a little later.

Several other members of the Academy reported at different sittings, cases more or less resembling those. Thus in Dr. McKew's experience: "It is a continued fever lasting five or six weeks, with somewhat erratic thermometric phenomena, no diarrhœa as a rule, no rose spots, no intellectual impairment, no involvement of the pulmonary mucous membrane, no tenderness in the iliac regions, tongue free from typhoid characters. One case exhibited very obstinate constipation."

Dr. Thomas, Dr. Van Bibber, Dr. Williams, and Dr. O'Donovan gave accounts of their fever cases. Dr. Thomas considered his to be typho-malarial; not so Dr. McKew, who said "there was nothing of the typhoid character in it except continued fever. It is a zymotic poison, the nature of which is entirely unknown."

As the world is very intolerant of nameless diseases, we may call such cases typho-malarial in our daily rounds, conventionally, whatever may be said of them in medical discussions.

Malarial fevers proper are pretty uniformly held to be *intermittent* or *remittent*, but they may be *continued*, at least, without any typhous complication. A very excellent paper on this subject, under the title of "Fevers of the Mississippi Valley," appeared in the American Journal of the Medical Sciences (April, 1881), from the pen of Dr. R. B. Maury, of Memphis.

The malarial continued fever is not to be confounded with the bilious remittent, which, as Dr. Maury says, has a natural tendency to defervesce on the fifth day, may be terminated on the third, and only in exceptional cases will last until the seventh or ninth day.

The malarial continued, on the other hand, "presents a stadium of increase of about one week, a stadium of height of about five or six days, and a stadium of decrease, which terminates completely on the twenty-first day."

Is this typho-malarial fever? By no means, though often so designated.

"Its thermometric range is decidedly lower than that of typhoid. It seldom goes above 103.5° F. Vomiting of bile is a common symptom during the first days of the attack. Bronchial catarrh is generally present. Constipation and a concave abdomen are marked features."

Appreciable splenic dulness or enlargement was very rarely observed.

"All the essential features of typhoid or enteric fever are absent. There is no diarrhœa, no ileocæcal tenderness or gurgling, no meteorism, no eruption of rose-colored spots. As a rule, there is entire absence of abdominal symptoms."

This form begins, continues, and ends, says Dr. Maury, as a continued fever. It is somewhat notable that he declares "its duration to be in no way affected by the exhibition of antiperiodic remedies. The 'status typhosus' is not one of its characteristics. When it occurs it is exceptional, and is due to extraneous causes. The abdominal symptoms are absent, hence there would seem to be no relation to typhoid."

Some of our Baltimore cases correspond pretty much with those reported by Dr. Maury. I do not observe in them, however, any irregular relations between pulse and temperature, as noticed in this city and elsewhere, in our continued fevers, however they may be designated.

Prof. Johnston, of Washington City, describes some cases of mild continued fever which prevailed in that community (American Journal of the Medical Sciences, October, 1882). In his view such cases are truly typhoid, however imperfect the development. He gives an illustrative case of continued fever without typhoid symptoms for sixteen days, after which the patient was taken unexpectedly with "vomiting and violent pain in the abdomen, which soon became tense and painful; he was restless and very thirsty. The temperature had risen to 104° F., and continued to rise, and the pulse was 154. During the day he sank into collapse, with cold sweats, and died at 10 A.M. on the following day. The diagnosis of typhoid fever was justified by symptoms pointing clearly to intestinal perforation."

We suspect that Dr. Woodward would have had no hesitation in calling this an attack of typho-malarial fever.

It may be noted, *en passant*, that Dr. Johnston, in speaking of the influence of quinine upon his cases, says, "It lowers the temperature, but does not arrest the disease."

What must we think of this continued fever that in so many experiences resists quinine? It is not typhus, but is it malarial, typho-malarial, or typhoid? Or none of these, but one *sui generis?* The fact is, that with all our efforts at precision, and with all our attempts to confine a disease in a nosological strait-jacket, it will not be so restrained, for the simple reason that it rarely arises from a single cause, or if the cause be single, as some one miasm, contagium, bacillus, or germ, there are always modifying conditions to change its nature, as in the measles presented in the early part of this paper.

The medical sagacity which never makes mistakes in diagnosis, considering the liability to changes of form in most maladies, is rarely quite trustworthy. Yellow fever, for example, may come on as a remittent—indeed it is usually a remittent—the remission occurring, according to Sternberg, on the third, fifth, seventh, or ninth day; just as Maury says of the Mississippi remittents: "This fever often terminates on the third day; as a rule, it subsides on the fifth day. In the fall, it is occasionally prolonged until the seventh, and I have seen it prolonged to the ninth day."

Are not such observations very suggestive? I myself have seen corroboration of the following statement made by the late Dr. Fenner, of New Orleans:

"Physicians may say what they please about being able to distinguish a case of yellow fever as soon as they examine it. We do not believe it possible according to their ideas. Rarely does a summer pass in which we do not hear of some intelligent and experienced practitioner being perfectly astonished at what he had pronounced a case of intermittent or remittent fever terminate in black vomit or other hemorrhage."

Besides the cases of my earlier experience in the tropics, and subsequently among cases coming hither from Norfolk and Portsmouth, in 1855, I have seen an isolated case much more recently in which the patient was attacked, as I learned upon sufficient authority, with a remittent form of fever six days before his death. Under the influence of quinine, the fever remitted, but, before his death, the patient became quite yellow, and passed, while unconscious, bloody urine in bed. Urine drawn when dying gave no blood or albumen, but there was a pretty lively fermentation when nitric acid was added. I saw him only in this condition, and remarked then that I had seen similar cases in which black vomit was found in the stomach *post mortem*, though none had been ejected. And so it turned out. Upon examination of the viscera, the lungs showed at the base hypostatic congestion; the heart was soft, as in low fevers; the liver very small and anæmic; the kidneys congested, and showing various hemorrhagic spots of rupture or exudation. The bowels were congested. The mucous membrane of the stomach was somewhat eroded, and there were perhaps eight ounces of what would surely have been called in Vera Cruz *vomito prieto*, though, it being an isolated case, the physicians did not think it advisable to publish it as yellow fever. [I have since learned indirectly that, notwithstanding the macroscopic resemblances to yellow fever, the microscopic examinations subsequently made gave results tending to show that very rare disease, acute yellow—or I should rather say *red*—atrophy of the liver.]

Dr. Rush says the physicians of Philadelphia had thirteen different names for yellow fever as it appeared there under his observation.

Now that Dr. Carmona, of Mexico, has found a yellow fever fungus as distinct as Koch's bacillus tuberculosis, perhaps modern pathologists may find a ready solution of all doubts in regard to the diagnosis of this particular fever. Perhaps they will; more probably they will not. The world teems with germs, no doubt, that are destroying agents, or potentialities, but it will be a long time before their exact relations are understood to the disease with which they are found associated. Every thing about us perishable, or all that "wears the muddy vesture of decay" seems to have a being prepared to consume it. One low creature may find its nidus and food in tubercle, another in the white corpuscles of the vitiated blood of eruptive fevers; and there be saprophytes for the last consumption of decayed organic matter, but these are consumers, not producers. Many pernicious bacteria, we must believe, carry infection, which is rather *adherent* than *inherent* in their natures.

In the treatment of our fevers until we learn to cure them all by germicide agents, and allow our patients to die of nothing but accident, or old age, we must consider how best to use the two opposite classes of reconstructive and spoliative remedies, which may be fairly represented by cinchona bark, mercury, and bloodletting.

Such are potent agents for good and for evil; we wish to get from them the most of the one and the least of the other. The bark (quinine) is antidotal to malaria, tonic in small doses, sedative in large doses. By some property (germicidal?) it neutralizes the poison of malaria; it helps to build up the debilitated subject; it is competent to reduce temperature. These are obvious influences. Perhaps, when properly used, it is the best drug in the materia medica. But it is not, therefore, a panacea. Such agent does not exist in medicine. Granted its potency against the direct pernicious influence of malaria, it is not of peculiar efficacy against secondary lesions. It no more removes the after-effects of the poison than the antidotal chalybeates would cure gastritis or other secondary effects from arsenical poisoning.

Many of its partisans place in it too exclusive a trust. I have many times given it day after day in all kinds of doses when fever was yielding, but with unmitigated malaise on the part of the patient until some mild mercurial would be given for a few days, when, *presto*, the patient would improve in every sense. In the case of a lady now under treatment, suffering with malarial malaise, quinine offended the stomach and impaired the appetite until a few fractional doses of calomel came to the rescue and gave much relief.

In the various cases and conditions previously referred to in this paper, quinine, whether useful or not, was inadequate to cure. It was given freely in the typhous measles with whiskey, without preventing the fatal issue.

It appears to the writer that there is a great waste of this valuable agent of late years as, *e. g.*, when given in large doses for the reduction of temperature, when so many other medicines, to say nothing of ice or cold water, answer such purpose quite as well, if not better.

But it may prove a mischievous agent withal. Dr. W. O. Baldwin, of Montgomery, Ala., has published observations upon this subject; and showing such facts more recently, a paper published in The Medical News of July 21, 1883, from the pen of Dr. E. D. McDaniel, of Camden, Ala., gives confirmation to such views.

Dr. McDaniel reports eighteen cases of hemorrhagic malarial fever in his own practice, in which there were thirteen recoveries and five deaths. It is very significant that in six cases in which no quinine was used the result is stated thus: "In the six cases without quinine six recoveries, or 100 per cent."

Whereas, it is also stated, "In twelve cases with quinine five deaths, or 41.66 per cent."

Besides these eighteen, Dr. McDaniel saw six other cases in consultation. He had given all of his own small doses of calomel, with or without quinine. In regard to these six, he says that calomel was used in larger doses, and quinine and spirit of turpentine were freely given. The result was five deaths and one recovery.

It is by no means easy always to appreciate cause and effect in medicine, but if these cases had all been treated *à la* Rush, with the free use of the lancet, the unfortunate result would have been attributed directly to that agency. Physicians still have something to learn as to the proper use of quinine and bloodletting; the one, according to the fashion of the day, being too much used, and the other too much neglected. May it not be safer to reduce fever by the abstraction of a few ounces of blood than by drugging the whole mass of it as it circulates through every viscus and tissue of the animal economy?

Let us bring quinine to its right and proper uses, and reserve it for such purposes.

As to eliminants in fevers they do not play an inferior part, except in counteracting the first effects of malaria.

The observers of the last century were not men to have eyes and see not, as the men of to-day seem to suppose. It is true our eyes are aided by the microscope and other instruments of precision, but our fathers had good-sense and good senses, and made good use of their gifts.

"Sir John Pringle," says Rush, "long ago taught the inefficacy of bark in certain bilious fevers. But Dr. Chisolm has done great service to medicine by recording its effects in the Boulam fever. 'Headache,' says the doctor, 'a heavy, dull eye, with a considerable protrusion from its orbit, low spirits, thirst, and a total want of appetite, were the general consequence of the treatment with bark without the previous antiphlogistic.'"

I know not what particular antiphlogistic was preferred in these cases, but I am quite sure that a vomit and a purge (say with ipecacuanha and calomel) in the beginning generally render efficient service. I do not doubt that Warburg's tincture, which so often does good when bark has failed, has its good effect by elimination, and just such elimination as may be obtained from mercury and aloes.

Dr. Murchison would sustain this view. Mercury, in his opinion, "exerts a beneficial action in many functional derangements of the liver, in whatever way this may be explained. Patients of the greatest intelligence, suffering from hepatic disorders, constantly declare that they derive benefit from occasional or repeated doses of mercurials which no other medicine or treatment confers; and the scepticism of the most doubting physician would, I believe, be removed should he unfortunately find it necessary to test the truth of their statement in his own person." (*Croonian Lectures.*)

And what fever is known in which there is not functional derangement of the liver? This same authority further remarks, touching such derangements resulting in lithæmia, "I have repeatedly known patients in this state improve at once on substituting abstinence from alcohol with aperients, blue pill, alkalies, and careful regulation of diet, for quinine, iron, the mineral acids, and stimulants; the strength, flesh, and color returning under what, at first sight, might have appeared a lowering treatment." I have often seen similar beneficial results from such change of management in many other morbid conditions as well as in lithæmia.

A medical address was sent to me some months since entitled "Fifty Years Ago," by Prof. Henry Gibbons, M.D., of San Francisco, which offers some interesting reminiscences as to the early use of quinine, *inter alia*, in this country. The white powder was brought from France, and "people were greatly astonished that eight grains of it should do the work of an ounce of bark, that is, arrest or break an intermittent. It was given with great caution. From eight to ten grains was the limited quantity. According to my recollection, the dose was more decidedly and permanently effectual than the large doses now employed. But the older doctors always prepared their patients first by a mercurial purge, or a few blue pills. They had an eye to the condition of the liver and spleen, and other organs which suffer from malarial diseases. Their practice in this respect might well be imitated by the present generation of practitioners, who too generally depend altogether on the one remedy in the treatment of intermittent fever."

The profession has become too much afraid of depletion, and has taken to depend too much upon quinine, tonics, and nervines. I attended a lady lately who has been a martyr to nervous headaches for years. A few small doses of mercury gave her more relief than any remedy she had previously taken.

I was called some months ago to a lady of full habit, whose flushed face, full pulse, and headache gave indications of cerebral disorder, perhaps of apoplexy. She was attended by an intelligent physician who had drugged her freely and had had her cupped on the back of the neck. I advised venesection, to which the doctor assented, and I drew from her arm about sixteen ounces of blood. Relief was prompt and, so far, permanent, for she has since been in better condition than for a long time previously.

We underrate the intelligence of our fathers when we pronounce that their bleeding and purging were all bad practice. That there was a great deal of bad practice in the abuse of such agencies may be freely admitted; but if we drop out of use all medicines capable of doing harm when misused, I know not what would be left, not even excepting chloride of sodium. Now, as of old, according to Ovid, *Nil prodest quod non possit lædere idem.*

The mercurial chlorides which had such vogue among the physicians a few decades back would not have commanded such universal confidence without some reasonable justification. Perhaps they will become rehabilitated in professional estimation as the germ theory advances, for, like quinine, they too are potent germicides, and it may be that a large part of their efficacy was due to this power, which was and is real, whether appreciated or not.

Be that as it may, I beg leave to declare, as the result of no small experience of my own, as well as that cited from others, that there is at this day too great reliance upon bark (quinine) to the neglect of depleting agents in fever; that quinine is not only wasted, but that it is used extravagantly, and even injuriously, and that *less* of it will accomplish a better purpose than *more,* when used with eliminants, always discreetly, of course, whether the agents be bloodletting, vomiting, or purging. An old-fashioned nitrous powder, or a few drops of Fleming's tincture of aconite, judiciously administered, will reduce fever more effectively than quinine, and then that transcendent agent may be used for purposes which no known medicine can equally well accomplish.

BALTIMORE, August, 1883.

ON THE VALUE OF IODINE IN MALARIA.

BY FRANK FINNEY, M.D.,
PHYSICIAN TO THE QUAPAW AGENCY, INDIAN TERRITORY.

IN view of the elaborate and carefully written article of Drs. Atkinson and Woods in the July number of THE AMERICAN JOURNAL OF THE MEDICAL SCIENCES on the use of iodine in malarial fevers, and an editorial in THE MEDICAL NEWS of July 7th on the same subject, I feel called upon to give a brief account of thirteen cases of malarial fever treated by me during September and October, 1882, which very strongly coincide with the experience given in the above-named article. The treatment of my cases differed slightly from the above mentioned, since in all of them I used iodine in combination with carbolic acid, as advocated in the editorial referred to. The combination I used was tincture of iodine one ounce, glycerite of carbolic acid one drachm. This mixture I gave to adults in fifteen to twenty-drop doses four times a day, reducing the dose in proportion to the age of the patient.

CASE I.—Female, age two years; quotidian intermittent; had been sick one week when I was called; gave castor-oil cathartic, and followed with the iodine mixture, four drops in water four times daily. The child recovered, after having two more slight chills, with no other treatment.

CASE II.—Male, age 13, quotidian intermittent; gave a cathartic, and followed with iodine mixture, fifteen drops four times a day. He had one slight chill, followed by temperature of 101°, after beginning the treatment, and then recovery was complete.

CASE III.—Male, age 20, tertian intermittent; treatment same as Case II., with complete recovery without a second chill.

CASE IV.—Male, age 50, quotidian intermittent; gave the mixture in twenty-drop doses four times daily for seven days without any improvement, when it was abandoned, and quinine given with almost immediate success.

CASE V.—Male, age 10, quotidian intermittent; gave eight drops four times a day, with gradual improvement in all of the symptoms, until the fourth day, when vomiting and diarrhœa set in. By the sixth day, these symptoms were so severe that the iodine had to be abandoned. I then gave bismuth and morphine, followed by quinine, with success.

CASE VI.—Female, age 8; treatment and result same as Case V.

CASES VII. and VIII.—Adult males, treated for quotidian intermittent for seven days with fifteen to twenty drop doses of the iodine mixture, without improvement. Quinine was then substituted with success.

CASE IX.—Female, age 5, suffering from chronic malaria; chills every third day. Gave five drops of the iodine mixture four times a day, with iodine tincture externally over the enlarged spleen. The result was gradual recovery after severe jaundice.

CASES X., XI., XII., XIII. were all adults suffering from acute quotidian intermittent fever, and were treated with the iodine mixture in fifteen to twenty drop doses four times daily. Nausea and vomiting became troublesome in Cases X. and XI. on the fourth and fifth days, and it was abandoned. The iodine treatment was kept up for six days in XII. and XIII. with no improvement, when quinine was substituted with the usual success.

It appears from the above notes that *four* out of the thirteen cases treated recovered under the iodine treatment, while the large majority of *nine* had to have the usual quinine treatment before the disease could be controlled.

THE ELECTRO-MAGNET IN THE EXTRACTION OF FOREIGN BODIES FROM THE EYE.

BY OLAF PAGE, M.D.,
OF VALPARAISO, CHILI.

ON the 10th of July a workman from one of the large foundries in the city presented himself at my consulting-room. He said a piece of iron had struck him in the left eye. On removing the bandage I found a clean cut through the lower eyelid about one-eighth inch long, and another equally clean cut through the sclerotic and lower third of the cornea and iris. A clot of blood completely filled up the pupil. Having procured an assistant, I connected the magnet with a Stöhrer's battery of twenty cells, and applied the point of the magnet to the wound. I immediately heard the clicking of the foreign body against the magnet, but on attempting to draw it out, it fell back into the eye. This I did three or four times, but finding the iron could not come through the linear cut, I got the assistant to hold the point of the magnet in the wound, and then, with a pair of iris-forceps, I was enabled to lay hold of the iron and literally drag it out. The fragment, on weighing, proved to be a trifle over eight grains. It was bayonet-shaped, with sharp, serrated edges.

In cases of this kind I believe ivory forceps would be found very useful in connection with the electric magnet.

MEDICAL PROGRESS.

CANCER OF THE RECTUM; SCRAPING WITH SIMON'S SPOON; RELIEF FOR THIRTEEN MONTHS.—DR. J. CRAWFORD RENTON reports the case of a man, æt. 40, who had been suffering for six months from pain in the lower bowel, accompanied at times by considerable bleeding. On examination, the rectum was found filled with irregular hard masses, which passed for four inches up the bowel, commencing immediately above the anus; behind the urethra they were very extensive and closely attached to it, so that, anteriorly, it was difficult to separate them, they bled easily, and were evidently villous in character. Owing to their urethral attachment, he decided to operate by scraping the surface of the new growth, and not excising the rectum. He therefore scraped away a large number of the masses with the spoon. The urethra was closely involved with them, so that it would have been hazardous to its safety to have removed the rectum. The amount of bleeding was less than he expected, and was easily controlled by finely powdered matico. Chloride of zinc was freely applied to the raw surfaces previous to the introduction of the matico on lint. In forty-eight hours the lint was removed and the rectum washed out with weak Condy's fluid and water; and the following day the patient had a movement of the bowels without any trace of bleeding, the first time for four months that it and pain had been absent. He progressed favorably, and was sent home in a fortnight from the time of operation, and was ordered to take Chian turpentine internally. Since then he has continued free from pain and hemorrhage, and as a consequence looks much stronger. The bowel, when examined early in January of this year, showed that whatever growth had taken place had been slight. The patient declared that he felt great benefit from the Chian turpentine.

The great success attending the late Prof. Simon's operations on the womb in cancer led him to adopt a similar treatment in the above case; and he thinks that although we cannot expect any permanent benefit from it, if we can arrest hemorrhage and relieve pain for a few months by means of it we are entitled to do so. The masses removed were carefully examined and showed appearances characteristic of scirrhus.—*Glasgow Medical Journal*, Sept. 1883.

REMOVAL OF HYDATID TUMOR FROM UNDER SURFACE OF LIVER DURING PREGNANCY.—MR. F. C. BATCHELOR reports the following case: Woman, æt. 34; five children. About a year ago she began to suffer from severe pains in the right side, about the region of the liver. Three months later she consulted the reporter, who found a hard, irregular, solid-feeling tumor, about the size of a kidney, deep in the right lumbar region; it was movable, and could be dragged into the middle line, but returned on discontinuing traction. It descended somewhat on inspiration, and was covered in front by the colon. According to the patient's account, it was increasing rapidly in size. It was painful to the touch, and there were aching, shooting pains through it which kept the patient from sleep at night. Menstruation had been missed for three periods. Careful vaginal examination revealed a retroverted uterus, thought to be in the third month of pregnancy. From the history of the tumor, its hard, irregular feel, and the loss of flesh and pain, the diagnosis seemed to rest between a cancerous growth and a caseous gland. From its increasing size, it was determined not to delay operative measures on account of pregnancy. The abdomen was opened under Listerian precautions. The tumor was found to be an extremely thick-walled, irregular hydatid cyst growing out from the under surface of the liver. The cyst was drawn through the incision, and laid freely open, the delicate, lining membrane removed, and the sac well sponged out with a 1 in 20 carbolic solution. The cyst was separated from the adherent omentum with the finger-nail, and finally cut off level with the liver-substance. There was no bleeding of consequence. The wound healed by first intention, and only required one dressing. There was no constitutional disturbance whatever, and the patient was able to leave her bed in less than a fortnight. Pregnancy ran its natural course, and she was safely delivered.—*Australian Med. Journal*, June 15, 1883.

SALICYLATE OF SODA IN PHLEGMASIA ALBA DOLENS.—M. VIGAR states that he has attended four cases of this affection. In the first he used no internal remedies, limiting himself to the local measures advised by various authors, keeping the patient in bed two months, and even then a certain degree of œdema remained, with a few nodosities on the course of the inflamed veins; these disappeared very slowly, and at the end of five months slight traces of them were still discoverable.

In his other three cases he used the salicylate of soda, with very good results. He gave it to the extent of one drachm per day, and after the first day found that the temperature fell very decidedly, the pulse became slower, and the œdema diminished to a very notable extent; the disease passed through its phases of inflammation and repair in so short a time that not one of the three patients was confined to bed longer than the third week. No signs of œdema or of nodosities on the limb remained.—*Glasgow Medical Journal*, Sept. 1883.

DIMINUTION OF UREA IN CANCER.—DR. W. ROMMELAÈRE, publishes a series of clinical observations illustrating a new fact in the pathology of cancer. He finds, in thirty-four cases, that in persons subject to cancer, the amount of urea daily eliminated progressively diminishes until it is below ʒiij. By studying the urea eliminated in cases, for example, where doubt exists between gastric ulcer and cancer, a diagnosis can be made. In twelve cases of ulcer of the stomach, the daily amount of urea eliminated was about ʒvj.—*Medical Record*, September 15, 1883.

QUEBRACHO IN DYSPNŒA.—DR. MARIANI, from recent experimental and clinical studies of the action of quebracho, draws the following conclusions:

1. Quebracho is a medicine whose principal effects are shown by a diminution of the number of the respirations and cardiac contractions.
2. Its action seems to be especially concentrated on the circulatory centre, on which it has a tonic action in regulating the contractions, either directly or by the intermediation of the nervous system.
3. Quebracho may be considered as the only medicine which has a manifest antidyspnœa. It combats the dyspnœic symptom alone, and without the aid of other medicines.
4. It is highly probable that the symptomatic dyspnœa of acute affections of the thoracic organs may be amenable to quebracho.—*Journal de Méd. de Paris*, August 25, 1883.

MOLLUSCUM CONTAGIOSUM.—MODRZEJEWSKI reports one of the most curious and interesting cases of this affection on record. The tumors numbered more than three thousand, varying in size from that of a pea to that of a child's head. M. inclines to the opinion of Recklinghausen, who considers these tumors of the skin as neuro-fibromata, and therefore calls the affection neuro-fibromatosis.—*Gaz. Hebdom.*, Aug. 24, 1883.

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

Communications are invited from all parts of the world. Original articles contributed exclusively to The Medical News will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

Subscription Price, including Postage,

Per Annum, in Advance, ... $5.00.
Single Copies, ... 10 cents.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in registered letters.

Address, HENRY C. LEA'S SON & CO.,
Nos. 706 & 708 Sansom Street,
Philadelphia, Pa.

SATURDAY, SEPTEMBER 22, 1883.

THE FEVER AT RYE BEACH—SEPTIC OR TYPHOID?

In a previous editorial on "Sanitary Sins at Rye Beach," we explained the local conditions producing a form of fever at that place. We have now to consider the fever, and ascertain, if we can, the nature of this morbid complexus. Is it septic or typhoid? That we may not be misunderstood, the sense in which we employ these terms must be defined. By *septic*, we mean a form of fever produced by decomposing organic matter received into the system of man. Decomposing organic matter, in contact with the solids and fluids of the body, sets up a change at the points of impact, which gradually extends, until widespread alterations ensue, and a febrile condition is established. Probably we should say. *not all, but some kinds of organic matter* are capable of inducing this process of change. It is to this morbid process that we venture to apply the phrase—*septic fever*.

On the other hand, the disease known as *typhoid fever* derives its existence from a germ, a microbe, an organism. Although this object has not been demonstrated, the facts warrant us in assuming its existence, and hence it can be affirmed that, without the presence of the typhoid germ, there can be no typhoid fever. Is the fever at Rye septic or typhoid? Can the presence of a typhoid germ be predicated on any facts in the disease history of the place? Has the fever at Rye the clinical characteristics of typhoid? We can answer both of the latter questions in the negative.

In respect to the development of fever at one point, but two of the cottages are concerned—one new, and occupied for the first time; and the other six years old, standing within forty feet of the former. The first cottage was occupied by a family free from illnesses of any kind, and a careful investigation has demonstrated that there had been no cases of fever in the other family during the six years of their residence. The occupants of the beautiful new cottage, admirably equipped in every way, except in respect to the pollution of the water-supply, could not, then, have received typhoid germs, although they were unfortunately made to imbibe decomposing organic matter. The water-supply of other boarding-houses in which cases of fever occurred may or may not have been free from typhoid contamination. We are thus able to eliminate typhoid germs as a cause of the fever in the case of the occupants of the new cottage. We are absolutely certain that the water-supply contained a large quantity of organic matter—animal matter in a process of decomposition.

The clinical characteristics of the fever in the cottages have a special diagnostic value in view of the absence of any source whence typhoid poison could have reached the inmates. Without entering into minute details of the differentiation, certain broad marks of difference may be readily stated. The prodrome consisted in the state known as *malaise*, and did not differ from typhoid except in the irregularity of its development. Instead of a gradual increase in the severity of the symptoms, there were periods of apparent restoration to health, of variable duration, so that the progress made was in a succession of leaps. There can be no formulated statement made of the temperature when the disease was fully developed. In other words, the temperature-curve followed no definite law. There were no regular periods of exacerbation and remission, and during the apparent maximum of the fever, a decline of temperature, sufficiently rapid to be like a "lysis," would occur, and for several days the normal thermal line would be established. During the protracted evolution of some cases, there occurred several of these apparent attempts at convalescence, so that the course of the fever was made up of a succession of relapses. It would be mere supererogation to point out the fundamental differences in the thermal range of this fever and that which is so characteristic of typhoid.

In respect to the nervous symptoms, the differences between these fevers were even more marked. In the cottage cases at Rye there was a more or less profound adynamia, but no stupor, no delirium, nothing of *coma-vigil*. The slowness of intellection observed was that of cerebral anæmia, and was not comparable to the mental hebetude, the low muttering delirium, and the coma of typhoid.

There was no eruption—none of the rose spots of typhoid; but in one case there were large vibices on the sacrum and on the great trochanter. The formation of these occurred at the time of greatest depression, and were coincident with more or less bleeding at the nose and gums. The condition of the blood—probably, for there were no means available at that place for its proper investigation—was the chief element in the morbid complexus.

Complete anorexia—an absolute loathing of food, indeed—the tongue heavily coated, and the breath fetid, were usual symptoms. Diarrhœa was the exception, constipation the rule; in the former condition there was more or less tympanites when gurgling in the right iliac fossa occurred on pressure; in the latter condition the abdomen was rather flat, and in both it was observed that the flatus and the stools had a marked degree of fetidness.

In severity and duration there was no uniformity. A ratio between the severity of the cases and the quantity of polluted water consumed could usually be made out, but in the fatal case at the cottage, and in another one at a private hotel, there were complications, in a large sense accidental, which had much to do with the termination. Unfortunately, no post-mortem examination was allowed, so that we are denied the final facts of the clinical history, and of the means of confirming or rejecting our theory of the fever.

We may shortly see in print, we hope, from the pen of Dr. Nichols, the physician at Rye, an elaborate and entirely accurate account of the cases of fever which have occurred there, together with the valuable and pertinent observations which he has made on the etiological factors. We can only give the general impressions of an observer having the opportunity of personal contact with the more important and salient facts. The reader will gather that our observations tend to establish the proposition that the fever developed in the new cottage at Rye had its origin in the pollution of the water-supply with decomposing organic matter, and that the type of this fever is different from typhoid. Clinically it presents some analogy to relapsing fever. We believe, however, that it is a distinct form, and may be entitled *septic fever*, if our definition be accepted.

COLLECTIVE INVESTIGATION OF DISEASE.

The first number of the *Collective Investigation Record*, recently issued by the Committee of the British Medical Association in charge of this subject, enables us to judge more accurately as to the possibility of coördinating the work of individual and scattered members of the profession so as to produce valuable results, and also as to the merits of the particular method to secure this end adopted by the Committee, than was possible at the time of our comment on this subject last month.

It certainly seems that the plan is a good one, and that interesting and useful results have already been obtained. Vague conjectures and guesses as to the connection of a given disease with certain circumstances of the environment, or as to the connection or relative frequency of certain symptoms, derived from a limited field of observation, can be replaced by positive data sufficient in number to permit of the application of statistical methods.

Much praise is due to the Committee for the manner in which they have thus far managed the work, which must have involved an enormous amount of labor. Over 1000 English physicians sent in answers to the question as to observed facts bearing on the communicability of phthisis, the majority it is true being simple negatives, and over 400 reports were sent in on the subject of pneumonia. This is a good commencement, and it is time that the physicians of the United States should begin to aid in the work.

It will be remembered that the coöperation of American physicians was invited by the English Committee in a communication which was presented to the American Medical Association, and was referred to a standing committee, of which Dr. N. S. Davis, of Chicago, is chairman.

In an editorial on the subject in the *Journal of the American Medical Association* for August 25, Dr. Davis suggests that "if each State Medical Society could be engaged in the work of establishing the proper sub-committees in the several districts or counties of its own State, and through a State committee receive the returns from the sub-committees, and after their examination and arrangement, transmit them to the General Committee of the National Organization, it would be more likely to secure results of value, both in regard to quantity and quality, than by any other method." It seems to us that a less complicated method than that suggested is desirable, at least for a commencement. There certainly seems to be no necessity for having the returns sent back through sub-committees and State committees for examination and arrangement. Why should not each observer send his return directly to the Chairman of the General Committee?

Moreover, the Chairman of the General Committee ought to be able to select at once from the members of the Association at least half a dozen physicians in each State, and call on them to make a commencement, using at first the sets of questions prepared by the English Committee. When these gentlemen have become familiar with the work by actual trial, they will be the proper persons to bring the matter before State and local societies, and secure a larger body of observers.

No doubt we shall have questions of our own presently, enough and to spare, but at first it seems to us that the wisest thing that can be done is to obtain answers to the English queries, and to forward these answers to the English Committee for collation and comparison with the data which they collect in their own country. The results will appear in their record, which will thus become an international one. There need be no fear of loss of individuality, and very soon we can in turn call for aid from across the Atlantic in the solution of some of our own special problems. The best way to make a beginning is to begin, and to secure this, individual, direct effort is worth any number of committees.

In the editorial above referred to, Dr. Davis gives the English memorandum on pneumonia and the schedule of information desired for each patient suffering from this disease. Are there not among the members of the Association, all of whom receive the Journal, two hundred physicians willing to commence at once to make observations, and forward reports, if asked to do so by the General Committee? We certainly think there are, and that the sooner such a request is made the better. No doubt some of the returns forwarded at first will not be complete, or specially valuable, but even these will have an educational value to those who make them, and in this way the real workers will become manifest. It is to be hoped that the experiment will, at all events, be tried without waiting for the action of State societies; in fact, as suggested above, it will be an excellent means of securing action on the part of such societies, the importance of whose coöperation we by no means undervalue.

EXTIRPATION OF THE THYROID GLAND.

With the exception of Billroth, of Vienna, no surgeon has had so large a personal experience with strumectomy, thyroidectomy, or extirpation of the thyroid gland for benign and malignant tumors as Kocher, of Berne, who has made a most valuable contribution to the subject in the current number of the *Archiv für klinische Chirurgie*. From having been one of the most fatal, it has, under improved methods of operating, which refer principally to the avoidance of hemorrhage and aseptic measures, gradually become one of the most successful of the major surgical procedures, especially when the gland is the seat of the innocent neoplasms. The truth of this statement is shown by the statistics which Kocher has collected from various sources, the majority of the cases having, however, been met with in Switzerland. Thus of 70 operations performed prior to 1850, 41 per cent. proved fatal, while of 146 practised previous to 1877, only 21.2 per cent. were lethal. Since 1877, 268 cases show a mortality of only 44, or 16.4 per cent., the rate of deaths for the malignant having far exceeded that for the benign growths. Of 28 examples of the former, 16, or 57.1 per cent., perished, while of 240 instances of the latter, 28, or 11.6 per cent., were fatal. It is, moreover, of great practical interest to note that, of the 268 cases, the entire gland was removed in 115, with a mortality of 12.1 per cent., which is not greater than that after partial extirpation.

The individual experience of Kocher relates to 101 cases, of which 13, or 12.8 per cent., died, a most excellent result, when the magnitude and dangers of the procedure are taken into consideration. Of his last 43 operations, which were performed with antiseptic precautions, all save 3, or 6.9 per cent., survived. Of these, 4 were for malignant growths, and 39 were for innocent tumors. Of the former, 1, or 25 per cent., was fatal, while of the latter, 2, or 5.1 per cent., perished. This small mortality forms a striking contrast with the experience of Julliard, of Geneva, recorded in the *Revue de Chirurgie* for August of the present year. Of 31 operations performed by that surgeon for benign formations, 5, or 16.1 per cent., proved fatal. Of 8 partial extirpations, all recovered, while of 23 total excisions, 2 died upon the table, and 3 succumbed subsequently.

In a voluminous and exhaustive paper, contributed to the *Bulletin de l'Acad. Roy. de Med. de Belgique*, for 1883, Liebrecht, of Lüttich, has analyzed 322 cases of strumectomy, with the result of confirming the conclusions of Kocher. He shows that total extirpation is not more fatal than the removal of portions of the gland, and that the mortality has progressively decreased, under more careful management, until it has reached 14.81 per cent. for the past six years.

THE AMERICAN GYNECOLOGICAL SOCIETY.

The eighth annual meeting of this Society in Philadelphia, the proceedings of which we give in another column, calls forcibly to mind the remarkable progress of this specialty in the comparatively short time it has existed. It is quite within the memory of the younger members of the profession when gynecology was little more than a name, scoffed at by the teachers of "Obstetrics and Diseases of Women," and regarded with some curiosity by others in the profession, whose field of labor this new department did not invade. But in a very few years the obstetricians have seen this new birth grow into a most vigorous and brilliant adolescence. In so short a time the representatives of the specialty of gynecology have contributed not only to the saving of life and health in their own domain by ways heretofore unthought of, or deemed impracticable, but also to the solution of some of the gravest questions in the practice and philosophy of general surgery.

Gynecology now stands before the world as a well-defined and, it must be admitted, a well-regulated specialty. It contains within itself the elements of safe guidance; for among the number of its most devoted and most eminent followers are to be found those who constantly warn their less discreet fellows of the impropriety and danger of zeal without knowledge.

In the meeting just held, for example, several of the most distinguished speakers condemned the practice of too readily making vaginal examinations of young unmarried women, which not only is—as it was there characterized—a sin, but also has brought reproach on the specialty. The duty of refraining from operation when not clearly demanded was also dwelt upon. Thus it is seen that the principles of true conservatism did not lack able support in this meeting, and a large amount of attention was there bestowed upon subjects which make no appeal to a love of glory. The discussions were full and intelligent. The various subjects, almost without exception, elicited the opinion of those best fitted to speak concerning them, and the papers and discussions together constitute an important and valuable addition to the literature, not only of gynecology, but also of the science of medicine, of which it is just now so conspicuous a part.

Several of the New Jersey seaside resorts are busy on the subject of water-supply. Long Branch finds its supply insufficient to the extent it has endeavored to furnish. Atlantic City has now a full and abundant supply.

Ocean Grove has just completed a driven well which furnishes an abundant supply of good water. An analysis has been made by Prof. F. A. Wilbur, of New Brunswick, which shows it free of all organic matter. The mineral matter gives but 8 grains of solids to one gallon of water. The success of this well will probably lead to the driving of several others in different parts of the town, which will be controlled by the Association, and will furnish an abundant supply for all.

The issues of the *Melbourne Argus*, between May 26th and June 21st, are teeming with correspondence in relation to the case of one Rev. Mr. Danne, who, after serving, as is alleged, as a dresser or clinical clerk in a hospital for twelve months, and having attended certain courses of lectures in an irregular and unsystematic manner, came to America, and at the end of nine months returned a full-fledged M.D., with a diploma from the Medico-Chirurgical College of Philadelphia.

We ascertain that Mr. Danne did graduate from the Medico-Chirurgical College in March last, but we can hardly think it possible that he was graduated with a knowledge by the Faculty of the limited preparation charged in the Australian journals. It is more likely that he claimed *ad eundem* qualifications which were unwittingly received by the Faculty. Too much vigilance cannot be exercised by our medical schools in admitting to advanced standing, and only the most conclusive evidence should be received as to instruction claimed to have been received elsewhere. The standard claimed by the Medico-Chirurgical College is a high one, and if adhered to, in view of existing competition, reflects great credit upon it.

The affair is to be regretted, because it furnishes foreign journals a chance to give another fling at the American medical diploma, which is already low enough in estimation abroad, where no discrimination is made as to its source, almost all schools sharing alike in the general opprobrium.

Since it is impossible to elevate the general reputation of the American diploma, in the face of the constant indifference of certain schools at home, it is important that those colleges which do affect a high standard should live up to them.

SOCIETY PROCEEDINGS.

AMERICAN GYNECOLOGICAL SOCIETY.

Eighth Annual Meeting, held in Philadelphia, September 18, 19, and 20, 1883.

(Specially reported for The Medical News.)

First Day, Tuesday, September 18th.

Morning Session.

The Society met in the Hall of the College of Physicians, and was called to order at ten A.M., the President, Dr. Gilman Kimball, of Lowell, Mass., in the Chair.

Dr. Duer, of Philadelphia, made a short address of welcome.

On motion, the following gentlemen were invited to attend the sessions as guests of the Society:

Dr. Alfred Stillé, President of the College of Physicians of Philadelphia; Dr. W. M. Welch, President of the Philadelphia County Medical Society; Dr. R. A. Cleeman, President of the Obstetrical Society of Philadelphia; Dr. James Tyson, President of the Pathological Society of Philadelphia; Dr. R. P. Harris, of Philadelphia; Dr. J. R. Page, of Baltimore; and Dr. Robert Wilson, of Baltimore.

Dr. Joseph Taber Johnson, of Washington, D. C., then read a paper on

SUPERINVOLUTION OF THE UTERUS.

In this he said he wished to call attention to a disease of the uterus which Sir James Simpson named and described over thirty years ago; but in regard to the settlement of the true etiology and treatment of which so little progress has been made, that he introduced the subject here with the hope that a discussion might follow which would throw light upon it.

Though scarcely referred to by the text-books, Barnes believes this condition to be far from uncommon.

Frommel found it present in twenty-eight out of three thousand gynecological cases, that is, in almost one per cent. of all cases treated.

Superinvolution should be distinguished from atresia of the uterus, undeveloped uterus, or one whose cavity has become obliterated by inflammatory process not involving the diminution of the organ. As the name implies, superinvolution occurs only after the process of involution has been set up after the emptying of a uterus once occupied by some body which has produced an increase in its size, as, for instance, after hydrometra, physometra, hydatids, the removal of uterine tumors, as well as upon the conclusion of utero-gestation, or abortion. The process may be carried from the slightest shortening to the complete disappearance and obliteration of the entire uterus and ovaries.

As a clinical contribution to the subject, he related points in the history of four cases in his practice.

The first case, aged 26, began to menstruate at 14, and continued without interruption until her pregnancy, five years ago. She was delivered with the forceps. The child was still-born. The mother did well until the third day, when symptoms of septicæmia developed. A laceration of the cervix and perineum was found, but no metritis. She made a good, though somewhat slow, recovery from the septicæmia. Later on, she had a continuous leucorrhœa, offensive at the time of her menstrual periods, backache, and distressing sick headache, culminating in absolute prostration on the day when the menses should have appeared. After two years her abdomen enlarged, and she believed herself pregnant, but at about the date of her supposed accouchement she began to lessen in size, and soon regained her usual figure. During this spurious pregnancy there had been a notable general increase of flesh, which remains to the present day. She had not menstruated since the date of her actual conception. Being asked to see her on account of this fact, two years ago, the only explanation of her persistent amenorrhœa found was a uterus measuring less than two inches in depth, hard, fibrous, and movable in all directions upon the point of the sound. Manipulation caused not the slightest pain. The shortness of the uterus being attributed to a distinct bilateral laceration of the cervix, he supposed that its restoration might perhaps cause a reappearance of the catamenia. The edges of the laceration had never healed. She had lost all sexual desire, intercourse was distasteful, and was at times followed by a slight flow of bloody mucus.

The operation proved successful only so far as to relieve the existing lesion, to cure the offensive leucorrhœa, and backache, and to restore the sexual appetite. The sick headaches became less severe than formerly, but did not quite disappear. The uterus remains hard and firm, and still measures less than two inches. The menses have not returned, and she is now only twenty-six years of age. She was subsequently treated with minute doses of ergot, nux vomica, galvanism inside and outside of the uterus, over the ovaries and sacral region, small blisters and massage, but nothing has been accomplished toward the development of the uterus or rousing it into functional activity. The patient now presents the appearance of the most robust health, though entirely without a sign of returning catamenial discharge.

The second case, aged 30, was in the best of health until nine years ago, when she had brain fever, followed by slow convalescence. Soon after getting up she had typhoid fever, and has since found it necessary to live free from mental or nervous excitement. Several years ago, she had a miscarriage, from which she made a good recovery, no fever or inflammation following. Four years ago, her uterus enlarged during eight months, but finally discharged a great quantity of water, since which time she had seen but little of her sickness. This began with uterine pain, backache, and headache, and continued less than two days; the discharge was red at first, soon became pale, and shortly ended with scarcely a stain. In December, 1882, her periods were about half a day and were growing less. The sexual instinct was strong. Her uterus measured less than two inches, and was hard, firm, and painless upon manipulation. She was treated with galvanism, minute doses of ergot, strychnia, counter-irritation, and massage, for three months, with excellent results, so far as the development of the ovarian and uterine functions were concerned. She menstruated seven days at her last period. Her husband tested her capacity for impregnation on the last day of her menses. She missed her next period, and during the next two months experienced many of the usual gastric and nervous disturbances of pregnancy. When she left the city, she was believed to be about two months advanced in utero-gestation; but her anticipations were never realized. The symptoms of pregnancy continued but a short time; the periods came on again, profuse at first, but gradually diminishing in quantity, until she had scarcely any, and showed no benefit whatever from her treatment.

The third case menstruated at 17. Her periods were always painful, irregular, and, as a rule, scanty, though several times they were quite profuse. She had been married three years when she presented herself for treatment, and was twenty-nine years old. Like the other two women, she was very anxious to become a mother. Upon examination, her uterus admitted the sound not quite two inches. She had never been pregnant, and therefore her case might hardly be called one of superinvolution, but it resembled the others so closely in the dimensions of the uterus, symptoms, and indications for treatment, that it was included in the paper with this qualifying statement. The uterus was freely movable. The roughest manipulation caused no pain nor hemorrhage. An electrode was passed through the internal os, while the opposite pole was held alternately over the uterus and ovaries, and occasionally over the sacrum for half an hour, three times a week. Her general health being good, no medicine was given. In the course of the second month of treatment, the organ gained somewhat in capacity, and the menstrual flow slightly increased. She suspended treatment July 1st, and went into the country for the summer, expecting to return and resume in October; but her periods have since shown so little change that she is discouraged, and thinks that it is of no use to persist. Had she remained longer under treatment, she might, perhaps, have been permanently benefited.

The fourth case had had two children. They were both dead, and she was anxious for another. She was only twenty-seven years of age, but thought her change of life had occurred, as her periods lasted now but a few hours, and after the first show the discharge became quite thin and pale. Her uterus measured but one inch and three-quarters. It was hard, very movable, and, like the others, painless upon manipulation. She was treated about like the others, but failed entirely to get any permanent good.

These experiences are far from encouraging, but the results are no worse than usually occurs in the experience of others. Sir James Simpson, who first called the attention of the profession to the symptoms, prognosis, and treatment of superinvolution of the uterus, in an article published in the *Edinburgh Monthly Journal of Medical Sciences*, in August, 1852, met with no better success.

The literature of this subject is not extensive, many of the text-books upon diseases of women not even mentioning its existence. The points upon which all writers agree, who devote any space to its consideration, are, that excessive involution of the uterus does, from some unknown cause, take place; that galvanism and electricity should be faithfully tried, but that the great majority of cases are incurable. Sinclair, of Boston, read a paper on superinvolution before the Boston Obstetrical Society in November, 1876, in which he explained the production of superinvolution as due to a lack of force in the nutrition with consequent enervation, whereby the fatty degeneration of the uterine fibres was carried beyond the normal point of arrest, with a failure in the renewal of the muscular fibres from their nuclei. Barnes says, superinvolution is produced when the disintegrating process set up after delivery goes on to such an excessive degree as to reduce the uterus to a size decidedly below its normal dimensions in the unimpregnated state. Dr. Walter Whitehead relates a case in the *British Medical Journal* for October, 1872, in which the uterus and ovaries completely disappeared after labor. Courty and Scanzoni mention these atrophied uteri following labor and abortion, and adopt Simpson's name. Hart and Barbour say frankly that the cause of this condition is unknown. Frommel attributed most instances to protracted lactation. This could not have been the cause in two of the author's cases, as in one the child was still-born, and the other followed a miscarriage. Inflammation causing a destruction of the ovary by atrophy, or by compression by the products of inflammation, may result in atrophy of the uterus. Klob has seen cases associated with the tuberculous diathesis. Edis says that cases not unfrequently occur where the mere effort of reproduction has been too much. Superinvolution of the uterus occurs and amenorrhœa follows. As a natural consequence there is a cessation of all further functional activity of the generative organs. When this condition occurs there is little or no hope of accomplishing restoration by any known form of treatment; but judging from the first and fourth cases of the author, where the physical organization remained so perfect it would seem that something might yet be done to enable these patients to bear children.

Dr. Fordyce Barker said that this trouble was likely to occur, not only in conception, but also after any abnormal development of the uterus; after fibroids, for example, the same process taking place as after labor. So after some cases of uterine catarrh. In all these conditions the uterus is increased, and afterwards there follows a state of retrogression. In all, the trouble depends upon the fact that this process passes its normal point. In regard to frequency, the experience of each one would be influenced by the fact that he was engaged in private practice, or had a large consultation practice. The latter would naturally see more cases than the former. He wished also to refer to a practical point, not mentioned by others, not even by the author of the paper; he had never formulated it himself before, although he had spoken of it to his friends. The point was in regard to the treatment—where treatment could be undertaken hopefully and where not. This depended upon whether there was an associated diseased condition of the ovaries. If the superinvolution was associated with arrest or deficiency of ovulation, very little could be effected by treatment; but when associated with active ovaries, it can be treated, and, he believed, much good could be done. He then gave the signs indicating activity of ovulation, and illustrated his point by a case in which, after an accident to a lady six months pregnant, miscarriage occurred, after which her menses were never normal, though she had the indications of functional activity of the ovaries, and was a great sufferer at her menstrual periods. He dilated her cervix before each period, and treated her with iron and other tonics during the intervals. The result was that she became pregnant again, and has had another child. He also narrated two other cases of the same sort.

Dr. A. Reeves Jackson expressed his surprise at the evidence of comparative frequency of this condition, as indicated by the author of the paper. He had seen but a single case, and that was of doubtful diagnosis. A patient of his after labor had defective lactation; her menstrual flow did not reappear; her mammary glands shrivelled; her skin wrinkled, and she had all the appearance of premature old age. Her cervix was button-like and small. No os was discernible. The body was felt with great difficulty, and was very small. The ovaries were not detectable at all. A sound could not be passed into the depression in the cervix which he took to be the os. Finally he took a probe, and pressed it in, and it passed on and on until he was alarmed, and concluded that he had punctured the fundus. This, however, did no harm. He tried the use of a galvanic stem pessary, but this did no good. He questioned whether this was a case of premature climacteric, or one of superinvolution. He considered the point in regard to treatment made by Dr. Barker to be of great importance.

Dr. Van de Warker, of Syracuse, called attention to a possible source of error, depending upon the atrophy of the posterior lip of the cervix, so common in lacerations. This would make the uterus seem to measure much less than normal.

Dr. H. P. C. Wilson, of Baltimore, said that while he has seen many cases of undersized uteri in unmarried women and those who have not borne children, he has seen only two or three cases in those who have been pregnant. He considers this a very rare occurrence, much more rare than would be supposed from the paper just read. Dr. Barker, he thought, got at the kernel of the matter in deciding as to the prospect of recovery, and his experience would bear out that of Dr. Barker.

Dr. Robert Battey, of Georgia, spoke of this condition as one of the results of the operation known by his name. The removal of the ovaries is the cause of atrophy of the uterus. The question is one of the ovaries and not of the uterus. The condition of the uterus depends upon want of proper ovulation. He does not agree with Lawson Tait in depressing the influence of the ovaries. The latter regards them of comparatively little importance. The best treatment consists in the use of electricity applied so as to influence the ovaries rather than the uterus. At the same time, the cavity of the uterus may be dilated with tents or by some other means.

Dr. Byford, of Chicago, said that the subject was one not yet exhausted. There still was a great deal of confusion in connection with it, and little actual knowledge. The process was not well understood, but a distinction should be made between superinvolution and atrophy. The question is, whether superinvolution is one of the stages toward atrophy or not. So long as the uterus retains its characteristic fibres, there is a chance of its recovery. He would divide the subject into simple and complicated superinvolution. In the former, the uterus alone is affected; in the latter, both the uterus and the ovaries. After labor there is a change in the whole of the pelvic contents, the ovaries as well as the uterus. But sometimes the involution of the uterus is greater than that of the ovaries. The condition of the ovaries naturally affects the question of the cure, since the uterus shares the processes of the ovaries. He agreed with Dr. Barker as to the indications for treatment. He would use before the periods, uterine pessaries to cause local congestion, which the ovaries would keep up.

Dr. H. F. Campbell, of Georgia, did not think it necessary that the ovaries should be involved or that there should be atresia. He cited a case where sterility followed great distention of the uterus by dropsy of the amnion, though ovulation continues.

Dr. Johnson closed the discussion. He expressed pleasure at the point made by Dr. Barker, in regard to treatment. He also thought that superinvolution of the ovaries might be a cause of superinvolution of the womb, but did not think it could be regarded as the only cause; and when the activity of the ovaries continues, treatment of the uterus is likely to be successful. Where the ovaries are involved, all treatment is ineffective. In regard to the point made by Dr. Van de Warker, he would say that, in a case where the latter supposed there might have been laceration of the cervix, he had taken note of this point, and it might be remembered that he had operated and cured the laceration, but the superinvolution was not benefited.

The next paper was by Dr. R. Stansbury Sutton, of Pittsburg, Penn., and was on the

IMPORTANCE OF CLEANLINESS IN SURGICAL OPERATIONS.

He said that, having been out of the country for some time, he would endeavor to bring before the members of the Society something which had been suggested by his observations while absent. He reminded his hearers that the era of open treatment, in which wounds were encouraged to suppurate and granulate, had been brought to an end by the treatment of quacks, who closed wounds up with a variety of substances. Formerly, the belief had been that all bad influences upon wounds came from within. In the present era the current theory is that all bad comes from without. The cell theory was soon followed by the germ theory. Organisms were found in wounds, which were believed to set up noxious processes.

Mr. Lister has endeavored to meet these dangers by carbolic acid and cleanliness. The consequence was greatly improved results. These were attributed at first to the carbolic acid, but it was afterwards ascertained that the amount of carbolic acid used was not enough to destroy the micrococci. A war of arguments and statistics followed, the outcome of which has been to prove that, under Listerism, surgery has achieved better results than ever before. But much of the misunderstanding has depended upon the assumption that Listerism is carbolic acid, and carbolic acid is Listerism. It has been shown by the experience of Keith, Bantock, and Tait that equally good results can be secured without the use of Listerism, yet it is premature to condemn the theory. There may yet be found another antiseptic, which will give better results than carbolic acid. It has been clearly shown that all bacteria are not malign. Bacteria swarm at the orifices of the body, yet we do not hear that the dental surgeons are troubled about them; and Mr. Allingham, in his operations upon the rectum, has had almost invariably good results, under what might be supposed to be the most disadvantageous circumstances. Nor is the danger uncommonly great in vaginal operations, yet some precaution should always be taken against noxious influences. Special cleanliness should always be observed in surgical operations. Since this was impressed upon the surgical world by Mr. Lister's methods, septic disorders have greatly diminished. For the attainment of the greatest cleanliness, time, knowledge, and constant practice are demanded, and Lister has taught us this, if anything. Carbolic acid, it should be said, is not to be denounced because of occasional unfavorable consequences, unless it can be shown that it does more harm than it does good. Very often the different results attained by those who practise Listerism and those who are opposed to it can be attributed to the difference of ability to attain cleanliness of person and instruments, and assistants and nurses, on the part of different surgeons. Keith has become such an expert in cleanliness that for him the spray was a disadvantage. In a three months' visit which he had made to Keith, all of the cases of the latter in which he had used the spray, occurring in the public hospital, died; and no case occurring in Keith's private hospital, treated without the spray, died. The Germans have received very great advantage from the use of Lister's method, for this has taught them the highest degree of cleanliness. German surgery is supposed to have formerly been extremely dirty, Now it is absolutely clean. If, after this lesson has been learned, the spray be dropped, the comparative effect of spray and cleanliness can be ascertained, because of the lesson of cleanliness taught by Listerism. He would recommend all surgeons to practise the antiseptic method until this lesson was thoroughly learned; then they may modify the system as experience may dictate.

Dr. Barker moved that the Nestor of American Surgery, Dr. S. D. Gross, who was present in the room, be asked to open the discussion. The motion was carried.

Dr. Gross thanked the Society for the compliment, but said he came to listen, and not to talk.

Dr. Emmet, being called upon by the Chair, said he had nothing to add. He would simply observe that he agreed perfectly with the remarks of the author of the paper. As he had elsewhere stated, he believed in cleanliness, and that the surgeon often carried the death-warrant of a patient under his finger-nails. He trusted to soap and water more than to any disinfectant. He spoke of the difficulty of controlling one's assistants, and stated that Tait does his own sponging, and does not allow his assistants to touch any instrument or dressing if possible.

Dr. W. T. Lusk, of New York, said that some things in the description of Listerism in the paper just read, would suit the most ardent Listerite. He agreed with the main point of the paper, but he objected to the inference which he thought might be drawn from it, that the spray was not only useless, but also harmful. Lister thinks there are certain influences adverse to healing, which are not appreciable by the senses, and he trusted to the spray to do away with these. Though micrococci resist five per cent. solutions of carbolic acid, yet this strength is fatal to the germs which produce putrefaction, and it is in the presence of putrefaction that the micrococci are dangerous. For himself, he felt that he could not give up entirely the use of the spray, although he knew the importance of the other points urged, since he had seen it effect such changes in the results of surgical operations in the hospital with which he was connected. In regard to the statement, that during Dr. Sutton's visit to Keith all cases treated with carbolic acid died, while all treated without it recovered, he must express his opinion that it was not attributable altogether to the carbolic acid; for, in 1878, when he saw Mr. Keith, the latter showed him the records of his operations, exhibiting a large number of consecutive recoveries under the spray, and told him that the English surgeons would have to come to the use of carbolic acid. At that time he was using the method of Lister, and yet his results were extremely favorable. Thornton, who still uses Lister's method, gets admirable results. Mr. Tait is the strongest believer in simple cleanliness, and scoffs at many points in Listerism, but he had the impression that Mr. Tait's success was largely due to exceptional address and skill on the part of the operator. For many of his abdominal operations he made a very small incision and operated with the greatest rapidity.

Still, while Keith, Bantock, and Tait may be allowed to do as they please, he thought that for many of us Listerism is a very good thing, and that it enabled even tyros to enter the ranks of the great coryphæi of surgery.

DR. WILSON, of Baltimore, referred to the obligation all surgeons are under to Lister. All practise, more or less, the method of Lister, although many of them abandon the spray. It has brought about such changes in the operation of ovariotomy, that not long ago Mr. Keith said that he thought no woman should die from the operation if she came to be operated on soon enough.

DR. CAMPBELL, of Augusta, Georgia, spoke in defence of the cleanliness of old operators, and repudiated the idea that they had learned cleanliness from Mr. Lister.

DR. SUTTON, in closing the discussion, said, in allusion to the statement that Mr. Tait used carbolic acid on his sponges, that he carefully washes all the carbolic acid out of them before using them in his operations. He thought that the day of the spray had gone by, and that if it ever did any good, it was by wetting the floor, and entangling the germs, so that they could not rise. Some of the most successful British operators were scrupulous in regard to their assistants. Mr. Keith had only one; Mr. Tait only one. On the contrary, Dr. Billroth had very many, and his methods were very different from those of Tait. He had remarkably good results, although he operated upon the most desperate cases, refusing no one who had any chance of life. He had no faith in statistics, in regard to laparotomy—so much depends upon the individual operator, and upon the different kind of cases which each may happen to have.

AFTERNOON SESSION.

On motion, Doctors R. P. Maury, of Memphis; Wm. E. Mosely, of Baltimore; W. P. Chunn, of Baltimore; and S. D. Gross, of Philadelphia, were invited to participate in the proceedings.

DR. ALBERT H. SMITH, of Philadelphia, then read a paper entitled

HOT WATER IN SECONDARY HEMORRHAGE AFTER PELVIC OPERATIONS.

The use of hot water, he said, had been first suggested in 1859 by Dr. Emmet. He himself had later begun the cautious employment of it to control hemorrhage after labor, and then adopted it regularly for the treatment of post-partum hemorrhage, and had come to regard it as the only needful treatment. He now uses it as a prophylactic, heated to a temperature of 115° to 120°, disinfected, and injected into the vagina in all cases of labor. He continues the injection until the water comes away clear of all tinge. He finds it grateful to the patients, and satisfactory to himself. In regard to operations, he spoke of the confusion and difficulty caused by hemorrhage. Here the hot water was not only harmless, but absolutely beneficial. In secondary hemorrhage, we have in the hot-water douche a remarkable aid.

He referred to some operations of Dr. Skene, in which the results had been very adversely influenced by hemorrhage, which influence might have been successfully controlled, and the results made successful, had Dr. Skene been familiar with the use of hot water as a hæmostatic. He narrated a very striking case of his own in which secondary hemorrhage occurred after a very difficult operation for the restoration of a badly lacerated perineum, and recommended the use of the hot-water douche on account of its simplicity and efficacy.

DR. REAMY, of Cincinnati, said that he had been for some time in the habit of using a stream of hot water on the perineum, instead of sponges, in every operation. He has also used hot water in secondary hemorrhage.

DR. CHADWICK, of Boston, being called upon by the Chair, endorsed the remarks of Dr. Smith.

DR. WILSON, of Baltimore, spoke of the method recommended by Dr. Smith as invaluable. It was apt to be overlooked because it was simple, but there was nothing so good in post-partum hemorrhage. He cited the case of a friend of his who encountered profuse hemorrhage after a Battey's operation. The hemorrhage came through the opening in the cul-de-sac of Douglas. At his suggestion, the nozzle of a syringe was passed into the peritoneal cavity, and hot water injected until it came away perfectly clear. The patient recovered. He thinks she would have died, except for this expedient.

DR. H. F. CAMPBELL spoke of the use of the tincture of iodine, one part to three of water, in post-partum hemorrhage, which he has found very satisfactory.

DR. MANN, of Buffalo, said that all the remarks thus far made had been favorable to the method, and he was sorry to have to say that his experience had not coincided entirely with that of Dr. Smith. About a year ago, he had used the hot water in an operation for cancer of the cervix which terminated fatally. He had removed the new growth with scissors all the way up to the internal os. He then injected vinegar until the whole cervix was perfectly clear and white. Seeing a small piece which he thought should be removed, he raised it and snipped it off; instantly the vagina was filled with blood. He injected vinegar, but it did no good; he then injected hot water, and the hemorrhage, if anything, was greater than before. He then tamponed; this, too, failed. He then used the Paquelin cautery, which checked the hemorrhage a little. He then tamponed with the persulphate of iron, but the patient became pulseless, jactitation came on, and in ten minutes the patient was dead. Dr. Mundé had a case of secondary hemorrhage, with the same result. The method was not infallible, and could not be relied on in every case.

DR. GOODELL, of Philadelphia, said that Dr. Mann asked too much of the hot water in his case. He had found the hot water particularly good for some cases, namely, those where there was oozing. It sometimes fails. It is not fair to compare hot water and vinegar. Hot water does good beyond the surface which it reaches, while vinegar only does good where it comes into contact. This he had found in cases of menorrhagia, where the use of hot water is successful, although it does not come in contact with the bleeding surface. In most operations he prefers vinegar, but for hemorrhage in general he thinks the best hæmostatic is hot vinegar, because with this we have the advantages of vinegar together with those of heat. At the Preston Retreat he uses constantly a mixture of vinegar and hot water after labor.

DR. FORDYCE BARKER, of New York, called attention to the necessity which sometimes occurs for great haste in checking hemorrhage. Sometimes one cannot wait. He cited a case, occurring last winter, where a newly married couple, arrived at New York, and on the first night the bride had a violent hemorrhage. A physician who was called in tamponed the vagina, and, this failing, packed it very thoroughly a second time. In a few minutes, however, the hemorrhage reappeared. He now cleared out all the clots, applied Monsel's solution, and filled up the vagina with cotton. In a few minutes oozing reappeared and he made a second application of the same kind. After this, he sent for Dr. Barker, who used the hot-water douche, but it acted very slowly, and the woman nearly lost her life from hemorrhage. He sometimes questioned whether the force of the hot water did not do harm. In a second case, somewhat similar to the one just mentioned, he had checked the hemorrhage by very gently applying cotton dipped in ergot. His objection to the hot water was that it took too long to act.

Dr. Byford, of Chicago, being called upon from the Chair, expressed his concurrence in Dr. Smith's views.

Dr. Smith, in closing the discussion, expressed gratification at the almost unanimous testimony in favor of hot water. In regard to Dr. Mann's case, he said that he had seen similar ones where the hemorrhage was completely controlled by the hot water. In such cases, when hemorrhage is profuse, one must get some slowing of the blood-current by elevating the hips, so that when the hot water comes in contact with the bleeding surface it shall be able to produce its full effect. Dr. Goodell, he thought, was really using hot water, when he spoke of the use of hot water and vinegar. This was simply water medicated with vinegar. In Dr. Barker's case, where the persulphate of iron had been used, he thought much of the difficulty may have been attributable to the action of the iron in preventing the possibility of the usual action of hot water. He, himself, had seen cases of post-partum hemorrhage where the uterus was firmly contracted, and yet a stream of blood the size of a goose-quill was issuing from it, where the application of hot water had stopped it promptly and effectually.

Dr. Goodell rose to explain that what he spoke of as hot vinegar was not simply medicated hot water, as Dr. Smith supposed, but vinegar heated by the addition of hot water.

Dr. C. D. Palmer, of Cincinnati, then read a paper on

SOME POINTS CONNECTED WITH THE SUBJECT OF DYSMENORRHŒA.

He spoke of the importance of the subject, its effects, direct and remote, and referred to the diverse opinions which are even to-day entertained concerning its true pathology and appropriate treatment. A short history of the mechanical theory, as advanced by Macintosh, Simpson, Sims, Barnes, and others, was given, the acceptance of which was most natural, because of its directness, simplicity, and plausibility.

In the light of modern gynecology, and with the present facility for thoroughness of pelvic exploration, no one can doubt that obstructions in the uterine canal do exist, and that these may serve to create pain in menstruation. They may arise from abnormities of the cervix, stenoses, congenital or acquired. These stenoses are by far more common at the external os than at the internal. Organic stenoses at the internal os, except from flexion, are quite uncommon. Obstructions may arise along the uterine canal from flexions and fibroids. Membranous dysmenorrhœa is a clear sample of impeded menstrual flux. Objections were made to much of the mechanical doctrine for the following reasons: A want of uniformity between the seeming causative lesions or abnormities, and the manifestation of symptoms. This want of uniformity is noticeable in the seat, degree, kind, duration, and time of the occurrence of pain.

When real obstructions do exist, the most severe attacks of pain are rarely present. A patient may writhe in the agonies of the most severe menstrual pain, when a medium-sized sound can easily be passed. Nor are labor-like pains characteristic of obstruction. Pain may reach its climax with the uterine cavity empty, and while not a single drop of blood escapes on the introduction of a bougie.

In reference to flexions, the pain is not in proportion to the degree of flexion, and straightening of the uterus by no means always cures it. A considerable proportion of cases of flexion are unattended by any menstrual pain, at least till some other disease is superadded.

The following varieties of cases have doubtless been witnessed by every gynecologist, and illustrate the want of uniformity referred to.

1. Instances of dysmenorrhœa, when no abnormal condition of the uterus, as to size, shape, position, circulation, or in the ovaries, or any pelvic tissues, can be detected on the most thorough exploration.
2. Instances of stenosis of the os externum, of most marked kind and degree, the result of chronic inflammation, or the use of caustics, and no menstrual pain.
3. Instances in which there are well-defined abnormities of the uterus, as in pin-hole os, elongated cervix, constricted canal, flattened and ill-developed body, flexion (ante-), and no dysmenorrhœa.
4. Instances of well-defined acquired flexion of the uterus, and no dysmenorrhœa.
5. Instances of stenosis of the os externum and cervical canal, associated with dysmenorrhœa, where treatment of a surgical nature proves successful in the relief of the former, while temporary or no relief attends the latter.
6. Instances of uteri with patulous canal and dysmenorrhœa.

From the evidence afforded by a study of the clinical history of these cases, we are forced to the conclusion, that not only is dysmenorrhœa not obstructive in all its kinds and cases, but that any impediment to the menstrual flux, as a factor in the production of pain, rarely, indeed, exists. The theory of dysmenorrhœa, based on mechanical obstruction, is not demonstrated.

The nature of the disease is best determined by studying uncomplicated cases, and finally, such as are associated with some organic affection of the uterus.

Reference was made to the extreme sensitiveness of the uterus, at or above the os internum, on the introduction of the ordinary sound in this disease. A slight discharge of blood sometimes follows; but this is not owing to congestion alone, being out of all proportion to it. The sensory nerves of the uterine cavity are in a state of hyperæsthesia or neuralgia. In such a condition, menstrual pain will be excited from the influx and flushing of the tissues with blood. The more dense these tissues, the greater the pain; the explanation of the greater frequency in the unmarried and nulliparæ. And, under such circumstances, local irritants, such as clots of blood, etc., may excite the uterus to painful contractions. But that clots cannot possibly be invariably the underlying cause is apparent by the occasional manifestation of these symptoms for hours prior to the presence of any flow.

Spasmodic action of the uterus as a condition of some dysmenorrhœas is abundantly proven, by the occasional behavior of the organ on the introduction of the sound, the ingestion of irritant fluids, and caustic crayons. Analogous action, we know, is found in the larynx, rectum, and bladder.

Dysmenorrhœa is, then, a functional disorder of the uterus, and, in its essential and underlying nature, a neurosis. It presents many features analogous to other visceral neuralgias, associated or not with organic disease, sometimes developed, but more often aggravated, by them. Clinical evidence points to the idea that the neurotic is the only feature in most cases, and is manifested to a greater or less extent in all.

The temperament of the dysmenorrhœic is generally highly sensitive and impressionable. The local neurosis is an expression of an impaired, disordered, highly developed nervous system. As a want of general development predisposes to this neurotic habit, so do imperfect sexual developments. To repeat: there is, then, such a condition as obstructive dysmenorrhœa.

It is, however, comparatively rare. Many obstructions are seeming and not real. Pain is developed by the local influx to and within an organ the seat of a neurosis, either purely local or a local expression of a general nervous disorder, very generally antedating any organic lesion, and almost always aggravated by such as become acquired.

Concerning treatment, but a few points were touched upon. In all cases of painful menstruation in young, unmarried women, treatment should be purely constitutional, at least for a time, until the necessity for a local exploration is clearly and justifiably apparent. If there is a sin in the profession, it is the unnecessarily frequent and unwarranted liberty assumed on the part of many practitioners, women as well as men, that, because a young female suffers pain at the menstrual period, she must have some local uterine disease, and is a fit subject for local treatment. In thousands of instances all over the country is this injustice being done young women, an injury which must reflect itself back on the profession. At this age and social condition there is, excepting it may be some congenital abnormity, seldom any local disease, or one so trifling and insignificant as to require no local treatment. Local treatment may be needed, fortunately, rarely, and only, after a failure following a general treatment, thoroughly and fairly tested.

During the interval, every attention should be directed towards an improvement of the general health by hygiene, proper diet, dress, and exercise.

Iron and arsenic—each has its indications according to conduct of menstrual flux in quantity, duration, and frequency. Galvanism of the hypogastric plexus and of the spinal centre occasionally accomplishes great good. Failures are also experienced. It is a remedy indicated only in the purely neurotic, spasmodic, or rheumatic forms of the disease.

The author has experienced decided benefit, in some cases, from a prolonged administration of mercuric bichloride and potassic iodide, in small doses, three times a day—results not owing to the relief of any syphilitic complication, or the melting down of any periuterine inflammatory infiltration. The only lesion was a chronic endometritis, and the menstrual pain seemed to be spasmodic.

The author also expressed confidence in the efficacy of the concentrated tincture of cimicifuga and tincture of pulsatilla, given during the attack. He condemned, in strong language, the frequent and uncalled-for administration of opiates, especially morphia hypodermically, which never cure the disease, but which tend to induce a condition of the nervous system more difficult to overcome than the original affection.

Dilatation by sound and bougies did good in stubborn cases, not by securing a larger canal, but by blunting the sensibility of the uterus, and by stretching the irritable fibres of the internal sphincter.

Believing that stenosis is more frequent at the external os than at the internal, it can be understood how, on this ground, sterility is also more frequent and peristent than dysmenorrhœa. It is easier for the menstrual discharge to get out than it is for the spermatic fluid to obtain entrance. Although stenosis may not be a direct factor in the production of dysmenorrhœa, it is, nevertheless, a potent one in creating disease of the uterus — dilatation of the upper cavity, thickening and softening, and granular degeneration of the endometrium, and consequent stubborn catarrh. The uterine walls, likewise, in time, undergo hyperplastic changes. Incision here is preferable to dilatation—an operation which doubtless has been greatly overdone; still, it has stood the test of time. Time has fixed its proper field of utility. With proper restrictions, its dangers are slight and results good. Very little can be added to our knowledge of the *technique* of the operation given us by Simpson, Sims, and Emmet, although Fritsch has proposed some ingenious methods, as applied to the methods of obviating the various forms of stenosis of the external os.

Dr. Chadwick, of Boston, agreed very much with what had been said. For some years he had entirely given up the theory of obstruction, and never used incisions, except those confined to the external os. Some of the causes of dysmenorrhæa, he regarded as purely local, others were constitutional, as, for example, in neurotic cases. These must be treated on a nervous basis. He uses for a week beforehand the bromides, in ten to twenty grain doses, producing some blunting of the sensibilities. During menstruation he used cocoa and carbonate of ammonia, never morphia. He had no faith in dysmenorrhœa being due to flexion, though he knew it might occur as a coincidence.

Dr. Barker, of New York, shared the opinion of the author that obstructive cases constitute but a small proportion of the whole, though they do occur. He thought there were two sorts of pain, one uterine, the other ovarian. For tonic treatment, his preference was for the lactate of iron, which he generally associated with chlorate of potash. He had got very good results from the use of apiol. The way to secure these is to commence its use at least two days before the menstrual period. He gave it in capsules after each meal, and continues it through the menstrual period. In cases where there is ovarian excitement, as manifested by the signs already mentioned, without the relief of a discharge from the uterus, he uses the bromide of sodium in ten to fifteen grain doses. He prefers this to bromide of potash, because he thinks it less likely to cause bromide eruption, which is a matter of great consequence to young ladies. He also arranges the doses so that they shall be taken in the middle of the forenoon, and in the middle of the afternoon, and the last dose just before going to bed, so that the patient does not have the stupefying effects during the day.

Wednesday, September 19th, Second Day.

Morning Session.

The meeting was opened by the reading of *The President's Address* by Dr. Gilman Kimball, of Lowell, Mass., entitled

A BIOGRAPHICAL SKETCH OF DR. NATHAN SMITH, FOUNDER OF THE DARTMOUTH MEDICAL COLLEGE.

In opening his address he said: Although it has been the custom with those who have filled the position which I now occupy, to devote the hour to the consideration of some subject pertaining to the department of gynecology, I propose to deviate from that rule and devote this, which seems a fitting opportunity of paying a just tribute to one who, by the course of his genius, by his indomitable will and unflagging energy, has done more to advance the practice of medicine and surgery than any other single individual in our country. I refer to Dr. Nathan Smith, the founder of Dartmouth Medical College.

In regard to ovariotomy, he is said to have been the second to perform it successfully, which he did in July, 1821. The operation of Dr. Smith was truly original, and except that McDowell's operation was performed nine years previously, the two operations stand alike. McDowell has been termed the father of ovariotomy, and it is not my purpose to raise any question as to the justice of this claim, but while I do complete justice to McDowell, is there nothing more to be said of Dr. Smith than that he had the courage to follow in the footsteps of McDowell? Dr. Smith performed the operation without any knowledge of the previous operation of McDowell, and should therefore receive equal credit.

Dr. Smith was born in September, 1762. His early life was spent in Chester, Vermont, where his father followed the occupation of farming. He received what education he could obtain from the district school during the winter. At times he himself taught in the school. He was led to study medicine by witnessing an operation. He desired to begin the study at once, but was advised to first perfect his general education. He began the practice of medicine in the town of Cornish, N. H., when he was thirty-five years of age. At the end of two years, he resumed his medical studies at Harvard College, from which institution he received the degree of M.D. He then returned to Cornish, and continued to practice for six years.

The difficulty of procuring a medical education in New England was so great that he decided to give instruction, and in order to fit himself for this work, he went to Europe to perfect himself. Before starting, he proposed to the authorities of Dartmouth College that they should organize a medical department. His proposition met with favor. He returned in September, 1797, and delivered his first course of lectures during the ensuing fall. In the following August, he was elected Professor of Anatomy, Surgery, Chemistry, and the Theory and Practice of Physic.

In 1812, Yale College decided to establish a medical department, and called upon Dr. Smith to take the position of Professor of the Theory and Practice of Surgery. He began his lectures in this institution in 1813, when fifty-one years of age. In 1816, he was reëlected a professor in the Dartmouth College, but declined to accept, and, in 1817, removed his family to New Haven. In 1821, he went to Boston, and remained there five years. During the last thirty-two years of his life, Dr. Smith gave instruction in about one hundred and thirty-eight special courses. This work began to tell on him, and, while in possession of full mental power, he died on the 28th of August, 1829.

The speaker then referred to the manner in which Dr. Smith had filled the various positions of life, illustrating his remarks by several anecdotes. Dr. Kimball again alluded to Dr. Smith's performance of the operation of ovariotomy, and claimed that Dr. Smith was entitled to the same honors as had been bestowed on McDowell.

DR. S. D. GROSS said that he had thought that Dr. Smith had performed his operation with the knowledge that it had been previously performed by McDowell; his operation having been done thirteen years after that of the latter gentleman, who had operated in 1809. An account of the operation was published in a Philadelphia journal in 1816. Dr. Gross thought that it was very unlikely that Dr. Smith failed to see it. He thought that Dr. Kimball had omitted to refer to the greatest of all Dr. Smith's achievements—he referred to the creation of Dr. Nathan R. Smith, of Baltimore.

DR. KIMBALL.—It will, I think, be in order for me to make a few remarks in reference to the statement of Dr. Gross. It should be remembered that intercourse between the east and west was at this time very difficult. Matters which had occurred in one part might not be known for a long time in the other. In a discussion with Dr. Reuben D. Mussey, who was Dr. Smith's successor in teaching surgery at Dartmouth, I received a detailed account of this operation of Dr. Smith. I fully believe that he knew nothing of McDowell's case.

DR. THADDEUS A. REAMY, of Cincinnati, then read a paper entitled

A RARE FORM OF ABDOMINAL TUMOR.

He described three cases, the first of which was seen by him in July, 1873. The patient was thirty-eight years of age, had been married fifteen years, and was sterile. She had enjoyed good health until three years previously. At this time she discovered an abdominal tumor, just below and to the right of the umbilicus. This tumor had enlarged gradually until it reached the size of the uterus at the eighth month of pregnancy. The woman had always menstruated regularly. She had menstruated two weeks before examination. She appeared well nourished, but there was a little change of the complexion as in the incipiency of the cancerous cachexia. An examination of the patient in the erect position showed the form of the enlargement to be striking. There was bulging in the median line from two inches above the umbilicus nearly to the pubes. The lateral borders could almost be determined by the eye alone. The abdominal wall was comparatively thin. The surface of the tumor was irregular and lobulated. There was fluctuation at every point. At some points the tumor was more tense than at others. This was probably due to difference in the thickness of the cyst-walls. This thickening was especially marked at about the umbilicus. The tumor could be moved a little from side to side, and to a limited extent upwards and downwards. There was intestinal resonance in both iliac fossæ; the bladder was empty. Digital examination per vaginam revealed a normal vagina and cervix. The cervix was slightly anteverted in agreement with a slight retroversion of the uterus. The os was somewhat patulous. The sound gave the measurement of scant three inches. There was no bulging into the vagina. There was no pain or tenderness on pressure.

Supposing it to be of uterine or ovarian origin, Dr. Reamy decided to tap, and he introduced a trocar in the median line, about four inches below the umbilicus. The fluid gushed out with such force as to fall at least two feet from the patient. It had the appearance of blood. The quantity obtained was six quarts.

The fluid was examined microscopically, and was found to contain red and white corpuscles. The size of the abdomen was reduced one-half by the tapping. No inflammatory complication followed. A letter just received states that the enlargement remains about the same.

The second case was seen June 4, 1881. The patient was a widow, fifty-eight years of age, and the mother of five children. Her husband died six years previously of cancer of the stomach. Two years before, an abdominal enlargement was discovered. The patient had noticed it first as a small lump below and to the left of the umbilicus. In two years it had reached the size of the fifth month of gestation. Her general health was good, and the menopause passed. A few days before the family physician was called, she had colicky pains, which were relieved by some domestic remedies. Some tenderness of the abdomen remained. A physician was sent for, the tenderness was relieved, and the case passed from observation until the time when Dr. Reamy was called. The patient was taken sick at midnight, with violent abdominal pain, attended with vomiting of mucus colored with bile. The pain was intense, and continued notwithstanding the free use of anodynes. The abdominal enlargement had increased, since the patient had been last seen, to the size of the uterus at the eighth month. It had remained at this size for one year. The general health had been fair. There was no cachexia. Occasional abdominal pains had been experienced. The patient had a temperature of 103°, and a pulse of 120. The abdomen was very tender. It was clear that the patient was suffering from peritonitis, and it was thought that this might have some connection with the tumor. Opiates were freely administered, and Dr. Reamy was called in consultation the next morning. The temperature was then

100°, and the pulse 130. The woman was delirious. Physical examination revealed marked dulness from above the umbilicus to the pubes, and resonance in each iliac fossa. Fluctuation could be clearly made out. Vaginal examination showed that the vagina and uterus were normal, and that there was no bulging downwards. The diagnosis of general peritonitis was clear enough, but its relation to the tumor was not so clear, although such relation was believed to exist. It was thought possible that the cyst had ruptured, and that part of its contents had entered the peritoneal cavity. It was, however, clear that the amount of escaped fluid could not be great. The tearing of adhesions was thought of, but not seriously considered. The rupture of omental or other bloodvessels was thought of as probable.

As there was such severe peritonitis the performance of any operation was not considered proper. It was decided to increase the amount of opiates, administer stimulants, apply ice poultices, and await further developments. This, Dr. Reamy thought, was a blunder. The abdominal cavity should have been opened. This would have afforded the woman a chance, for, although the tumor proved to be a sarcoma, he could see no reason why it could not have been successfully removed. The patient died soon after.

At the post-mortem, a tumor somewhat pyriform in shape was found. The walls of the cyst were thick at the upper and thin at the lower part. Notwithstanding that the removal of the tumor was done with great care, it gave way, and a portion of its contents escaped into the abdominal cavity. The fluid seemed to be almost entirely blood. There must have been at least two and a half gallons. The tumor appeared to be composed of connective tissue and bloodvessels; there was no connection with the uterus or ovaries. The point of origin must have been the omentum, and, indeed, the greater omentum had entirely disappeared. There were no adhesions to the abdominal walls or organs. Microscopical examination showed that the fluid contained a large number of blood-corpuscles, some of which were normal, but many were broken down. The fluid was colored red by the coloring matter of the blood. There was also a considerable amount of granular detritus. The semi-solid matter which was found presented the appearance of blood-clots.

The third case was seen in November, 1882. The patient was a married woman, fifty-two years of age, and the mother of eleven children, the youngest being ten years old. Menstruation had been regular until three years before, when it stopped suddenly. Five years ago, she noticed enlargement of the abdomen. It was first found below and to the left of the umbilicus. It could be moved slightly from side to side, and was not tender, even on deep pressure. Two years before, she had an attack of pain in the region of the growth, which seemed to have been paroxysmal. This lasted for a day, and was followed by soreness which continued for several days. The tumor then grew more rapidly, and in the next six months reached the size of about an eight month's pregnancy. It then ceased growing and remained stationary until about one week before the patient came under observation. There was then a repetition of the attacks of pain. During the past six months she had lost weight, and her complexion was decidedly sallow. Later she suffered from peritonitis, believed to be due to changes in the tumor. The attack had been ushered in with soreness over the abdomen, and followed by some tympanites.

On examining her, Dr. Reamy found, extending from the umbilicus to the lower portion of the abdomen, a tumor which was spread out like an apron in front of the intestines. The surface of the growth was irregular and lobulated; there was fluctuation; the intestinal resonance was well marked in the iliac fossæ. Examination showed the vagina and cervix to be normal. The sound was not passed.

Impressed with the striking resemblance in history and the results of the physical examination between this case and the two which he had mentioned, he advised tapping, which drew off five quarts of fluid presenting the characters of blood. Microscopical examination of the fluid showed that it had the same characters as that removed from the other cases. After the removal of the fluid, the cyst collapsed, except at a point between the left iliac fossa and the middle line. At this point fulness and fluctuation remained. Thirteen days later, fluctuation having become more marked, he again aspirated, removing sixteen ounces of pus. The patient made a tedious but complete recovery.

He saw this woman last week, and she now looks stout and healthy. She has gained twenty pounds above her ordinary weight.

The foregoing cases seem so much alike that he felt justified in grouping them together. They are sufficiently rare to warrant him in believing that a report of them would not be without interest. He then referred to a number of cases, somewhat resembling those described, which he had found in looking up the literature of the subject.

It is a matter of clinical interest that the first and third cases, which were tapped, recovered, while the second case, which was not tapped, died, and the post-mortem revealed a sarcoma. This raises the question whether these other cases would have become sarcomatous if not tapped, or whether it could be possible that this one had degenerated into a sarcoma. It is possible that these women may yet die of sarcoma.

He then presented the specimens removed from the second patient, and read the report of the post-mortem. The walls of the tumor varied in thickness from that of tissue-paper to a thickness of three inches. The cyst had evidently existed for some time, as some of the following conditions will show. It had formed between the layers of the omentum. The outer lining membrane of the cyst was very thin and friable; closely attached to it were numerous masses of fibres. The wall of the large cyst contained a number of tumors which varied in size from a hickory nut to a hen's egg. Under the microscope these tumors presented different appearances. Around all of the tumors was an evident capsule. There was no broken-down centre in them, though a few hemorrhagic foci were found scattered through them. These tumors were not very vascular, but, wherever a vessel was found, its walls were infiltrated with spindle-cells. Some of them were found to consist of spindle-cells, with large nuclei and very little intercellular substance. Others were smaller and presented a chocolate or brown appearance, and under the microscope resembled cavernous tissue. These were extremely vascular. Here and there were found large hemorrhagic foci. The vessels had been so infiltrated with round and spindle-cells that their tissue had been destroyed. They appeared merely as channels through the growth. In the vascular tumors the round cells predominated.

From the specimen it would appear that it was a cyst which had developed in the omentum; that in the walls of this cyst numerous sarcomatous tumors had developed. One of these tumors had ruptured into the cyst, and there had been recurring hemorrhage which had produced rupture of the main cyst into the peritoneal cavity causing peritonitis from which the patient died.

DR. CHARLES C. LEE, of New York, concurred in the statement that these tumors of the omentum were very rare, and thought that if tapping were more generally resorted to, our knowledge of them would be advanced.

DR. R. S. SUTTON, of Pittsburg, spoke of the rarity of the tumors and said that he had seen two or three in the practice of foreign operators. He claimed that it was not possible before the abdomen was opened to say whether a tumor was carcinoma or sarcoma of the omentum. It is generally possible to determine that the tumor is in all probability in the omentum, by exclusion, showing that the tumor is not connected with any of the other abdominal organs. If there were fluctuation, whether distinct or indistinct, he considered it a very dangerous practice to plunge a trocar or even an aspirator into the growth. If the surgeon thinks that before he is justified in opening the belly, he must have some of the fluid for microscopical examination, the hypodermic syringe will remove all that is necessary. He also believed that in such cases the surgeon was justified in discarding, not only the aspirator and trocar, but also the hypodermic needle, and making an exploratory opening of the belly. When the abdomen is opened it is possible to determine the location and attachments of the growth and the possibility of its removal; but the exact pathological character of the growth cannot be determined until after removal. If the tumor be sarcoma or carcinoma, there is little hope of prolonging the life of the patient. Sarcoma is as malignant as carcinoma. While carcinoma travels by the absorbents, sarcoma travels through the bloodvessels, so that sarcoma will lead more surely to general infection than will carcinoma. In the latter the liability to return depends upon the character of the sarcoma. The giant-cell variety is by no means so likely to return as the spindle-cell variety. The round-celled and the mixed variety return almost as certainly as the sun after night.

Does sarcoma ever pass into carcinoma, or does a benign growth ever degenerate into sarcoma? In regard to the first proposition, sarcoma never changes into carcinoma. The growth is either one or the other *ab initio*. Of the cases which he had observed, one was in the practice of Hancock, of London. A large carcinoma was removed, but the patient soon died. The remaining two cases were in the practice of Billroth. In one, after the nature of the growth was determined, the abdomen was closed; in the other case the operation was performed. He believed that when the exploratory incision shows that the tumor is malignant, that the abdomen should be closed and the tumor not interfered with.

DR. HENRY F. CAMPBELL, of Georgia, considered the cases of great interest. He thought that it was certainly worth the risk to remove tumors of the omentum if there were no extensive adhesions, and the exploratory incision had been made.

DR. REAMY said: I shall only reply to one or two points. I cannot quite consent to the doctrine which Dr. Sutton advocates, especially in the sweeping way in which he makes it. I understand him to say that it would be more judicious to open the abdominal cavity and examine the tumor than to use the aspirator. I freely agree with the recommendation that it is better to use the hypodermic needle, if it is desired to obtain the fluid for microscopical examination. But that is not all that we want; where we have a tumor lying in contact with the abdominal wall, where evidence is against its being connected with the ovaries or uterus, and in favor of its connection with the omentum, and where there is fluctuation, it seems to me that in such a case it is justifiable to operate for the relief of the symptoms.

Let me also call attention to the fact that the two patients who were tapped recovered. The first case had some emaciation; the second case had marked emaciation and pronounced cachexia. One of these cases occurred several years ago, and the other several months ago. There is a second point in this connection. It is that we know from pathology that sarcoma invades the system through the bloodvessels and carcinoma through the absorbents. At the same time, it is a curious fact that in the second patient, where the tumor was proven to be sarcomatous, no cachexia was present. The other two cases could not have been due to sarcoma, because they recovered.

The next paper was by DR. HENRY F. CAMPBELL, of Georgia, and was entitled

CONGENITAL FISSURE OF THE FEMALE URETHRA, WITH EXSTROPHY OF THE BLADDER.

After making some general remarks upon abnormalities of the genital organs, and the failure of operations in most cases, he described the following case, which occurred in a little girl, two years old, brought to him by Dr. R. The parents of the child noticed something wrong about the vulva of the child, and called Dr. R.'s attention to it. On examining the patient, he found a red tumor, about the size of a strawberry, at the upper part of the vulva, in the situation of the meatus, and apparently obstructing the passage of the urine. The tumor was very vascular, and evidently constricted, as was shown by its purplish hue. The doctor thought of removing it by a ligature, but, before doing so, resolved to consult Dr. Campbell in regard to it. He saw the case in July, 1880. The tumor presented the appearance above described; but the appearance of the swelling led him to believe that it was composed of the wall of the bladder, and on pressing it, it slipped back, at first slowly and finally suddenly, into the bladder. There was a gush of urine at the moment, but not to any great amount. The upper wall of the urethra presented a flattened appearance, but very little trace of a lateral border, indicating the presence of a cleft. The hymen was perfect, and the posterior commissure and the other parts of the vulva were normal. Careful examination of the symphysis showed that the pubic bones were fully developed.

The whole interest which attaches to this case, beside the rarity of the occurrence, is as regards the proper time to operate. The child is now four years old. There is hardly enough tissue to allow of the necessary paring and bringing together of the parts. He thought that it would be more advisable to operate after puberty, and in the mean time to use such apparatus as will afford the most comfort to the patient.

DR. B. B. BROWNE, of Baltimore, described a somewhat similar case, in which the child died before operation.

DR. M. D. MANN, of Buffalo, related a case which, while not being of the same class of cases as Dr. Campbell's, might throw some light on the point as to the proper time to operate. He had brought to him a girl who had fallen on a broken chair, and produced a laceration of the perineum through the sphincter. He advised an immediate operation. This was performed, and the result was a perfect cure.

DR. CAMPBELL, in concluding, said that his case was an exaggerated hypospadias, and that he thought that the chances of success would be increased by postponing the operation until puberty.

The next paper was by DR. THOMAS ADDIS EMMET, of New York, and was entitled

A STUDY OF THE ETIOLOGY OF PERINEAL LACERATION, WITH A NEW METHOD FOR ITS PROPER REPAIR.

He referred to the fact that for a number of years he had devoted more attention to the subject of laceration of the perineum than to any other in the whole range of gynecology. It has not been generally recognized that the suffering from lacerated perineum was not in proportion to the extent of the lesion. All have seen cases of severe laceration of the perineum, unaccompanied by symptoms. On the other hand, marked symptoms have followed apparently trivial lacerations. Various modifications of Baker Brown's operation have been employed since he first united the lacerated surfaces, but none of them have done more than relieve the discomfort resulting from the want of unity.

He then described the attachments of the pelvic fascia, and pointed out that the parts above are supported by this fascia. He then referred to a paper which he had presented at the last meeting, describing a transverse laceration of the urethra produced by digital dilatation; the laceration occurred at the sigmoid portion of the urethra where it is surrounded by the pelvic fascia. When the finger reaches this point, the fascia must be put on the stretch or carried forward in front of the finger, and transverse laceration is produced. In a similar way, the head of the child separates the pelvic fascia from the vagina.

In the usual operation for lacerated perineum, it is customary to denude a large part of the surface of the lips on each side. I have seen the denudation carried almost to the level of the urethra. These operations often interfere with sexual intercourse, and if pregnancy occurs, the results of the operation are destroyed. The pain suffered by such an operation is severe.

It is about twelve years since I began to dispose of a rectocele by bringing it up behind the laceration. Observation has shown me that the chief support is obtained in this way. Three years ago I had the opportunity to operate in a case of subinvolution of the vagina. This occurred in a woman aged 35 years. She had had two children. Since the last labor, which occurred a number of years previously, she had suffered from great relaxation of the vagina. There was no rectocele, and no appreciable laceration of the perineum. It seemed as if the running string of the mouth of the bag had been lost. I determined to unite the posterior wall of the vagina, and bring it up behind the perineum at about the former seat of the hymen. The line ran as a crescentic fold across the vagina, and the horns were lost in the sulcus on each side. The dilated vagina was reduced to the size of the vagina in a married woman who has not borne children. After the operation, the line of sutures was entirely within the vagina and out of sight. On passing the finger within the vagina, it was found that the tissues forming the perineum had been drawn up to the pubes.

When the laceration extends to the anus, it is necessary to modify the operation, although the principle is the same. In performing the operation a tenaculum is introduced into each lip at the position of the carunculæ, a third tenaculum catching the posterior wall of the vagina, and these three points are brought together. Traction draws the labial surface upwards and inwards, and reduces the size of the entrance of the vagina. When this procedure is carried out, it is surprising to what an extent the laceration is reduced. Sutures are introduced through the labial surfaces, and a central fold is drawn up to the posterior wall of the vagina. The sutures are first introduced at the angles of the crescentic fold, and alternately on each side. Usually only two or three sutures are required. The most common mistake in performing this operation is made in taking up too much of the posterior wall, the sutures cutting out. In conclusion he gave the following *résumé* of his paper.

Laceration of the perineum does not produce the troubles attributed to it. It is not lacerated as it seems to be. After the laceration, the tissue in front of the rectum may be thicker than it was before the injury.

There is no such body as that which has been termed the perineal body, as has heretofore been taught, and which operators endeavor to build up. This can be proven by any one who puts one finger in the rectum and another in the vagina. He will then find that there is no thick tissue between the fingers.

I hold that even if the lacerated perineum is not restored, you can leave it entirely out of the question, if the posterior wall of the vagina is in contact with the entrance of the vagina where it joins the soft parts.

I hold that we may exclude everything in regard to the external organs of generation, outside of where the hymen runs around the vagina. All sewing together of the outside tissues is a waste of time and structure.

The fascia forming the sulcus on each side of the vagina is all-important in keeping up the perineum and posterior wall of the vagina. It acts just as a pair of suspenders does in keeping up the pantaloons. By bringing a crescentic fold across the vagina, we restore the attachment of the fascia. The perineal trouble can be left entirely out of the question. If the tissues are brought together as I have described, the perineal lesion will be found to be very superficial. The symptom which we attribute to lacerated perineum may be relieved by the operation I have referred to.

Its advantages are that it produces less disturbance of the parts; there is no comparison as to the comfort to the patient between this and the former operation, and the operation is so simple that it may be performed by many men who cannot perform the old operation.

I want to call particular attention to the *rôle* which the fascia plays in supporting these parts, and to the fact that the perineum has little or nothing to do with producing the symptoms complained of.

AFTERNOON SESSION.

The afternoon session began with a discussion of the paper read by Dr. Emmet.

DR. THADDEUS A. REAMY, of Cincinnati, said that he would like to ask Dr. Emmet if he had not seen cases where the only tissue separated was the posterior commissure up to the entrance of the vagina. This injury is purely confined to those parts which Dr. Emmet claims are of no importance. He had another inquiry in regard to the operation. If he understood him rightly Dr. Emmet proposed to leave a surface inside, which was undenuded, which is to be covered over, leaving a cavity. When he described this it reminded him very forcibly of Dr. Sims' operation for cystocele, in which two points on the anterior vaginal wall below the os were denuded, and brought together. This operation was afterwards modified by the distinguished author of the paper just read. The modification consisted in carrying the line of denudation entirely across the vagina, for it was found that in the old operation the cervix settled into the pocket that had been left. It is also a better operation, for the reason that it leaves no cicatrix, but solid, firm union. It seemed to him that if the new operation for lacerated perineum were the better one, that it could be improved by denuding the entire surface.

He supposed that it was customary with every operator where there is great redundancy and prolapse of the posterior wall of the vagina, to close this first and subsequently operate on the perineum; and that everyone has found that in cases where the sphincter is not divided, the same results can be accomplished by taking out the redundant tissue in the posterior wall and including all in one operation.

He thought that the operation which had been described was an admirable one for a particular class of cases, but the number of these cases, he believed, was limited. He did not think that it was a substitute for the operation for lacerated perineum.

Dr. Frank P. Foster, of New York, said: I think I understand Dr. Emmet to say that the restoration of what is called the perineal body does not contribute to the rectification of the troubles which are complained of. Such being the case, although it is with some hesitation that I do it, I wish to put myself on record as being even more radical. I deny that the perineum has anything whatever to with supporting the uterus under normal circumstances. I think that this doctrine has nothing to recommend it but plausability. I do not think that there is an instance in human anatomy of an organ resting upon anything beneath it. The brain does not rest on the base of the skull, for if the base is removed the brain still remains in contact with the vault of the skull. The heart and lungs do not rest on the diaphragm. The liver rests upon nothing, but is supported from above. The womb does not rest on the perineum any more than it does on the woman's hand. If a healthy woman is examined in the standing position, and the perineal structure is depressed as much as possible, neither the uterus nor the anterior vaginal wall is affected by it. None of the structures that enter into the roof of the pelvis will follow the finger. What the perineum will do, and what it often does, is to sustain a uterus which has lost its normal support from above. The perineum has no sustentative function, but it does not, therefore, follow that the perineum has no function. It serves as a *point d'appui* for a number of muscles.

Dr. R. S. Sutton, of Pittsburg, hoped that he misunderstood Dr. Emmet in saying that no such body as the perineal body exists. He could not believe that he meant to say that there is no such body as the lozenge-shaped body which exists between the rectum and vagina. In frozen sections it is seen to consist largely of connective tissue and muscular fibre. We have been taught that when the perineum is lacerated, the transverse perinei muscles draw the two lips asunder. That is correct, and so long as anatomy stands, we cannot get away from that fact. Dr. Emmet had said that the tissues in front of the rectum are thicker after than before a laceration. He could conceive how the thickness might be greater from the presence of an enormous rectocele, but if there is no rectocele, it is anatomically impossible that the thickness can be greater. It has also been said that the symptoms attributed to the lesion do not necessarily follow it. Dr. Gaillard Thomas has said that a woman had better break her leg than rupture her perineum, and he did not know but that he was about right. He admitted that in many cases symptoms requiring surgical aid do not occur. There are cases of cystocele, of rectocele, and of prolapse of the vaginal walls dragging the uterus down, which have been always attributed to laceration of the perineum, and which as a rule are found only in women who have sustained laceration. Again, when the outlet of the vagina is broken, the vagina becomes a receptacle for atmospheric air, so that when the patient stoops, the air is forced out of the vagina. Such women exhibit a train of nervous symptoms which disappear after the operation.

It has been said that the uterus is not supported by the perineum, or the broad ligament, or the round ligament; and now, if we prove that the peritoneum does not support it, we shall soon be able to show that the uterus is in mid-air, and not supported by anything. It is supported by every thing surrounding it.

If the perineum is of no importance, why is it that laceration of it is followed by cervical catarrh, vaginal catarrh, relaxation of the vaginal walls, and a train of nervous symptoms which are clearly attributable to it? Why is it that in women with partial laceration you almost constantly find anal fissure? In this class of women anal fissure and hemorrhoids occur seven times more frequently than in women who have no laceration.

In reference to the operation just proposed, he can see very clearly how, where the laceration has been limited to the superficial tissues, that it will restore the parts; when the laceration has extended through the perineal centre he cannot believe it. Dr. Sutton then closed by referring to the similarity between this operation and that of Hegar.

Dr. Emmet then closed the discussion. He stated that he did not deny the existence of the perineum, but he did deny that there existed any such body as the perineal body. Everything in the pelvis is supported by fascia. He thought that when the members have had an opportunity of reading his paper that they would not see so much to object to in his plan of operation as they now do.

Dr. Charles Carroll Lee, of New York, then read a paper on

THE MANAGEMENT OF ACCIDENTAL PUNCTURE AND OTHER INJURIES OF THE GRAVID UTERUS AS A COMPLICATION OF LAPAROTOMY,

in which he gave the details of seven cases of this rare complication, including one that had occurred in his hospital practice. These are all that are known to him in medical literature. From them he drew the following conclusions:

1. The pregnant uterus may be punctured or otherwise wounded during abdominal operations without necessarily causing abortion.

2. Both from *a priori* and clinical evidence, abortion in such cases seems to depend on injury of the uterine contents, not of the womb itself, however severe.

3. If the former has certainly occurred, Cæsarean section is indicated, and should be done at once. In this case, the utmost care must be taken to secure thorough subsequent drainage from the uterine cavity.

4. If the uterine walls alone are injured, the wound is to be treated on general principles. If a deep puncture or incision, it must be sutured with the minutest care, with exact coaptation of the edges. For this purpose, fine silk sutures, rendered antiseptic, are the best. If a nick or superficial puncture, it must not be ligated, for ligatures cut quickly through uterine tissue; if too small to be sutured, the bleeding points must be lightly touched with the thermo-cautery until all oozing has ceased.

Good surgery and the dictates of humanity alike demand that in such circumstances a chance of survival be given the child as well as the mother.

Dr. H. P. C. Wilson, of Baltimore, said: I have had some little experience in the closing of wounds of the uterus in laparotomy during pregnancy. Last fall, I performed ovariotomy in a woman four months advanced in pregnancy. The condition was made out before the operation was attempted. On opening the abdomen, it was found that the ovarian tumor had a strong attachment to the uterus. It was found necessary to transfix this adhesion, and tie it in two sections. There were a number of other adhesions to the uterus, the separation of which caused considerable oozing. This was checked by the use of Monsel's solution. The tumor was removed, the pedicle touched with the iron salt, and the abdominal incision closed. This woman did exceptionally well. In two weeks she was sitting up. She then began to have pains in the abdomen, fever and chills. These increased in severity. At the end of a week or ten days, I felt a hard knot in the abdomen, and I was at first disposed to think that I had overlooked a second ovarian tumor; but I finally concluded that there must be a deep-seated abscess. I was considering whether or not to introduce an exploring needle, when the woman miscarried. This was about three weeks after the operation. The abscess broke at the same time, discharging a large quantity of pus. This abscess gave a great deal of trouble, filling and refilling. It was finally cured by applications of iodine. The patient recovered.

DR. GARRIGUES, of New York, had seen the case described by Dr. Lee, and made some remarks confirming and explaining what Dr. Lee had said.

DR. BYFORD, of Chicago, desired to express his opinion upon some points connected with this subject. First, as to the point of avoiding the danger connected with the operation of ovariotomy, of wounding the uterus. It seems from Dr. Lee's paper that in all cases in which the uterus was wounded, except his own, that pregnancy was suspected, and that consequently there must have been some defect in his examination. In the case which he had, he did not make a thorough examination; he was deterred from making it by the statements that the patient was entirely above suspicion, and he felt that it was not right to subject her to the examination.

The second point is as to our rule of action when the accident has happened. Before hearing this paper, he had concluded that it would always be proper, when the uterus had been wounded, to open the organ and remove its contents. From Dr. Lee's case, he must conclude that an exception to this rule would be favorable. He has reported a case where the contents of the uterus were not removed, and the wound of the uterus was sewed up. In this case pregnancy had probably not advanced beyond three months. At that time the fibres of the organ are not so soft, and they do not tend so strongly to draw open the wound, as at a later period. He thought that if pregnancy had advanced to seven or eight months, that the stitches would not hold. In his own case the wound in the uterus made by the trocar was about the size of his finger. In ten minutes, it was as large as a silver dollar. The traction of the muscular fibres was so strong that he felt convinced that stitches would have been torn out. The plan recommended by Dr. Lee might be used in the early stages of pregnancy; but when the uterus is sufficiently large to cause the kind of traction spoken of, he should be inclined to remove the contents of the organ, even if the wound had not involved its whole thickness.

Another point of the paper seems to be, that in all cases in which the wound was sewed up, the patients recovered, while in all the cases in which it was not closed the patient died. He thought the rule ought to be as he before stated.

DR. LEE said, I have but a few words to add. In regard to Dr. Wilson's case, it does not properly come under the class of cases embraced in this discussion. It was a case in which miscarriage occurred from contiguous inflammation. I should not recommend the application of iron styptics in the pelvic cavity; I think that the thermo-cautery is much safer. I am not disposed to take issue with Dr. Byford in regard to the treatment of wounds of the uterus at early and late periods of pregnancy. It is very probable that at a late period the uterus could not be safely repaired by sutures. One important point in Dr. Byford's case was that the child was viable.

DR. A. REEVES JACKSON, of Chicago, then read a paper entitled,

IS EXTIRPATION OF THE CANCEROUS UTERUS A JUSTIFIABLE OPERATION?

In medical and surgical practice the results obtained from any means or method of treatment are proper tests by which their value may be judged. And, in accordance with this principle, whenever any therapeutic agent has been found, after adequate trial, to generally fail in effecting the purpose of its use, or to be habitually dangerous to health or life, candid and honest men have ceased to employ it.

During the past few years there has been a rapidly growing tendency to a bold, fearless—may I not say reckless?—progressiveness in the surgical branches of our profession that would have appalled our predecessors. When we consider that some of these achievements are scarcely more than ante-mortem examinations, whose chief usefulness consists in demonstrating how long their owners are able to survive the loss of certain bodily organs, we may properly ask whether there is to be any limit to these exhibitions of surgical temerity.

I propose to discuss this question: In view of known facts, is it justifiable to extirpate the uterus for carcinomatous disease?

It is notorious that in almost all instances in which surgical operations have been done for the removal of cancers, they have only been of temporary benefit—if beneficial at all. Nevertheless, so long as these procedures were comparatively free from danger to life; so long as they did no actual harm, they were doubtless proper in many cases, because they added for a time to the patient's comfort. They rarely did more than this. But when the operations themselves become so dangerous as to destroy 70 per cent. of lives within a few hours, or a few days; and when, of the few who escape the operation, 50 to 75 per cent. die from recurrence of the disease within a few months; and when, further, of those who yet remain all, or nearly all, die as soon as though no operation had been performed, we should halt to consider whether our calling, thus exercised, is beneficial or injurious.

The removal of the whole uterus is not a very novel operation. Andreas A. Cruce removed the organ, per vaginam, for scirrhus in 1560; and similar operations were done by Wrisburg, and by Monteggia at the end of the eighteenth century. Blundell operated in three cases in 1828, two of the patients dying, and one surviving a year, and finally dying from a recurrence of the disease.

In 1878 Prof. W. A. Freund reported a new method, under antiseptic precautions, whereby the uterus could be, as he thought, more safely removed than hitherto. In the early part of 1879 he had operated in ten cases, with the result of five deaths and five recoveries, and in September of that year, at the International Medical Congress, at Amsterdam, he reported four additional cases of his own. In one of these the operation was unfinished; the other three were all fatal. Paggia (*Giornale Internazionale delle Scienze Med.*, fas. 3, 4, 1883) furnishes the latest table of operations by Freund's method. It includes 91 cases; 66 died; 25 recovered; mortality 72.5 per cent. Yet at the London Congress, Freund made the astounding statement that the operation may be undertaken as a not very dangerous one in the early stages of carcinoma and sarcoma, in which it gives promise of a radical cure!

In consequence of the frightful mortality following the abdominal method, Czerny, Schrœder, Martin, and others have practised the removal of the uterus by the vagina, and thus far with better results. A table compiled by Sänger (*Archiv für Gynäkologie*, Berlin, 1883) includes 143 cases, of whom 72 per cent. recovered, and 28 per cent. died.

Extirpation of the uterus for cancer does not save, but destroys life. In order to show how much life has been sacrificed by it, I accept all the known fatal operations as the full number, although it is certain that there have been many more. They amount to

159 cases—97 by the abdominal and 60 by the vaginal method. If we grant that in all these cases the disease affected the cervix, and that the average length of life would be seventeen months, the calculation would show more than 222 years of life—over two centuries—sacrificed by the operation. If we consider that in many of the cases the disease affected the corpus uteri, as it surely did, in which the average duration of life is two and a half years, the aggregate amount of life destroyed would be even greater.

To summarize, I have endeavored to show that

1. Diagnosis of uterine cancer cannot be made sufficiently early to ensure its complete removal by extirpation of the uterus.
2. When the diagnosis can be established, there is no reasonable hope for a radical cure; and other methods of treatment, far less dangerous than excision of the entire organ, are equally effectual in ameliorating suffering, retarding the progress of the disease, and prolonging life.
3. Extirpation of the cancerous uterus is a highly dangerous operation, and neither lessens suffering—except in those whom it kills—nor gives reasonable promise of permanent cure in those who recover. Hence, it fails in all the essentials of a beneficial operative procedure, and should not be adopted in modern surgery.

Dr. Van de Warker, of Syracuse, said that in a recent editorial expression of opinion, he took substantially the same ground as that held by Dr. Jackson upon the advisability, as a matter of expediency, of the operation of removing the uterus, as an exemption from suffering and a means of prolonging the life of the patient. Since then he has had no reason to change his views; on the contrary, he had every reason to hold to that view.

After a few general remarks on the value of scraping and the application of the cautery, he described his plan of operating, which is simply the result of carrying Dr. Sims' method to its logical conclusion. Instead of using a solution of five drachms of chloride of zinc to the ounce, he employs a saturated solution. By this plan he has a harmless extirpation of the organ. The uterus is first thoroughly scraped, it is then packed with cotton saturated with Monsel's solution in order to check bleeding; subsequently it is packed with cotton containing the saturated solution of chloride of zinc, the result is an enormous slough of the cavity of the uterus. He exhibited a number of sloughs which had been removed in this way. In one of the cases, while scraping, he found that he was almost in the bladder; he, however, decided to apply the caustic: the result was an enormous opening into the bladder. In about six weeks the opening had contracted to one-quarter inch in diameter, the woman retaining control of the sphincter in the erect position; there was some dribbling when lying down. This patient has just died. The operation was done in January, 1883. One of the specimens had been obtained eighteen months before; the woman was still well. He had operated on eight cases, three of which had since died. He considered it simply to be a question of prolonging life and arresting the downward course of the disease.

Dr. Emmet, of New York, said that he had been much pleased with the paper because it expressed his own views in regard to the operation. His experience is limited to one case, and that was unsuccessful. He now disapproves of the operation. About two years ago, a middle-aged, unmarried lady was sent to him with amenorrhœa and nervous symptoms; her family physician had made an examination, and found what he considered to be the remains of an old laceration of the cervix. She denied ever having been pregnant. On examining her, he found the same condition, and felt almost satisfied that the woman had been pregnant. About five days after the first examination, he saw eight or ten minute granulations springing up in the scar, just like wheat in a furrow. In ten days the whole cervix was covered with a mass of epithelioma. On being pressed, she acknowledged that twenty-five years before an abortion had been induced. He determined to remove the womb through an abdominal incision. The operation was a difficult one, but he finally succeeded in removing the entire uterus—the woman had no shock, and the case progressed without trouble for five days. Then came blood-poisoning. He opened the wound in the vagina, and flooded her with water. She died, and he found that, from lying on the back, several ounces of fluid had collected in the hollow of the sacrum, which were not removed by the drainage-tube or washing. If the operation is ever to be done, it should be done by the vagina, and should be confined to removing the uterus for sarcoma.

Dr. Baker, of Boston, said that he had operated in several cases, some so long ago as six years, which have not yet died. By the operation which he performed it is possible to remove the entire supra- and infra-vaginal portions of the cervix, as well as from one-third to one-half of the body of the uterus by a comparatively simple operation. He is sure that he has operated at least thirty times without a single death, and he can recall six cases, of at least five years' standing, which have absolutely recovered.

The operation is as follows: An incision is made at the junction of the anterior wall of the vagina with the cervix, and the dissection is carried up to the level of the internal os in the connective tissue covering the cervix. The same is done on the posterior surface of the cervix. The whole cervix is then removed by a transverse cut. A cone-shaped incision is next made, removing from one-third to one-half of the body of the uterus. The thermo-cautery is then applied to the denuded surface. The advantage of the actual cautery over chloride of zinc is that the patient can be kept absolutely at rest. He is sure that the diagnosis may be made early in these cases, and, if made early, he believes that the diseased tissue can be entirely removed. The cases in which total extirpation is advisable are extremely rare, and comprise those in which the disease begins in the cavity of the uterus.

Dr. C. D. Palmer, of Cincinnati, said that, so far as total extirpation of the uterus for cancer is concerned, the cases may be divided into two classes: 1. Those in which it is clearly unjustifiable. 2. Those in which it may be justifiable. The first would include almost every case of cancerous disease beginning in the cervix. The second would include those cases of sarcoma starting in the uterine body, which are very rare. It is usually impossible to determine whether the disease has extended beyond the uterus itself. He has always declined to perform the operation. Last spring he had a case which illustrated the impossibility of determining whether the disease has gone beyond the uterine body. It was a case of soft sarcoma in the body. The infravaginal portion of the neck was free from disease; the womb was freely movable, and no evidence of disease could be detected in the vagina or rectum. He was asked to remove this uterus, but declined. A few days later, he was asked to assist in the removal of a uterus. The case was the same upon which he had declined to operate. With great difficulty the organ was removed, and three small nodules were found in the anterior wall of the rectum and in the connective tissue around the uterus. The woman died in a few hours after the operation. The disease would certainly have returned in a short time.

Dr. Sutton, of Pittsburg, in speaking of the removal of the uterus per vaginam, said that it was not as fatal as ordinary ovariotomy. Schröder lost only one out of thirteen from the operation. Martin told him that his longest case lived twenty-two months after the operation. He then described the operation as performed in Europe. The woman is placed in the lithotomy position, and Simon's speculum is used to elevate the anterior vaginal wall and depress the posterior. Lateral retractors are also used. In order to prevent the constant presence of blood in the vagina, a stream of carbolized water is thrown in. An incision is made across the cervix, just below the vaginal attachment. A curved needle is then passed through the upper lip of the incision and the ends drawn out together and turned over the pubes. With the thumbnail everything above the cellular tissue is skinned back until the peritoneum between the bladder and uterus is reached. The incision is then carried across the neck. The posterior lip is then treated in the same way. The peritoneum is then opened and the opening dilated with the finger. A volsellum forceps is next passed through the opening, grasping the fundus and drawing it into the vagina. With a curved needle a double ligature is passed through the broad ligament and firmly tied. A clamp forceps is applied to the ligament, and the ligament cut. The uterus is then drawn down and the ligament on the opposite side is treated in the same way. The opening in the vault of the vagina is not sewed up. Schröder puts a large drainage-tube into the pelvic cavity, one end of the tube being outside of the vulva. The vagina is then packed with cotton saturated with iodoform. Martin sometimes simply stuffs the vagina with antiseptic material, and the patients recover. So far as the advisability of the operation is concerned he had not made up his mind.

DR. JACKSON, in closing the discussion, reaffirmed the conclusions which he had laid down in his paper.

THURSDAY, SEPTEMBER 20TH, THIRD DAY.

BUSINESS MEETING.

The Society assembled at 8.30 A. M., for the transaction of business, with closed doors.

Upon the adjournment of the business meeting it was announced that the following had been elected

OFFICERS FOR THE ENSUING YEAR:

President.—Albert H. Smith, M.D., of Philadelphia.

Vice-Presidents.—James R. Chadwick, M.D., of Boston; S. C. Busey, M.D., of Washington.

Secretary.—Frank P. Foster, M.D., of New York.

Treasurer.—M. D. Mann, M.D., of Buffalo.

Other Members of the Council.—Drs. T. Gaillard Thomas, of New York; Fordyce Barker, of New York; T. A. Reamy, of Cincinnati; R. S. Sutton, of Pittsburg.

It was decided to hold

THE NEXT MEETING

at Chicago, on the last Tuesday in September, 1884.

MEDICAL SOCIETY OF VIRGINIA.

Fourteenth Annual Meeting, held at the Rockbridge Alum Springs, September 4, 5, 6, and 7, 1883.

(Specially reported for THE MEDICAL NEWS.)

(*Continued from page 300.*)

THURSDAY, SEPTEMBER 6TH, THIRD DAY.

AFTERNOON SESSION.

DR. JOSEPH A. WHITE, of Richmond, Va., Surgeon-in-Charge of the Richmond Eye, Ear, and Throat Infirmary, read an interesting report of

CASES ILLUSTRATING DIFFERENT INJURIES OF THE EYE, WITH REMARKS ON INJURIES OF THE EYE AND THEIR RESULTS.

Compression of an eye by a blunt instrument may cause ecchymosis, opacity, with or without inflammatory suppuration of the cornea, rupture of the sclerotic near the sclero-corneal ring, hemorrhage into the anterior chamber or into the vitreous, laceration of the iris, paralysis of the sphincter of the pupil, suspension of accommodation, bursting of the capsule of the lens, stretching or laceration of the zonula of Zinn, and disturbances of the retinal function. If the eye is thrown into violent oscillations, as by concussion, some of these results may follow. Strictly speaking, there can be no such thing as *contre-coup*, so far as effects the eyeball. The damage is usually the result of flattening of the eyeball, the flattening ordinarily occurring in the antero-posterior axis, or at an acute angle to it, and the stretching in the equator or near it, thus stretching apart the sclero-corneal ring, and disarranging the tissues connected with it.

Dr. White then narrated a number of illustrative cases, and made some *Remarks on Stretching of the Zone of Zinn and Dislocation of the Lens.* Injury from compression or concussion of the eye almost invariably results in stretching this suspensory ligament of the lens, and generally results in opacity of the lens, either directly or mediately, through changes effected in the choroid or vitreous. Dislocation of the lens, besides resulting in cataract, often leads to degenerative changes, resulting in cyclitis, with shrinkage of the eyeball or secondary glaucoma, either of which may end in neuralgia or sympathetic disease of the other eye. In this connection, Dr. White reported an illustrative case, and described the operation performed by Dr. Buhl, of Bordeaux, for stretching and rupture of the external nasal nerve or infra-trochlear. A curved incision is made through the skin and subcutaneous tissue at the inner angle of the brow between the pulley of the superior oblique and the tendon of the orbicularis. A strabismus hook is carefully swept closely against the periosteum, and the nerve picked up. This is then separated from its vessels, and by gentle pulling with two pair of flat forceps, one after the other (hand over hand, as it were), it is stretched until rupture takes place. This operation has been performed for persistent ciliary neuralgia, chronic inflammatory and secondary glaucoma, intractable blepharospasm and photophobia, hydrophthalmos, and bids fair to be a great acquisition to eye surgery.

The second class of eye injuries considered are those due to entrance of a foreign body. Small iron filings penetrating the cornea may generally be removed with a magnet. The effect of a foreign body in the eye does not depend so much on its chemical nature or its size, as upon the fact that they are so frequently accompanied by germs of inferior organisms. Experiments have proved that particles of stone, glass, etc., introduced into the anterior chamber do not necessarily cause violent reaction. If they rub against the iris in its movements, then they cause pain and irritation. The same substances introduced into the vitreous humor caused no violent reaction. Iron and copper particles, although exerting a chemical action, do not necessarily induce violent suppurative reaction when introduced into the anterior chamber; but if introduced into the vitreous, sooner or later they cause detachment of the retina, or continual irritation without suppuration, and thus result in sympathetic disturbance of the uninjured eye. Iron does not produce suppuration in the anterior chamber, nor does copper in the vitreous; in the ciliary bodies only a local suppurative action results. Lead does not provoke suppuration anywhere. Metallic mercury causes inflammatory suppuration in either the anterior chamber or the vitreous.

After discussing at some length the various dominant theories of the manner of development of sympathetic troubles in the sound eye, he passed on to the consideration of the third class of eye injuries—from agents which, by their high temperatures, chemical properties, etc., affect the cornea, conjunctiva, and lids. Scalds, etc., should be treated by first thoroughly cleansing the part with warm water. A strong saccharine solution is useful in removing adhering particles of lime. Threatening iritis is to be warded off by ice-cold compresses. He opposes the local use of lead preparations. Repeated separation of the lids from each other and from the eyeball will prevent adhesions, provided the eschar does not include the cul-de-sac.

The paper concluded with a most interesting detailed account of a case of pulsating exophthalmos, in all probability due to aneurism of ophthalmic artery, with spontaneous cure.

THE REPORT OF THE COMMITTEE ON HYGIENE AND PUBLIC HEALTH,

by Dr. W. F. Barr, of Abingdon, Va., stated that nothing had been reported during the past year that was entitled to be termed an advance in this department. "Not even in our own State have any steps been taken to protect 'the people' from charlatans. Year after year have committees labored with the members of the Legislature to induce them to adopt *some* kind of a law regulating the practice of medicine, but all to no effect. Although our neighboring sister States, North Carolina and West Virginia have done good work in this respect, and Illinois, Michigan, Louisiana, and Texas have done likewise, yet in Virginia anybody who can pay the license-tax for the privilege of practising medicine, surgery, etc., can unfurl his banner, hang out his shingle, look wise, and with the assurance of Paracelsus, practise medicine. A good State Board of Health cannot be supported! But when yellow fever, cholera, or smallpox is heard of, some are aroused with a kind of 'graveyard religion,' and are willing for the doctors to labor free of charge to save them from disease and death." The report closed with an urgent appeal to the profession not to "faint in well-doing."

INVITATIONS

were received from the Blue Ridge Springs Company, the Rawley Springs Company, and a renewal of the invitation from the Rockbridge Alum Springs Company for the Society to meet next year at their favorite resorts.

Rawley Springs, Va., was selected as the

PLACE FOR THE NEXT ANNUAL SESSION,

at such time during the summer of 1884 as the Executive Committee might decide upon after conference with the managers of those Springs.

OPIUM HABIT.

The Recording Secretary, at the request of Dr. W. G. Rogers, of Charlottesville, Va., who was unable to be present, presented the following preamble and resolutions, which were unanimously adopted:

Whereas, the insidious habit of opium eating is daily increasing—a habit destructive to the health and morality of its victims, and a public calamity that should be abated by all rightful and legal means practicable; and since it is believed that this habit has been favored and increased, and doubtless, too, caused by the indefinite refilling of physicians' prescriptions by druggists, and by the selling of opium and its products in such prescriptions; therefore

Resolved, That we, the members of the Virginia Medical Society, in convention assembled, will use all proper means to prevent the *refilling* of physicians' prescriptions by druggists, whenever these contain opium, its products, or other narcotic poison, by writing upon each prescription "*this shall not be refilled*," or such other methods as may be deemed best to effect the object in view.

2. That we respectfully petition the Legislature of Virginia to enact such laws as will prevent *this evil*, by making it a penal offence for druggists to refill physicians' prescriptions containing opium, or other narcotic poisons, or to sell poisons or other medicines that are recognized as such, without the prescription of a practising physician, which shall not be refilled, but renewed by the physician, as in his opinion needed.

3. That a committee be appointed by the President of this Society to lay these resolutions before the Legislature at its next meeting, with such reasons for the same as may be deemed expedient.

4. That since this question concerns *all the people*, whose welfare and interests are so deeply involved in its solution, in a suppression of the evil, that not only the medical journals, but other papers of Virginia be requested to publish these resolutions.

Dr. H. D. Kerfoot, of Manassas, moved that the Committed appointed to petition the Legislature to enact certain medical laws, be continued, looking to a more perfect organization of the

STATE BOARD OF HEALTH,

as also to the establishment of a State Board of Medical Examiners, etc. Carried.

DIPHTHERIA,

the subject for general discussion, was then called up.

Dr. Rawley W. Martin, of Chatham, Va., opened the discussion by reading a paper on

DIPHTHERIA AS IT PREVAILED IN A CERTAIN SECTION IN PITTSYLVANIA COUNTY, VA., IN 1882,

in which he described the general range of the epidemic which so terribly devastated the southern section of this State during the summer and fall of 1882. The epidemic really began during the winter of 1881–82, and spread from a girl who attended a public school in the centre of the infected district. Since 1861, until this time, the disease had not been epidemic. The summer of 1882 was a wet season, and vegetation was unusually luxuriant. The character of the ground consists of a porous soil with a clay substratum. Several instances of direct contagion occurred. In some cases, the throat was so slightly affected as not to be complained of by the children. Among the most unfavorable symptoms were extensive swelling of the lymphatic glands and chest, and profuse epistaxis. Persistent refusal of the child to lie down was another unfavorable symptom. Some were doggedly determined to take nothing by the mouth—not even water, although thirsty. Diphtheritic paralysis was very fatal. Following the epidemic, a wide-spread epidemic of sore throat — not diphtheritic — prevailed throughout the county. The mortality was about one in seven of those attacked with diphtheria. Infants at the breast were seldom attacked. Few adults had the disease. The treatment from the beginning consisted in following the directions given in most of the works on the subject. Tincture of the muriate of iron disordered the stomach, and chlorate of potash locally did no good. Rectal alimentation was the common method of nourishing the children. Full purgative doses of mercury in the outset seemed to modify the trouble. Bichloride of mercury solution (one grain to ℥iv of water) in small doses, say a teaspoonful, acted well. Egg-nog was also valuable. In fact, alcohol was the one great remedy. From these facts, the Doctor drew the following conclusions:

1. No history of contagion could be satisfactorily traced and it is questionable whether the disease originated *de novo* or not.

2. In this, as in other epidemics, sanitary surroundings had increased the disease-producing properties of the poison germs and rendered the disease more malignant.

3. The disease requires different treatment in different epidemics.

4. That many lives could be saved if treatment could be carried out without resistance from the sufferer.

5. That mercury is not a hurtful remedy, but really seems to possess as much or more power of destroying the disease germs than alcohol.

6. That the disease may exist in the system and at the same time produce very slight sore throat.

7. That the mortality was not greater than is usual in epidemics of like malignancy.

Dr. Bedford Brown, of Alexandria, Va., followed in another paper, entitled

REMINISCENCES OF PERSONAL EXPERIENCE IN THE HISTORY OF DIPHTHERIA.

His experience, he said, dates back to 1856, as to diphtheria. Since that time he has seen the disease both in civil and military practice; both sporadic cases and cases belonging to severe epidemics. But treatment has not advanced *pari passu*. He narrated some of the first cases he met with, which prove that they were examples of the true disease; and some of the cases were so complicated with other troubles as to make their detail instructive and interesting. For instance, he speaks of a patient who had hemorrhoids at the time diphtheria attacked him. The infectious disease seized hold of the hemorrhoidal tumors, external and internal, and extensive membranous exudations formed, reaching high up the rectum, which he passed in defecation. Further on, he refers to the fact that no disease has a greater diversity of tendency to death. Thus there is tendency to death by toxæmia from diphtheritic laryngitis, nephritis, suppression of urine, uræmia, reflex paralysis, paresis, inanition, etc. Hence, always watch the route by which death is threatening, and guard with special care, that road. Dr. Brown is a strong believer in the "dual theory" as to the non-identity of diphtheria and membranous croup; arguing his point chiefly from the pathological and etiological standpoints. In his long experience before diphtheria began in his section, some twenty-six years ago, he never saw a case of membranous croup "followed by paralysis of the voluntary or reflex system of nerves." In no case of membranous croup, before diphtheria began in 1856, did he ever witness the kidney troubles that follow diphtheria so frequently. Membranous deposits never occurred on sores or elsewhere on the body, except as a laryngeal membrane before diphtheria was announced. Previous to, and during the process of membranous exudation in croup, the temperature is always high and continuous. On the contrary, who, knowing diphtheria, does not apprehend danger from sudden fall of temperature? Previous to the outbreak of diphtheria in 1856, he never saw in cases of croup, a membranous deposit in the rectum, vagina, or on the vulva, or skin. In diphtheria, the salivary glands often become enlarged; before 1856, he never observed such an effect from membranous croup. Diphtheria is to a greater or less extent infectious. Previous to 1856, he never saw a case of membranous croup that seemed to have the slightest element of infection.

Dr. Brown next referred to the action of diphtheritic poison on the sympathetic and vaso-motor system of nerves. This is chiefly manifested in its paralytic tendency, as shown by paralysis of the heart, stomach, and the digestive organs generally, as also of the kidneys, ending in suppression. Many other well-defined points of difference between diphtheria and membranous croup were brought out.

After this he passed to the *treatment of diphtheria*. Cauterizations are of no service ordinarily. Alum and tannin next came to the front. After their failure to arrest the throat affection, tincture of the chloride of iron was brought into use, and then tincture of iodine—each as a local application. Sulphate of copper and zinc, dissolved in honey and tar-water, then became a popular local remedy. Indeed, almost every conceivable form of astringent, stimulant, alterant, and caustic were resorted to as local applications. The earliest efforts at a *general* treatment of epidemic diphtheria probably consisted in the use of emetics followed by mercurial treatment. Chlorate of potash soon afterwards came into use; then muriated tincture of iron and finally quinia sulphate were added. In mild cases this combination is useful as constitutional remedies, but in addition, alcohol is needed as a nutrient stimulant in severe cases. Belladonna and strychnia have also proved valuable helps. Disinfectants and antiseptics are useful as local applications. Sulphurous, chlorinous, and other like vapors inhaled are serviceable. There are always digestive and assimilative troubles; especially in severe cases are these standing difficulties. In addition to nourishment and cleanliness of the air-passages, he recommends the following local antiseptic:

℞.—Listerine, ... f℥ss.
Cinnamon water, ... f℥iv.
Chlorinated solution of soda, . f℥ss.
Carbolic acid, ... gtt. vj.—M.
S.—Use with syringe or atomizer to throat or nose.

It combines well with the leading vegetable and mineral disinfectants.

For a local application over the salivary and cervical glands, he recommends the application of the following lotion:

℞.—Chloride of ammonium,
Chlorate of potash, . . . āā ʒij.
Rose water,
Alcohol, ... āā f℥iij.—M.
S.—Apply to the external swelling frequently and freely.

This combination is cooling or refrigerant.

For the hemorrhagic form of diphtheria, Dr. Brown recommends the combined influence of oil of turpentine, ergot, and digitalis internally, and the local spray of dilute Monsel's solution. As an internal disinfectant and tonic,

℞.—Tincture of the chloride of iron, . fʒij.
Chlorate of potash, . . . ʒj.
Tincture of nux vomica, . . gtt. xx.
Tincture of digitalis, . . . fʒss.
Water, ... f℥ijss.—M.
S.—Teaspoonful, to a child of two years of age, every one or two hours, in water.

℞.—Hyposulphite of soda, . . ʒij.
Sulphurous acid, ... f℥iij.
Water, ... f℥ij.
Glycerine, ... f℥j.—M.
S.—Teaspoonful every alternate hour, to be taken with above.

Dr. William Pepper, of Philadelphia, Penna., has written Dr. Brown that he uses, and with encouragement, minute doses of bichloride of mercury and tincture of nux vomica, but Dr. Brown has no experience in the use of this special formula.

Dr. Wm. Selden, of Norfolk, Va., gave the highest recommendation of chlorine water prepared according to *Watson's Practice*, 1st ed. He uses muriatic acid and chlorate of potash to make chlorine, and mixes one-half drachm to four ounces of water, giving one teaspoonful every half-hour, followed by whiskey toddy each time. He had never seen a patient die who was under this treatment. For a local application, he uses alum two drachms, salicylic acid one drachm, sulphur one drachm, with enough glycerine to make the preparation of the consistency of honey. This local and systemic medication is the general Norfolk treatment.

Dr. Wm. H. Coggeshall, of Richmond, gave Reiter's theory of diphtheria, which is that the fibrin-destroying function of the liver is not fulfilled as it should be, and hence fibrin accumulates in the blood. Dr. Reiter gives twenty grains of calomel at once, and ten grains every hour, until half an ounce is taken, and claims to cure all cases of the disease.

Session adjourned to 7.45 P.M.

(*To be concluded.*)

CORRESPONDENCE.

PROPER MODE OF REDUCING PARTIAL FORWARD DISLOCATION OF THE STERNO-CLAVICULAR JOINTS.

To the Editor of The Medical News.

Sir: The following letter of Prof. Cabell came too late to enable me to utilize it for the recent edition of my *Surgery*, and I therefore send it to The News, as I consider it too valuable to be lost. Yours truly,

S. D. Gross.

Dear Dr. Gross: If that part of the forthcoming edition of your *Surgery* which treats of Dislocations has not already been put to press, I wish to avail myself of your courteous offer, and to invite your attention to the particular features and treatment of a *partial* forward dislocation of the clavicle at its sternal extremity. I call it *partial*, as coinciding with the probable integrity of the costo-clavicular or rhomboid ligament, although in respect of the degree of displacement it may be fully as complete as any ordinary dislocation at this joint.

The costo-clavicular ligament is not a part of the proper articular apparatus of the sterno-clavicular joint, and yet its integrity or its rupture may very materially modify the indications in respect of the retentive means after a reduction of the dislocation. In order to reduce and retain the articular end of the clavicle in place, it is directed to carry the shoulder backwards, and maintain it in that position by such an apparatus as is used for fractures of the bone. This is doubtless correct in all those cases in which the costo-clavicular ligament is torn, but I have seen two cases in which the act of carrying the shoulder backwards greatly aggravated the forward displacement of the sternal end of the clavicle, and in which the dislocation could only be reduced by bringing the shoulder far forward; in other words, the clavicle moved exactly as it does in the normal mechanism of its movements—namely, as a lever of the first kind. The sternal end recedes as the shoulder comes forward, and *vice versa*. It is presumable that the fulcrum, during the execution of these normal movements, is at the costo-clavicular ligament, and that when this is completely torn up, the leverage action is destroyed. In such a case, the whole bone would have to be carried backwards in order to effect the return of the sternal end from its forward displacement; but if the fulcrum remains, then the shoulder has to be brought forward in order to carry the sternal end of the clavicle back into its proper place. Certainly this was found to be necessary in the two exceptional cases to which I have alluded.

That this is a more common occurrence than is supposed I think exceedingly probable, for some writers, notably Bryant, speak of the difficuly of keeping the articular end of the clavicle in place after reduction without forcible pressure directly applied. I think it probable that in some of these cases the difficulty would have been lessened by advancing the shoulder.

Very truly yours, J. L. Cabell.

University of Virginia,
June 12, 1882.

NEWS ITEMS.

ATLANTIC CITY, N. J.

(*From our Special Correspondent.*)

Atlantic City has at length accepted the views of the State Board of Health of New Jersey and of very many Philadelphia physicians, as to the necessity of sewerage. It has contracted with a company which, by means of approved sewers, will carry all fouled liquids to a pumping station outside of the city limits, from which it will be conveyed, by means of a force-pump, three or four miles away, and then filtered and precipitated so as to form a compost and to leave clear water. With this and its excellent water supply the city will have secured the first essential conditions of a health resort by the sea.

Typhoid Fever in New York.—According to the records of the Board of Health, typhoid fever has alarmingly increased in New York during July and August, and this increase will continue as cold weather sets in, and the city fills up with people from the country. A map of the cases, so far as prepared, does not show that the disease is confined to any particular locality, but is rather distributed generally over the city among those who do not avail themselves of early medical advice.

The Board calls attention to the neglect of proper disinfection in typhoid fever, as is shown in the reports of their inspectors. In several instances already, where there were no sanitary defects to account for it, five or six cases have occurred in one family. In these instances it has been found that the undisinfected excreta of the patients have been left for hours in the room where the sick and well have been together. The physician is often not called in until the disease has progressed into the diarrhœal stage, and the family are often unable to secure his continual services. He sometimes contents himself with advising disinfection, in a general way, without particularizing as to quality or method. It is no uncommon thing to find saucers filled with chloride of lime in one corner, and a pile of stained and infected bedclothes in another. It is of little use to empty a privy or repair a broken sewer if the sick-room itself is neglected. The vital point in the sanitary treatment of typhoid fever is the efficient disinfection of the clothing, bedding, and discharges of the patient, and this is considered to be an important factor in controlling the disease during the approaching winter.

The Board has issued an address to the public in which the importance of disinfection is insisted upon.

In this connection, we may refer our readers to our Special Article on the subject of typhoid disinfection which appeared in the issue of The Medical News for September 1, 1883, page 244.

Yellow Fever at Pensacola.—No case of yellow fever has appeared in the city of Pensacola, the disease having been confined to the Naval Reservation.

During the past week there have been reported at the Navy Yard eleven new cases of fever and one death.

Yellow Fever at Havana.—There were one hundred and fifty-two deaths from yellow fever at Havana during the month of August. During the week ending September 7th there were eighteen deaths from the same cause.

Yellow Fever at Vera Cruz.—At Vera Cruz there were nineteen deaths from yellow fever during the ten days from August 20th to 30th.

Yellow Fever in Mexico.—Surgeon-General Hamilton, of the Marine-Hospital Service, has information from Yuma, Arizona, of the existence of yellow fever in Guayamas and Mazatlan, in Mexico. He says, however, there is no reason for fear that the disease will spread into Arizona, and from his information as to the character of the country, and the climatic conditions of the region in Mexico in which the disease has appeared, he does not think it will spread much there.

Later reports state that the disease is abating at Guayamas.

Sanitary Inspection of the Mississippi.—Secretary J. H. Rauch has issued the following:

"The Executive Committee of the Sanitary Council of the Mississippi Valley hereby gives notice that its supervision of inspection at the port and in the city of New Orleans, and the inspection stations below Vicksburg, at Fort Adams, Miss., and below Memphis, at President's Island, Tenn., will be discontinued on and after Saturday, September 15th."

Smallpox in New Orleans.—For the week ending September 8th, there were eight cases of smallpox in New Orleans.

The Mortality in New Jersey.—The State Board of Health of New Jersey reports a marked decrease of mortality for the year ending July 1, 1883.

Leprosy at San Francisco.—A case of leprosy was brought to San Francisco by the last steamer from Honolulu. The quarantine officers refused permission for him to land. A writ of habeas corpus has been issued, and the matter will come up in the Superior Court for decision.

Best Method of Testing Milk.—Dr. E. H. Bartley, Chemist of the New York State Board of Health, recently delivered a lecture to the milk-dealers of Brooklyn, in which he said that milk which showed a specific gravity of 100, at a temperature of 60° by the common lactometer, and 10 per cent. of cream by the cream gauge, could be safely sold as pure milk.

American Academy of Medicine.—The annual meeting of the Academy will be held at the New York Academy of Medicine October 9th and 10th.

Death of one of the French Cholera Commissioners.—Dr. Thuillier, a member of the Pasteur Scientific Mission, died at Alexandria on Tuesday, the 18th inst., of cholera.

Professor Matthew Hay.—Dr. Matthew Hay, late assistant to the Professor of Materia Medica in the University of Edinburgh, has recently been appointed to the Chair of Medical Jurisprudence in the University of Aberdeen, rendered vacant by the resignation of Prof. Ogston.

"Hospital Saturday" in London.—On September 1st, collections were made in London and the suburbs for what is known as the "Hospital Saturday Fund." The collection was made in two ways. Money-boxes, which were in many cases in charge of ladies, were placed at the corners of streets, near coffee palaces, and at other places where there were likely to be large crowds of people. There were twelve hundred ladies thus engaged in various parts of London. A collection was also made in the workshops of the capital by means of subscription sheets.

There is every reason to believe that the collections will considerably exceed in amount those of last year. It is thought that the street collection will produce at least £3000, and the workshop collection £7000.

Nephrectomy in Birmingham.—On August 11th, Mr. Bennett May, excised the right kidney of a female patient, æt. 24, at the Queen's Hospital, Birmingham. The organ, which was the seat of tubercular disease, and weighed nearly a pound, was removed by lumbar incision. No urine was secreted after the operation, but, with this important exception, there was little indication of local or constitutional disturbance till the patient's death, which occurred suddenly five days afterwards. The necropsy showed, as the suppression of urine indicated too surely, that the other kidney was also disorganized by similar disease.—*British Med. Journal*, Sept. 1, 1883.

Health in Michigan.—Reports to the State Board of Health for the week ending Sept. 8, 1883, indicate that consumption, influenza, neuralgia, and puerperal fever have decreased in area of prevalence.

Compared with the average for the month of August in the preceding six years, remittent fever was considerably less prevalent; intermittent fever, dysentery, consumption, and whooping-cough less prevalent, and bronchitis and neuralgia more prevalent during August, 1883.

Including reports by regular observers and by others, diphtheria was reported present during the week ending Sept. 8, and since, at fourteen places, scarlet fever at twelve places, and measles at four places.

OFFICIAL LIST OF CHANGES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM SEPTEMBER 10 TO SEPTEMBER 17, 1883.

Bartholf, John H., *Captain and Assistant Surgeon.*—Station changed from Fort Lapwai, I. T., to Vancouver Barracks, W. T. —*Par. 2, S. O. 123, Department of the Columbia, September* 6, 1883.

Banister, J. M., *First Lieutenant and Assistant Surgeon.*—Assigned to duty at Fort Adams, R. I.—*Par. 3, S. O. 170, Department of the East, September* 10, 1883.

The Medical News *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the News *should be addressed to No. 1004 Walnut Street, Philadelphia.*

ORIGINAL ARTICLES.

OBSERVATIONS ON THE SALTS OF NICKEL, ESPECIALLY THE BROMIDE OF NICKEL.

BY J. M. DA COSTA, M.D.,

PROFESSOR OF THE PRINCIPLES AND PRACTICE OF MEDICINE IN THE JEFFERSON MEDICAL COLLEGE, PHILADELPHIA.

NICKEL and its salts have been very little employed in medicine. I cannot, indeed, find that they have ever been subjected to systematic study. Simpson made some slight trials with the sulphate of nickel, and thought it a gentle tonic, and useful in a case of severe and obstinate periodic headache; and I observe, in the last edition of the *U. S. Dispensatory*, that Dr. Palmer, of Florida, has made use of the same salt, and has reported it to be a sedative and soporific, and of avail when opium is not admissible. In the number of the *Lancet*, for January 27th of this year, Broadbent alludes to the salts of nickel having an action on the blood, and refers to a previous paper in the *Clinical Society's Transactions*, vol. ii., in which I find that nickel was given associated with iron or other tonics.

Our information about nickel and its salts is thus very slim, and when I began its employ, about a year ago, I was not aware that even this slight knowledge existed. The preparations which I have tested were made for me with great care by Mr. McKelway, and leave, in purity, nothing to be desired. He has made the chloride, the sulphate, the acetate, the phosphate, the bromide; but after investigating them all, I have settled down on the sulphate and the bromide as the best preparations. And in this paper, which is to be looked upon merely as a preliminary one, I shall give some of the results I have arrived at with reference to them.

As regards the sulphate, the preparation I employed was made by digesting nickel filings in dilute sulphuric acid and evaporating. A salt results of a chrome-green color, very deliquescent, and very soluble in water. I used it in solution from one to three grains; sometimes in pill. I found it, in the smaller dose, well borne by the stomach; I have given it up to five grains, but it then, in some persons, occasions giddiness and nausea. In this dose it has no decided effect on the pulse or temperature, perhaps lowering the former somewhat in frequency and slightly reducing the latter. Of its soporific effect I saw no evidence, but I have known sulphate of nickel prove something of an anodyne; for in a case of subacute rheumatism at the Pennsylvania Hospital in which it had been stopped, the patient asked to have it prescribed again, as his pains were much relieved while taking it. Of its striking tonic effect, I cannot say that I have seen any proof. I have tested it carefully for night-sweats, and found its action only very slight. But I have had some excellent results with it in small, frequently repeated doses, or in doses from one to two grains four times daily, in cases of obstinate diarrhœa. In one such case, a man at the Pennsylvania Hospital affected with trembling associated with beginning sclerosis and valvular disease of the heart, it proved successful, after many remedies had failed. Continuing it subsequently, the heart grew more regular; the nervous phenomena remained the same. In some instances of chronic catarrh of the stomach it has seemed to me to do much good, but in this respect the chloride answers even better. In the case of a professional man with marked indigestion and some albumen in the urine, in whom iron produced headache and otherwise disagreed, the digestive disorder was speedily influenced, and the albumen disappeared while taking one grain of the chloride three times daily. More than this did not agree. It had also a calming influence on the nervous system, and this has been mentioned to me also in other instances both from the chloride and the sulphate. I have tried the sulphate in some cases of typhoid fever in which diarrhœa was a prominent symptom. But while not having tested it sufficiently to have formed a positive opinion, I may say that its action was far less than I had anticipated, and that it disappointed me.

With reference to the bromide of nickel, which I do not think has been before employed in medicine, I have made a number of observations, and should have completed many more had it not been for the occasional giving out of the supply in the midst of them. The specimens which I had were very pure. They were made by digesting nickel filings in bromine and water, and evaporating carefully to crystallization. The salt is green in color, deliquescent, and soluble in water, and in the dose in which it is necessary to give it, is not offensive to the stomach. The skilled pharmaceutist who made these nickel preparations for me has prepared a syrup mixed with orange-flower water which is readily taken. A dessertspoonful contains five grains. He has also made some compressed pills of similar strength, but these do not keep well. Yet the remedy may be prescribed in the form of pill made with gum tragacanth. In using bromide of nickel I soon saw that I obtained from it the effects of the other bromides, but the effect came from very much smaller doses. Thus I find five grains to seven and a half grains an average dose; ten, a decided one. And, when this is indicated, it is best to give five grains soon repeated, as less likely to disturb the stomach.

The influence on the nervous system, of the bromide of nickel, is shown by its relieving headache, especially of the congestive form, in its effects on convulsive movements, and its general quieting tendencies. But the main question to be solved was: Does it prove of service in epilepsy? I found it act quite as well as any bromide, and as happens with all, we sometimes by a change to it obtain results which the others no longer yield. It is unnecessary to go into the details of many cases; but I will select a few illustrative ones. First that of a laborer, forty years of age, who has been under observation since February, 1881, at the clinic of the Jefferson Medical College. Dr. Hughes, the chief clinical assistant, who greatly interested himself in procuring an accurate history of the malady, found that it dated from 1865, since which time the man had had severe attacks of epilepsy, as many as three or four daily, and never less than two a week. There was no apparent cause for the affection; no history of epilepsy or kindred malady in the family; no injury or severe illness; no sunstroke; no syphilis; no signs of cerebral tumor. Ordinary doses of the bromides were found to be totally ineffectual, and bromide of potassium and bromide of sodium each thirty grains, with a few grains of iodide of potassium, were given three times daily; also two minims of Fowler's solution thrice daily. This treatment was continued for a month, when signs of bromism became marked; the dose was lessened one-half, and then given for another month. The result was that during the first month he had four severe attacks each week; during the second month one or two daily. Placed subsequently on biborate of sodium, ten grains three times daily, and kept on it for months, the effect was a decided reduction in the number of the attacks; but the improvement was not permanent, the seizures became as bad and as frequent as ever, and after trying various remedies he had to go back to the bromides to obtain any kind of relief, yet there was still no week without several fits. In December, 1882, he was placed upon nickel bromide, five grains three times daily, and for two weeks had no attack; during the six weeks in which the drug was taken, he had but five. Unfortunately at that time the supply gave out.

A yet more striking case was that of I. S., a laborer, 20 years of age, also under treatment at the clinic. When seen in March, 1881, he had been subject to epilepsy for fourteen years without discoverable cause. Two months was the longest period without an attack; for the three years previous to applying at the clinic, he had been having two attacks weekly. Strychnia was at first very beneficial, but ultimately lost its effect entirely, and he had two or three fits daily. Twenty grains of bromide of potassium with ten of biborate of sodium, given three and subsequently four times daily, kept the attacks down to about one a month. In December, 1882, nickel bromide, five grains, three times daily, was substituted and kept up for nine weeks; during which time he had no attack.

In the case of Alice S., a colored woman fifty years of age, at the Pennsylvania Hospital, epileptic seizures had been going on since the age of thirty. The fits happened at intervals of about a week, and always in the way that three or four occurred in one day, and then she had a week's freedom from them. She was always much improved by treatment, especially by the bromides; but when this was neglected the seizures returned in their original severity. When admitted into the hospital, they were of weekly occurrence, three or four in one day. There was no history of specific affection; the urine was normal, and disease of any organ could not be found. Bromide of nickel was administered in five grain doses three times daily during the first week. The remedy produced no gastric disturbance, the appetite was not interfered with, and the bowels continued regular. The temperature record carefully kept during this period by Dr. Grayson, showed a slight depression below the normal. At the end of the week there was no recurrence of the epileptic attacks. During the following week the remedy was increased to seven and a half grains at a dose; and this period also passed without any return of the convulsions. Ten grains were now administered three times daily, and for the succeeding ten days the woman continued free from any manifestation of her disease. At the end of this time, however, the controlling power of the nickel became less; the fits returned, although they were fewer and of brief duration. Bromide of potassium was then given, under which they remained as just mentioned. During the whole time of the administration of the nickel, there was no appreciable effect upon the heart's action; the urine was repeatedly examined and found free from abnormal ingredients, nor was there any alteration in the quantity or the composition.

Some of the points mentioned in this case, I have studied also in others, such as the effect on temperature, on the circulation, and on the secretions. But my observations are as yet not complete enough to warrant the enunciation of definite results. Yet I think I am right in concluding that bromide of nickel slightly lowers the temperature, has little or no influence on the pulse, if any, rendering it somewhat slower; and does not act on the skin or bowels, or on the composition of the urine, the quantity of which may remain normal or be slightly increased. Its effect on the nervous system is that of a sedative, without, however, producing a weakening or depressing influence.

The result shown from a smaller dose than that of the bromides which are generally employed, is a striking feature. Nor can this be accounted for by the bromide of nickel having in its combination a greater percentage of bromine. The combining weight of nickel is higher than that of sodium. Sodium is 23.3; nickel 29.5; potassium 39.2. There is, therefore, in the nickel bromide some special action.

Of course, this inquiry suggested a trial, in epilepsy, of some of the other salts, such as the sulphate and chloride, to see if by themselves they had any specific influence similar to the preparations of silver and of zinc, and I have prescribed these nickel salts to epileptics for some weeks before beginning with the bromide. The result was, the patients had rather fewer attacks. But while not inert, no striking influence was exerted by the drug; certainly, nothing that compared with the bromide salt.

In conclusion, it seems to me that the preparations of nickel, especially the bromide, will be found additions to our therapeutic resources; and are certainly worthy of more careful study than they have hitherto received.

SERPENT VENOM AS A REMEDIAL AGENT IN TETANUS.

BY A. O. AMEDEN, M.D.,
OF GLENS FALLS, N. Y.

A FEW years ago I experimented with the venom of the rattlesnake in a case of traumatic tetanus following a punctured wound of the foot, and with a most satisfactory result. The patient was a man about twenty-five, healthy, and by occupation a laborer. The first tetanic symptoms occurred the third day after receiving the wound. Twenty-four hours later there was complete opisthotonos and other symptoms of the most aggravated form of tetanus. A few hours later the patient was perceptibly worse, and the case presented no indications of a favorable termination. All the remedies at my command including chloral, bromide of potassium, and chloroform, were freely used, without any apparent beneficial effect. Woorara I could not obtain.

I marked the contrast between the appearance of tetanus and that of snake-poisoning. In the one, some subtle influence is at work in the nervous centres that causes extreme rigidity and spasm of nearly the entire voluntary muscular system. In the other, an equally poisonous principle attacks the medulla oblongata and spinal cord, producing paralysis of both the involuntary and the voluntary muscles. These two poisons so obviously antagonistic ought to counteract each other. If woorara, I thought, possesses curative properties in tetanus, serpent venom ought to do the same. Being then in a locality in which the rattlesnake is fearfully numerous, I resolved to make the experiment.

Availing myself of the services of an experienced snake-catcher, I soon obtained venom fresh from the fangs of one of these reptiles; with this I moistened the point of a hypodermic syringe and inserted it beneath the cuticle in the upper dorsal region near the spine. Symptoms of snake-poisoning rapidly followed, with a decided amelioration of the tetanic spasms and rigidity, which entirely ceased at the end of ten hours, and the patient enjoyed a quiet sleep of six hours' duration.

Thirty hours after the insertion of the poison, however, rigidity with slight spasms again came on. A second introduction of the venom was made as before, and no further trouble with tetanus was experienced, and the patient made a fairly rapid recovery. But extreme prostration followed the last introduction of venom, which necessitated active alcoholic stimulation, as in all cases of accidental snake-poisoning. There was no diffuse inflammation from the wounds, as frequently happens when persons are bitten in the limbs by these snakes, and no other results that would deter me from making a second experiment in the same manner.

I am of the opinion that the second insertion of the venom was too much, and might have been withheld. I believe that this snake venom, which has been properly called "crotaline," can be used with comparative safety, and may yet prove to be a valuable remedial agent in tetanus, and possibly in some other spasmodic diseases.

NOTES OF THREE CASES OF NERVE-STRETCHING FOR SCIATICA.

BY ROBERT PATTERSON ROBINS, M.D.,
OF PHILADELPHIA.

THE subject of nerve-stretching has recently been attracting considerable attention amongst surgeons, but the reports as to its efficacy in effectually relieving the extreme pain of an advanced case of neuralgia, have varied from an enthusiastic advocacy to a decided condemnation. Without an adherence to either of these extremes, I desire to add to the list already compiled, with laudable industry, by Dr. W. J. Chandler, of South Orange, N. J.,[1] three cases which have recently come under my observation, in which operative interference was attended with gratifying results. Before detailing these cases it should be noted that since the publication of Dr. Chandler's paper, Dr. Randolph Winslow, of Baltimore, has added one more case of successful operation[2] to the list made by Dr. Chandler. The details of the three cases of which I have made notes, are as follows:

CASE I.—James W., Irishman, æt. 42, brickmaker, first came under my notice March 3, 1883, suffering from severe continuous pain in the buttock and posterior aspect of the right thigh. This was his second attack, the first having taken place three months previously, and having disappeared after a persistent course of electricity had been applied. This second attack, however, defied the battery, and the pain was only palliated by large hypodermic doses of morphia, without being more than temporarily banished. This was the history of the case when I saw the patient for the first time. After a thorough examination of the affected member, I suggested operative interference, warning the patient, however, that failure to give more than temporary relief might be the result. He agreed to the operation, and on the fourth of March the operation was proceeded with. The patient was thoroughly etherized, and an incision was made in the line of the nerve in the upper-third of the posterior aspect of the thigh, and the nerve was easily discovered and hooked up within its sheath by the left forefinger to the lips of the wound. The left forefinger was now reinforced by the right, and strong continuous traction was made in both directions. After an interval of two or three minutes, traction was again applied in the same way, and the nerve was then returned to its position. A drainage-tube was inserted, the wound was closed by three silver sutures, and the whole was covered with a wad of oakum and loosely bandaged.

On the next day (March 5th) the patient was found in a very comfortable condition, without any pain, but complaining that his leg was "asleep." His pulse and general condition were good, his temperature was normal, and his appetite was ravenous. During that, as well as several succeeding nights, his sleep was disturbed, but small doses of bromide of potash removed this symptom. On the sixth day (March 10th) the drainage-tube was removed, and the wound healed kindly without any drawback. In a week and a half he was allowed to leave his bed, but was ordered to use a crutch in walking about the room. At the expiration of the third week I had the satisfaction of seeing him walk into my office, a distance of about a mile from his home, without any support whatever. Up to the time of writing (August 3d) he has had no return of the disease.

---

[1] Medical Record, Nos. 617, 618.

[2] Maryland Medical Journal, No. 98.

Case II.—Michael S., Irishman, æt. 36, also a brickmaker, was sent to me on March 27th by Case I. He was suffering from a severe attack of sciatica in the left buttock and thigh, and extending also along the course of the internal popliteal and posterior tibial divisions almost to the heel. When I saw him first in his own house, he was suffering acute pain which made it impossible for him to use the limb. For temporary relief from this pain I gave him a hypodermic injection of one-sixth of a grain of morphia; and instructed him to forcibly flex the thigh upon the abdomen and then to quickly straighten out the leg. This manœuvre was attended by instant, but only temporary, relief, and at his request I determined to operate. The next day (March 28th) the operation was performed by the same method as that pursued with Case I., and the wound dressed in the same manner. The next day I found the man entirely free from pain, but very much alarmed at the temporary paresis which followed the operation. This latter symptom gradually passed away, and the patient made a rapid recovery. He also has had no return of the sciatica up to this date.

Case III.—Ann C., Irishwoman, æt. 31, housewife, had a history of sciatica of several years' standing, and recurring every spring and autumn with perfect regularity. The pain was confined to a limited area extending from the crease of the buttock to about the middle of the thigh. The attacks were very severe, and were periodic, occurring at about 5 p. m., and lasting well into the night. Quinine sulphate in five to ten-grain doses would abort a paroxysm, but had no permanent effect upon the disease. Electricity and counter-irritation were tried in addition to the quinine, but without producing any lasting impression.

On April 14th, about a month after she came under my care, I operated upon her in precisely the same manner as in Cases I. and II., but kept up the quinia during convalescence. The wound healed kindly and she was free from any pain until May 5th, when she experienced a return of the disease, but of by no means so severe a character as her former attacks. This relapse speedily disappeared after a few hours, quinine and a blister having been used, and the patient has had no return of the disease; I should state, however, that she removed to a more healthy neighborhood within the three weeks succeeding the last attack.

These cases are too few to allow of any inference being drawn from them, but added to those previously reported, they will make a very large percentage of cases with favorable termination after operation. Dr. Chandler's list gives the statistics of 400 cases of nerve-stretching performed for various causes. Of these, 70 were done for sciatica, with 1 failure, 3 temporary improvements, 1 doubtful, and 65 cures, *i. e.*, 93 per cent.

As for the operation itself, it is of the simplest. One point of election is, of course, in the upper part of the thigh just below the crease of the buttock, where the nerve is covered only by skin and fascia. Dr. Winslow operated still lower down, "but above the popliteal space," where the nerve may be exposed, "as it passes under the long head of the biceps . . . and is easily exposed by drawing apart the biceps and the semitendinosus." (*Maryland Med. Journ.*, loc. cit.) But in the three cases just detailed, the first of these positions was chosen with the idea that it was better to stretch the nerve as high up as possible. I had no means of measuring the amount of tension upon the nerve, but it was not as great as in Dr. Winslow's case, where the leg was lifted from the table. This, I confess, I had not the temerity to attempt.

There was no especial treatment before or after the operation. The only indications were to lessen the extreme pain and to promote the speedy healing of the wound. When the drainage-tube was removed, ung. zinci ox. was applied until the wound was entirely healed. Tr. nucis vom. (gtt. v) and tr. cinchon. comp. (f℥j) were given three times a day for a week after the operation.

HOSPITAL NOTES.

HOSPITAL OF THE UNIVERSITY OF PENNSYLVANIA.

Service of Louis A. Duhring, M.D.,
PROFESSOR OF DISEASES OF THE SKIN IN THE UNIVERSITY OF PENNSYLVANIA.

(Reported by Henry Wile, M.D.)

EPITHELIOMA ET MYXOMA NASI.

A man, seventy-six years of age, has been sent here to get advice in regard to an affection of the nose. On the left ala, and extending upon the cheek, is an ulceration about the size of a silver half dollar, covered with a brownish crust, in the clefts of which we see a puriform exudation. The crust is distinctly granular, and within its border split pea-sized nodules can be seen which are very suggestive. Removing part of the crust, the surface exposed bleeds readily, and presents that unevenly elevated, granular appearance which is characteristic of epithelial cancer. It is a very common variety, and belongs to that class in which the lesion is more superficial, and on this account the prognosis is favorable. By proper operative interference the complaint may be cured. The operation depends greatly upon the locality and rapidity with which the disease seems to be spreading. The patient states that he has had the lesion about five years. As yet, the deeper elements of the skin are not involved; the sebaceous glands, however, around the periphery are enlarged.

On the right side, and protruding from the nostril, is a tumor about the size of a large cherry. The patient claims to have had this seven or eight years. It has no relation to the lesions before described, but has developed altogether independently, slowly, and has its own special characteristics. When seized between the fingers, it is distinctly soft and compressible, and upon pressure indentations may be made, also changes in size and shape. The surface presents a bluish-red hue, is smooth and shining, while here and there small telangiectases may be noticed. The clinical picture is sufficient to warrant us in designating the new growth as a myxoma. A microscopic examination would reveal the characteristic stellate and fusiform cells with a gelatinous intercellular substance. The tumor is benign, and gives no trouble beyond that, on account of its size, it blocks up the air-passage. The treatment will be radical, and consist of removal by means of the écraseur. The patient, however, has come here more on account of the lesion on the left wing of the nose; and in the way of treatment, we will direct the thorough application of caustic potash, with some simple dressing. This treatment is simple and effective. After the use of the potash, the percentage of cures is a large one.

ECZEMA SQUAMOSUM.

A boy, sixteen years old, presents a superficial eruption of a squamous type, in the form of pale-red patches on his face, more particularly the cheeks, and on the sides of his neck. The question of treatment in these cases is important. The use of strong ointments would irritate the skin and aggravate the disease. We would advise the use of some mild application, like a lotion of boracic acid; this to be used for one week; then a weak calomel ointment of twenty grains to an ounce of lard.

ECZEMA PAPULOSUM.

A man, forty-three years old, has, as you see, a slight eruption on both wrists. The lesions, *per se*, are insignificant, but they are enough to cause great inconvenience on account of the subjective symptoms to which they give rise. The scratches on the skin about the seat of the lesions give evidence of intense itching. This is a common phase of papular eczema, disfigured by scratches, in which the itching is entirely out of proportion to the amount of eruption.

Cases of this kind require both internal and local treatment. The internal treatment will consist of cutaneous tonics, and locally we will direct our attention to the itching, for which we will order the following:

℞.—Acidi carbolici, ... ʒj.
Glycerinæ, ... fʒij.
Alcohol. . . . . . f℥iv.
Aquæ, . . . q. s. ad. f℥viij.

followed later by an ointment of ammoniated mercury, thirty grains to the ounce.

ACUTE ECZEMA VESICULOSUM OF THE FACE.

A girl, sixteen years of age, pale and poorly nourished, was attacked three weeks ago with the eruption which now occupies the ears and the whole of the face, more especially the lower half. It presents a bright-red inflammatory appearance, and is characterized by flat vesicles and pustules. The ears are puffed and swollen. The patient states that she suffered a similar attack last fall.

In the treatment of such a case, we must be careful in the selection of our remedies, not to use them too strong, and thus aggravate the disease. For instance, a strong sulphur or tar ointment would here cause great irritation. We should use some mild, soothing application, as of oxide of zinc, or boracic acid, or black wash. In this case, we will order the black wash three times a day, to be followed immediately by the oxide of zinc ointment. The bowels should be regulated by means of a saline laxative, and the following be administered:

℞.—Liq. potassii arsenitis, . . fʒiss.
Vini ferri, ... f℥iv.
Sig.—One teaspoonful three times a day.

MEDICAL PROGRESS.

Localization of Motor Areas in the Brain.—MM. Charcot and Pitres have, in a second communication on this subject, taken into consideration destructive lesions of the motor area, the object being to prove that these always produce permanent paralysis, and lead ultimately to contracture of the paralyzed muscles and secondary degeneration of the spinal cord. The conclusions of their paper may be summarized as follows: Cortical lesions capable of giving rise to total permanent hemiplegia are always situated in the motor area, and they occupy the whole or, at any rate, a good part of the surface of this motor area. 2. Lasting paralysis of the arm and leg on one side, the face being unaffected, is due to lesion of the upper half of the cortical motor area of the opposite hemisphere. 3. Paralysis of the face and arm on the same side, the leg being unaffected, denotes a lesion of the lower half of the cortical motor area of the opposite hemisphere. 4. The cortical motor centre which governs voluntary movements of the face is situated at the lower end of the opposite ascending frontal convolution. 5. The cortical centre governing movements of the arm is situated at the middle third of the ascending frontal convolution, or perhaps a little above this. 6. The paracentral lobe is the seat of the centre for movements of the leg; and 7. Destructive lesions, even when very extensive, if situated in the non-motor area, never give rise to secondary degenerations, whilst destructive lesions of the motor area are always accompanied after the lapse of a certain period of time by descending changes in the pyramidal tract. In a subsequent communication (August) to the same periodical, the authors study the relations of partial epilepsy with cortical lesions. The following extracts will sufficiently express their views: "When during the interval between his attacks a patient who suffers from epileptiform convulsions shows no signs of any permanent paralysis, the lesion is either quite superficial, or else it is situated in the neighborhood of the motor area. When, on the other hand, the patient during the interval between his seizures is permanently hemiplegic or monoplegic, we should infer that there is situated in the motor cortical area a more or less limited destructive lesion. From the standpoint of diagnosis we must not take into account those transient, post-epileptic paralyses which come on immediately after a seizure, last from some minutes to a few days, disappear spontaneously at the approach of a fresh seizure, and are far from being uncommon. They appear to be the result of temporary exhaustion, of fatigue of the nerve-elements after the exaggerated activity which has provoked the attack, and have no diagnostic value as regards the locality of the cortical lesion determining the convulsions. . . . It is, then, the paralysis which must determine the diagnosis. . . . The existence of epileptiform convulsions of the Jacksonian type ought to make us think of a cortical lesion, and the coexistence or absence of any permanent paralysis ought to tell us whether or not the lesion is situated in the area of the motor convulsions.—*Med. Times and Gazette*, Sept. 8, 1883.

Absence of the Spleen.—Dr. Isidor Mehrer reports the case of a woman, æt. 45, who, on post-mortem examination, was found to have no spleen. All the other organs were normally developed. Rokitansky states that the spleen is only absent in acephalous monsters, and Birch-Hirschfeld has reported one case in an abnormally developed child.—*Wien. Medizin. Presse*, Sept. 2, 1883.

Danger from Glazed Earthen Vessels.—M. Pérusson, a chemist at Limoges, declares that the use of glazed earthenware vessels is dangerous, inasmuch as the glaze frequently contains lead oxide, which becomes soluble in the presence of acids. One hundred grammes of milk were left to ferment in a glazed receptacle, and over grs. iij of sulphate of lead were removed from it. When the glaze becomes rugged, the interstices are filled with metallic and fermenting substances; thus the danger is increased.—*Sanitary Engineer*, Sept. 20, 1883.

Nephrectomy.—The operation of nephrectomy was performed in Dublin in August by Dr. Kidd, Master of the Coombe Lying-in Hospital, on a woman, aged twenty-eight. She was first admitted into the Coombe Hospital in February, 1882, when she gave the following history: In October, 1880, she suffered from a severe wetting, and, from that time, menstruation, previously regular and normal, had recurred at fortnightly intervals, being profuse and accompanied by rather severe pain referred to the hypogastrium. From the same date, the patient had suffered from great irritability of the bladder, being unable to retain urine for more than ten minutes at a time, whilst micturition was constantly accompanied by very severe scalding or cutting pain referred to the external orifice of the urethra. The urine was then healthy, and no cause could be found either in the urinary or genital tracts to account for the pain. Some time afterwards, the urine became distinctly purulent, and the mucous membrane of the bladder, examined by means of the endoscope, was seen to be very red and vascular. The passage of a sound into the bladder gave rise to great suffering, and therefore a permanent vesico-vaginal fistula was established by operation, without, however, being followed by the expected relief. In May of the present year, the patient again came under notice, suffering from the same symptoms as formerly, but a movable tumor was now felt in the right hypochondrium, in general shape and consistency resembling an enlarged kidney. In the situation of this tumor, the patient complained of much pain, aggravated by lying on either side. The diagnosis was made of a right kidney enlarged by abscesses. In consequence of the severe pain and the irregular hectic and wasting of the patient, Dr. Kidd decided on removing the kidney, and the operation was carried out, under bichloride of methylene, on July 12th, and lasted altogether about an hour and a half. The incision was made through the anterior abdominal walls over the length of the tumor. The peritoneum was adherent over the front of the kidney, and there were several firm adhesions posteriorly also. There were a great number of separate abscesses found in the substance of the kidney. Hempen ligatures were used to tie the pedicle, which consisted of the renal vessels, ureter, etc.; and the pedicle was then dropped back into the abdomen, a glass drainage-tube inserted, the peritoneal cavity carefully cleansed, and the wounds closed up. The patient at first seemed to rally well from the operation, but died twenty-four hours afterwards from collapse, without any hemorrhage having taken place.—*Med. Times and Gazette*, Sept. 8, 1883.

The Third Sphincter Ani.—Dr. Edward Laimer, in an article on the anatomy of the rectum, concludes that the third sphincter ani is nothing more than a collection of the circular fibres of the intestine which have become heaped together by the action of the longitudinal muscular fibres on one half-side, and as a rule on the right; these are found, on cross-section, to consist of three-sided muscular bundles; whereas, if they do not become heaped together on the other side of the rectum, they at least retain their normal situation.—*Medizin. Jahrbücher.*, 1883, Hft. 1.

Infantile Menstruation.—Dr. A. Van Derveer, of Albany, reports the case of a child, æt. two years and seven months, who began a regular normal flow, lasting from four to five days, when she was four months old, and which has continued every twenty-eight days since. She weighs forty-nine pounds. Features and form are those of a girl ten or twelve years old. Her mammary glands are as large as a small orange. The mons Veneris is well developed, and covered with a full growth of hair. The external labia large, and all parts of the vulva fully formed. She is bright and intelligent, but easily irritated, especially so at the beginning of the menstrual epoch. She is not allowed, nor does she seem to care, to play with children of her own age. Her appetite and tastes belong to a child much older. All functions seem to be performed normally. Has never been troubled with leucorrhœa. Has never shown any disposition to handle her parts or masturbate in any way. Is, in fact, quite modest with her mother, and particularly so with her father, and when the physician made his examination.—*Amer. Journ. of Obstet.*, Sept. 1883.

Suture and Transplantation of Nerves.—Dr. E. G. Johnson, of Stockholm, in a recent number of the *Nordiskt Medicinskt Archiv*, after referring to the literature of the subject, gives the results of his own experiments made in the laboratory of the School of Medicine at Stockholm. In sixteen cases he reunited, by means of a catgut suture, the entirely divided ends of the sciatic nerve. The reëstablishment of the nervous influence by the cicatrix was observed on the fortieth day in the experiments on rabbits, on the thirty-first day in those on dogs, and on the twenty-fifth on fowls. In twenty experiments on rabbits the two ends of the sciatic nerve were not reunited, and the passage of the nervous influence by the cicatrix in these cases was not observed till after sixty days. The presence or absence of this influence was indicated by the excitation of the nerve, above the cicatrix, by means of a weak induction current or by mechanical excitation. In the experiments on rabbits, microscopical examination showed on the fortieth day in cases of suture of the nerve, and on the sixtieth day in those of simple section, bundles of amyelinic nervous fibres passing across the cicatrix from the central extremity of the nerve to its peripheral parts. In reference to the transplantation of nerves, Dr. Johnson has succeeded in inserting, in the deficient intervals of the sciatic nerve of two fowls, portions of the sciatic nerve of other fowls, and in the sciatic nerve of a third fowl a portion of the sciatic nerve of a rabbit. The first two fowls were killed at the end of twenty-eight days and thirty-four days respectively, and the third after twenty-three days. The portions of the transplanted nerve were perfectly grafted on the original nerve, but the nervous influence through the cicatrix did not exist in any of the cases. Microscopical examination exhibited a very evident contrast between the portion of the central nerve where the degeneration was but slight, the intermediate portion where the myeline was very much subdivided, and the peripheric portion where scarcely any traces of myeline were to be found.—*Medical Times and Gazette*, September 8, 1883.

THE MEDICAL NEWS.
A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

Communications are invited from all parts of the world. Original articles contributed exclusively to The Medical News will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

Subscription Price, including Postage,
Per Annum, in Advance, ... $5.00.
Single Copies, ... 10 cents.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in registered letters.

Address, HENRY C. LEA'S SON & CO.,
Nos. 706 & 708 Sansom Street,
Philadelphia, Pa.

SATURDAY, SEPTEMBER 29, 1883.

IS EXTIRPATION OF THE CANCEROUS UTERUS A JUSTIFIABLE OPERATION?

At the recent meeting of the American Gynecological Society, held in this city, Dr. A. Reeves Jackson, of Chicago, read a paper bearing the above title, in which he endeavored to show that hysterectomy should be discarded from practice for the reasons that it is a highly dangerous procedure, and that it holds forth no reasonable hope for permanent relief. A full abstract of the paper and of the discussion it elicited, which we had the pleasure of hearing, will be found in last week's issue of The Medical News, from which it will be seen that Dr. Emmet, whose personal experience is limited to a single case of laparohysterectomy, endorsed the views entertained by Dr. Jackson, as did, also, Dr. Van de Warker, of Syracuse. Dr. Sutton, on the other hand, regarded colpohysterectomy as an operation full of promise, and would not hesitate to have it resorted to were a relative suffering from carcinoma. Dr. Palmer, of Cincinnati, had always declined to perform it; while Dr. Baker, of Boston, would limit total removal to those cases in which the disease begins in the cavity of the organ. Hence, the Society may be said to be opposed to the removal of a carcinomatous uterus.

During the past few months important contributions to the statistics and details of the operation from the pens of Sänger, of Leipsic, Schatz, of Rostock, Demons, of Bordeaux, and Schrœder, of Berlin, have been made to vol. xxi., 1883, *Archiv für Gynäkologie*, the *Archives Générales de Médecine*, for August, 1883, and the *British Medical Journal* for Sept. 15, 1883, in which the authors, in common with the majority of German surgeons, regard the procedure as an eminently rational one in an affection so surely lethal when left to itself as carcinoma, claiming for it no more nor less than is to be expected from the extirpation of the tongue, the testis, the rectum, the breast, or the thyroid gland, for cancer.

The objection urged against extirpation of the uterus by Dr. Jackson, that it is a highly dangerous operation, is open to criticism. It is dangerous, but the mortality depends upon the manner in which it is done. Laparohysterectomy, or Freund's operation, is a frightfully lethal procedure. Of 93 cases collated by Hegar and Kaltenbach, 63, or 67.7 per cent., proved fatal, and the death-rate does not appear to be diminished by increased experience, since of 106 cases, inclusive of those just referred to, of which we have a knowledge, 72, or 68 per cent., died. The primary risks are, therefore, so great that abdominal hysterectomy should be reserved for special cases. Vaginal hysterectomy, on the other hand, yields the most promising results. To the 133 operations, with 38 deaths, collated by Sänger, we have to add 34 additional ones, of which 9 are from the practice of Schatz, 4 from that of Shrœder, 3 from that of Olshausen, 2 each from that of Dudon and Howitz, and 1 each from that of De Vecchi, Novaro, Guarneri, Pawlik, Müller, Demons, Mandrillon, Tauffer, Holmer, Studsgaards, Leisrink, Calderini, Paggi, and Wile. Of the 167, 115 recovered, and 52, or 31.13 per cent., died, which is nearly as good a result as is shown by ovariotomy in the hands of American and European surgeons. Thus, of 5153 ovariotomies, tabulated by Agnew, 1502, or 29.13 per cent., perished. Like ovariotomy, vaginal extirpation is progressively improving in its death-rate. Thus of 52 examples collated by Haidlen, in 1881, 19, or 36.6 per cent., died. Of 81 analyzed by Czerny in 1882, 26, or 32.1 per cent., were fatal; while, as we have just seen, of 167 collated by us in 1883, 52, or 31.13 per cent., perished. In the hands of surgeons who have had the largest experience, the mortality has been still further reduced. Martin lost 8, or 26.6 per cent., of his 30 cases; Olshausen lost 7, or 28 per cent., out of 25 cases; and Schrœder lost 7, or 30 per cent., of his 23 cases, the 78 operations affording a mortality of 28.2 per cent. From this beginning, colpohysterectomy should be persevered in, with the hope that it will ultimately become a far more successful measure than it has proved to be up to the present date. With such flattering results, however, before us, we have no hesitation in taking issue with Dr. Jackson, and in declaring that vaginal extirpation of the uterus is not a highly dangerous operation, when the gravity of the disease for which it is performed is taken into consideration. When resorted to for other conditions than carcinoma, the success of the procedure is noteworthy. Thus of 13 operations for prolapse and benign tumors of the uterus, only 2, or 15.4 per cent., were fatal.

The second objection which Dr. Jackson adduces against hysterectomy, is that it does not cure the disease. Indeed, he does not appear to believe that a case of carcinoma was ever permanently relieved, as he says: "It is notorious that in almost all instances in which surgical operations have been done for the removal of cancers, they have been only of temporary benefit—if beneficial at all." The general surgeon could inform him that fifteen per cent. of carcinomata of the tongue, and nearly eleven per cent. of carcinomata of the breast, have been cured; and he should know that one of Freund's patients was free from recurrence for four years and five months after abdominal hysterectomy. The decision of this important question is not a matter of sentiment; it must rest upon a far larger experience, and a more rigid following up of each case. Of the final results of the vaginal operation, the information is meagre. In at least nineteen cases there was freedom from recurrence for periods varying from three to twenty-four months, two remaining well for three months; two for five months; five for six months; two for eight months; two for nine months; one for fifteen months; two for eighteen months; one for nineteen months; and two for twenty-four months. In at least fifteen instances there was recurrence in from four weeks to ten months, or in four months on an average, and death ensued, on an average, in fourteen months after the operation, so that life was prolonged even in these fatal cases.

Is it true, as Dr. Jackson states, that "when the diagnosis can be established there is no reasonable hope for a radical cure?" To this we answer emphatically, No, and our proof lies in the results of partial operations, which are notoriously far less successful than when the entire organ involved is extirpated. Thus, Pawlik, in Heft. 12, 1882, *Wiener Klinik*, has published the statistics of Prof. C. Braun's removal of the vaginal portion of the uterus, for carcinoma, with the galvanic cautery. Of 136 cases, 33 were living free from recurrence for periods varying from one to nineteen years and a half after the operation. Dr. Baker, of Boston, also, in the discussion on Dr. Jackson's paper, brought forward some pregnant facts bearing upon this point. By a very ingenious operation, which deserves general adoption, he has removed the entire supravaginal and infravaginal portions of the cervix, as well as from one-third to one-half of the body of the uterus, and subsequently seared the denuded surface with the thermo-cautery, 30 times, and 6 patients were living entirely free from disease five years subsequently. If such results are attainable from partial operations, what may not naturally be expected from complete extirpation performed through the vagina at an early stage of the disease, when irregular and climacteric hemorrhage is its first indication?

We regret to have to disagree with the learned members of the Society, but the importance of the subject demands that we should present the other side of the picture to our readers. Operations upon the uterus for carcinoma must be persisted in, and we are inclined to endorse the views of Sänger, who holds that partial operations on the cervix should be reserved for those cases of malignant papilloma, in which the growth projects into the vagina, that supravaginal amputation of the body of the organ, after laparotomy, should be limited to those cases in which the diseased organ cannot be removed through the vagina, and that vaginal hysterectomy should be the rule in all other examples of carcinoma.

THE TREATMENT OF TUBERCULOSIS BY ARSENIC.

THE use of arsenic in pulmonary consumption is not new, but we are inclined to believe that it has been too much ignored in recent years. Comparatively recently, BUCHNER called attention to it in a paper on the "Therapeutics and Prophylaxis of Phthisis," and still more recently KEMPNER and LINDNER have repeated his observations. The results of the latter are published in the *Deut. med. Woch.*, for August 22, and confirm those of his predecessors.

Tested upon well-marked cases with extended dulness and in some with well-marked cavities, Lindner noted that there was no essential alteration of the local condition, but a decidedly favorable influence was exerted upon the quantity and quality of the expectoration, which diminished to from one-fourth to one-half its original quantity, and from being purulent became more mucous and, in some instances, pure mucus. There was no influence upon the fever, or at least none which would justify the ascribing of an antipyretic property to arsenic, although, as a rule, the temperature was lowered, in one instance amounting to actual temporary apyrexia. The appetite was also decidedly increased, and with the increased ingestion of food came increased strength, so that the patients easily got out of bed, and remained for hours in the fresh air. Night-sweats were slowly influenced, and gradually disappeared. At the same time Lindner admits that these results were not permanent. He employed arsenic also in local tubercular affections, especially in tubercular disease of the bones and joints, in lupus, and lymphoma. Here, too, there was some increase of appetite ascribable to the drug, but there was no evident change in the local disease.

We agree with Buchner that partially satisfactory therapeutics are better than no therapeutics; and if arsenic will produce the results above claimed for it in consumption, let us by all means avail ourselves of its effects, and give our dying phthisical cases one more chance of prolonging the life which is seldom else than sweet, let its sufferings be what they may.

ACCIDENTS DURING CONVALESCENCE FROM TYPHOID FEVER.

M. Vulpian has recently reported in the *Revue de Médecine*, August, 1883, two very interesting cases of accidents occurring during convalescence from typhoid fever. One was an inflammation of the right crural artery, which occurred some days after convalescence had set in, in the case of a young man twenty-one years of age. There were pain, œdema, and bloody extravasation in the skin of the lower antero-internal part of the right thigh. The patient recovered ultimately.

The second case was one of atrophy of the right deltoid muscle, observed also during convalescence from typhoid fever of mild form, occurring in a young man sixteen years old. There was at no time previously any evidence of the involvement of the nervous centres, nor had he ever had an affection of the nervous system. This complication was also accompanied by intermittent pain in the right upper extremity. On the fourth day after the appearance of the pain, there was noted swelling of the right arm, which increased. These phenomena M. Vulpian immediately ascribed to some alteration in the nerve centres, a suspicion which was confirmed two days later by the incontestable presence of paralysis of the deltoid muscle and of the muscles of the right arm, accompanied by a diminution of muscular contractility, more marked in the deltoid. To these symptoms succeeded atrophy of the deltoid muscle. M. Vulpian ascribed the condition to a local myelitis, and believes that in such cases a predisposition — a vulnerability — must exist in the spinal cord, which may be engendered by the occupation of the patient, which in this instance was that of a store-boy, accustomed to carry heavy articles upon his right shoulder.

The report of these cases is interesting, and we present them to the attention of our readers for comparison with their own experience.

THE DIAGNOSTIC VALUE OF KOCH'S BACILLI.

Further evidence comes to us from Germany in favor of the diagnostic value of the bacillus tuberculosis in the shape of a lecture by Dr. Gessler before the Munich Medical Society, and published in the *Deutsch. med. Wochenschr.*, August 22. He concludes that with the demonstration of bacilli in the sputum the presence of tuberculosis is established; and that, should long-continued investigation fail to discover bacilli, the presence of tuberculosis is rendered highly improbable, but not excluded.

It is to be regretted that so little attempt has as yet been made by hospital physicians in this country to determine the important questions growing out of Koch's discovery. With the exception of Dr. Prudden's excellent paper, and Dr. Formad's incomplete researches, we are aware of no extended practical results published by Americans. That our physicians are ever ready to test measures of treatment, but seldom willing to undertake observations requiring time and patience, implies that our training in the direction of laboratory exercise has failed as yet to show the results we have a right to expect from it. Much has been done at home in the way of collecting and arranging the literature of other countries on the influence of minute organisms in disease. Who will be the first to show us some practical manipulative work on the subject?

THE RECENT OUTBREAK OF GLANDERS.

The serious outbreak of glanders which has occurred in a car stable at Newark, has necessitated the slaughter of about fifty horses, and the quarantine and frequent examination of the rest. It has afforded a rare opportunity of seeing the different phases of the disease, and the comparative relations and effects of farcy, which is viewed as a modified form of glanders, and will impart the disease. As it is claimed that the bacillus of farcy can be identified, it is time for close experimentation as to attenuation of virus. Dr. Meyrick, of the British war office, in an article in the September number of Fleming's *Veterinary Journal*, discusses hopefully the question of the curability of glanders, and of the application thereto of a vaccinating system. As it involves the lymphatics, the Schneiderian membrane, and all the nasal surfaces as well as the lungs, it has been considered an incurable disease. Its communicability to men and to animals, and the fact that horses having it are often continued at work, render the spread of the disease greatly to be feared.

The relative strength of the National Code and New Code adherents in New York City will be exhibited at the annual election of officers for the New York County Medical Society, to be held at the next monthly meeting, on October 29. Two straight-out tickets, representing the two parties, have been placed in nomination.

SOCIETY PROCEEDINGS.

AMERICAN GYNECOLOGICAL SOCIETY.

Eighth Annual Meeting, held in Philadelphia, September 18, 19, and 20, 1883.

(Specially reported for The Medical News.)

(*Concluded from page 332.*)

Thursday, September 20th, Third Day.

Morning Session.

After the adjournment of the business meeting, Dr. Henry F. Campbell, of Augusta, read a paper on

MENSTRUATION AFTER EXTIRPATION OF THE OVARIES,

in which he said: By general consent the influence of the ovaries in menstruation has long been recognized, and there is nothing in my remarks that would deprive them of their important influence over this function. Ever since the removal of diseased ovaries became of frequent occurrence, it has been found that menstruation often continues after their removal.

This has been variously attributed, first, to habit; second, to periodical plethora; and more recently, to the failure to remove that which has been recognized as the real inciter of the menstrual nisus, viz., the Fallopian tube. Not denying any of these theories, I shall present some considerations in regard to these phenomena, which I think have not yet been given their full weight.

The ovaries are unquestionably the ordinary exciters of menstruation, and we might reasonably expect that, on their removal, menstruation would be modified or arrested. But are they the only exciters to activity in the genital organs? We recognize the influence of the mammary gland over the organs of generation, and also the fact that mental conditions may act on these organs. The ovaries are under the influence of the nervous system, and after removal of the organs this influence may still be continued. In many instances, menstruation and uterine action generally have been excited by stimuli external to the ovaries.

Not many years ago, I had a remarkable case. A little girl, between the ages of eight and ten, was brought to me by her parents, with the statement that she had twice menstruated. In appearance she was entirely healthy. She was then in her third period. After repeated questioning, I was informed that five months ago she had had mumps. I immediately concluded that this probably had something to do with the irritation of the ovaries. I learned that there had been some tenderness in the ovarian region at the time she had the mumps, and on examination I found tenderness. The breasts were slightly enlarged. I did not examine the pudendum. The two former menstrual periods had come at irregular intervals. The third had appeared after an interval of twenty-one days. The discharge was not very great. I told the parents that in all probability there would be no return, and such was the case. At the proper age she developed into a young woman, menstruating at about the age of fifteen.

I had a second case, where another point was the source of irritation. It occurred in a colored girl, about seven years of age. This child had more decided indications of puberty. There were enlargement of the breasts and decided development of the external organs of generation. There had been three or four menstrual flows. The only way in which this could be accounted for, was by an abscess which she had on the mammary gland. After a time, the discharge gradually disappeared. This case would indicate that the irritation might proceed from some other point than the ovary. In this example, the ovaries were only one link, and not the primary link, in the chain of phenomena present.

Some time ago, Dr. Clark, of Mississippi, detailed to me a remarkable case. It was that of two sisters, one the wife of a farmer living in the country, somewhat depressed in financial matters, but blessed with a large number of children. The other was married to a gentleman living in the city; she was in poor health and had suffered from amenorrhœa for a long time, but was very desirous of having children. This lady made it a rule to be with her sister during each of her numerous confinements. On one of these occasions, while nursing the baby she put it to her breast. This she repeated; in the course of about six weeks, menstruation appeared and milk developed in the breasts. She became healthier, returned home, and soon became pregnant.

I also know of a grandmother, who, by nursing the child, developed milk in the breasts, and nourished the child for a number of months. Do we not see from these various phenomena that there may be some other influence beside that of the ovaries and Fallopian tube?

The proposition to which I would call the attention of the Fellows is this: We know that the hypogastric plexus and uterine nerves must have a centric attachment somewhere. Anatomy and reason teach us that this centre ought to be about the lumbar or crural bulb, in the lower part of the spinal marrow. This bulb is an important centre in the whole lower part of the body. It receives the sensitive and motor nerves from this region. Frequently, after a limb is cut off, pains will be referred to the amputated portion. In a similar way, may it not be that there resides in the nerve-centres presiding over the function of menstruation an influence which may continue to act for a time after the removal of the ovaries? One objection that will be made will be that castration nullifies sexuality. But it is now well agreed that in the full-grown animal it does not entirely do so. If the operation is done at a period when the organs and nerve-centres are undeveloped, it does destroy sexuality. Ovariotomy is performed when the ovaries are well developed, often after they have, for a long time, been the seat of constant irritation. The controlling nerve-centre has acquired a peculiar sensitiveness, and after the removal of the ovaries the continuance of this reflex irritation causes congestion of the organ, and we have menstruation resulting, although the common exciter, which I admit is the ovaries, has been removed.

Dr. William Goodell, of Philadelphia, said: I am not inclined to accept Dr. Campbell's assertion that menstruation occurs very commonly after removal of the ovaries. In my experience it is very rare; but I am inclined to accept his view that it may be due to irritation of the lumbar bulb. I have never removed both ovaries without having a spurious menstruation appear in about five days, and I am disposed to attribute this to the irritation of the nerves included by the ligatures.

I have had but two cases in which menstruation returned after the removal of the ovaries. One was in a case of supposed fibroid tumor of the womb. The girl was bleeding to death, and about a year ago I removed both ovaries. For four or five months she went without menstruating, and gained flesh and strength. After a time, menstruation returned and became profuse. Making a careful examination of the uterus to decide whether or not it would be advisable to remove it, I concluded that there was a chance for enucleating the tumor. The introduction of the forceps for this purpose, brought away a new tissue which proved to be sarcoma. This bleeding was of course not menstruation, and this case may, therefore, be thrown out.

The second case was one in which both ovaries and Fallopian tubes were carefully removed. The lady has menstruated regularly ever since. I can only account for it on the supposition that either abnormally located ovarian tissue has been left behind, or that time enough has not yet elapsed to break up the habit of menstruation.

A liability to leave some of the ovarian tissue behind, led me to give up the vaginal for the abdominal operation. Once, in operating by the vagina, I had removed one ovary and had seized the second and was about to transfix the pedicle when the ovary tore away from the forceps, leaving a large piece in the grasp of the instrument. I was unable to secure the stump. Menstruation continued profusely, and, finally, I was compelled to perform the suprapubic operation. The portion of ovary that had been left was not larger than a bean. I am sorry to say that this case ended fatally, so that it was lost to science.

I am disposed to think that in some operations, followed by no break in menstruation, a little ovarian stroma was left behind. For in performing oöphorectomy, I often find it difficult to get a pedicle sufficiently long to avoid the ovarian structure. On several occasions, knowing that I had left at least a portion of the outer tunic of the organ, I have gone over the stump and teased away with forceps the supposed ovarian tissue.

Dr. Campbell's paper would have been of more value, had he given us some statistics to base his data on.

DR. EMMET, of New York, said that, without referring to the views advanced in the paper just read, he desired to put on record a case on which he operated about eighteen months ago, removing both ovaries. One was very large, and the other about the size of a goose-egg. He certainly removed the whole Fallopian tube with the larger tumor, and a portion of it with the smaller. When last heard from, she had menstruated for the thirteenth time, the periods having been regular. Before the operation, menstruation had been excessive, but since then it has been natural, lasting three days.

DR. GARRIGUES, of New York, said that in such a case as Dr. Emmet's, it must be taken into consideration that in exceptional instances, there are three ovaries. There is a very interesting instance of a young lady, unmarried, in whom both ovaries were extirpated. She subsequently married, and a year later was delivered of a living child; this, of course, can only be accounted for on the supposition that there were three ovaries.

DR. T. G. THOMAS, of New York, said: I presume that the main point of Dr. Campbell's paper is that there is in some part of the spinal cord, perhaps in this lumbar or crural bulb, a centre which has charge of the function of menstruation. Upon that point, I have had no experience, but I have listened with interest to the suggestions that have been made.

I have removed both ovaries between fifty and sixty times, many of the operations having been done for disease. The impression which I have formed from a careful study of the after-history of those cases which I could keep under observation, is that, whereas, while the ovaries are present, menstruation is the rule, when the ovaries are removed, menstruation is the exception. We know that many organs when removed from the direct influence of the nervous system, will maintain their ordinary functions for some time. A striking example of this is obtained by removing the sturgeon's heart and suspending it by a string. The heart will continue to beat until the muscle becomes so dry that it can be heard to rustle at each contraction.

I believe that many cases of menstruation after removal of the ovaries, are cases of metrostaxis. The uterus has been in the habit of menstruating, and even after the removal of the great factors, the organ continues its function. I have never met such a case as that described by Dr. Emmet. Almost invariably the bleeding has been due to a metrostaxis, which gradually diminishes and finally disappears.

In my experience with Battey's operation the rule is that menstruation ceases after the operation. Sometimes menstruation appears for five or six months, but it is irregular, and is a metrostaxis.

I have performed Tait's operation ten or twelve times, but the result has been the same as with Battey's. The difference that I should make is that, whereas Battey's operation consists chiefly in removing the ovaries, Tait's consists chiefly in removing the Fallopian tubes, and secondarily the ovaries.

There are a number of cases on record in which impregnation has taken place after removal of both ovaries, and a living child has been born. The following case probably affords an explanation of this fact. Six months ago I removed an ovarian tumor weighing forty pounds. The ovary was distinctly seen spread out over the tumor. The second ovary was as large as a duck's egg, and was also removed. My assistant then called attention to a third ovary, which was not quite so large as the normal ovary. There were two or three little cysts on its surface, which I punctured with a needle, allowing the ovary to remain. I have not since heard from the patient.

Dr. Campbell's suggestions are very good, but my increasing experience leads me to believe that the older view, that ovulation is the main factor in the production of menstruation, is the correct one. I believe that Tait's opinion that the Fallopian tubes are the exciters of menstruation, results from the fact that by his operation the ovaries are more thoroughly removed. My rule in operating is to not interfere with the Fallopian tubes if I can avoid it. If they are diseased, I remove them.

DR. BYFORD, of Chicago, said that the frequency with which menstruation occurs after the removal of the ovaries depends very much upon what is considered menstruation. If it is held that menstruation is complete only when ovulation takes place, menstruation is rare, and can only follow when some of the ovarian structure has been left behind. If menstruation is considered to be simply a discharge of blood, then it occurs in many cases. Almost invariably, if the periods of recurrence are traced, it will be found that it is simply a metrorrhagia, and not menstruation.

I have removed both ovaries in about seventeen cases, and with the exception mentioned by Dr. Goodell, that the women have a show soon after the operation, I have had but one case in which anything like a periodical flow took place. I am satisfied that there is no regular interval of twenty-eight days between the periods, and that they are due to exciting causes which might in any other woman produce metrorrhagia. There are none of the accompanying symptoms of menstruation. I have had another case, however, which, while it has no discharge, has all the other symptoms of menstruation. She has backache, pains in the limbs, etc., every twenty-eight days, showing that there is a continuance of the influence which produces ovulation. I think that sometimes some of the ovarian structure is left behind.

So far as my observation and reading go, they lead me to coincide with Dr. Thomas in thinking that the theory of ovulation is not disproved.

DR. M. D. MANN, of Buffalo, in discussing the paper, said that the apparent menstruation may be the result of disease of the womb. In one case in which I removed not only both ovaries, but also the womb as far as the internal os, there was a decided flow. It was not regular, and finally became so free that a tampon was required. On examining the patient I found in the anterior wall of the vagina and the remaining portion of the cervix a distinct epithelioma. In this way some of the cases may be explained. We should leave out of consideration all those cases which have not been under careful observation throughout the whole period during which menstruation is said to have occurred.

Dr. Campbell, in closing the discussion, said: It has been said that often some of the ovarian tissue is left behind. In one of the cases operated on by Dr. Battey in my presence, there could be no doubt that all of both ovaries had been removed. In that patient menstruation continued and extended to the amount of actual hemorrhage. There may be, as has been suggested, a third ovary, but in a long experience as a dissector I have never seen a case of this kind. It is possible that Dr. Tait, in removing the Fallopian tube, removes the nerves which carry the influence producing menstruation.

The experiment with the sturgeon's heart may be explained in another way. It has been proved that the heart has within itself certain nerve-centres, which will cause it to beat after the connection with the central nervous system is severed.

I think that we may say, then, that if there is a third ovary we may expect menstruation; that if all of the ovarian structure is not removed, we may expect menstruation; and that menstruation does sometimes occur after the removal of all of the ovarian structure. May not these cases be due to influences from the nervous system?

Afternoon Session.

Dr. William H. Byford, of Chicago, next read a paper entitled

REMARKS ON CHRONIC ABSCESS OF THE PELVIS.

He said that collections of pus in the pelvis may take place in many situations, the most common being between the folds of the broad ligament. Isolated collections may occur between the bladder and rectum, and between the vagina and rectum. They may be found sometimes in the peritoneal cul-de-sac behind the uterus in the peritoneal cavity, and rarely in the substance of organs as the cervix or ovaries. In some instances, pus exists in several localities, the most common of which are cases in which pus exists in the broad ligament and in the retro-uterine pouch of the peritoneum. The cavity in the broad ligament is usually unilocular, but not infrequently there are two or three loculi.

The progress of suppuration is modified according to the tissue in which it occurs. When an abscess occurs in the cellular tissue of the broad ligament, it is likely to discharge freely, because it is surrounded by elastic fibrous tissue exerting pressure. The cavity is more easily obliterated for the same reason. When the opening is near the vagina, it is usually direct and ample. When the opening is distant, the canal may be tortuous. When the opening is into the rectum, the contraction of the muscular fibres occasionally closes the orifice. When the rectum is filled with feces, the same thing takes place. When the abscess is in the retro-uterine pouch of the peritoneum, the discharge is imperfect, because there is no fibrous involucrum and compression does not take place.

The obliteration of the cavity of an abscess takes place in two ways: First, by contraction of its walls; secondly, by granulation from its internal surface. In the cellular phlegmon these two act together. In the serous abscess the granulation process is almost the only one. In an abscess which heals by granulation, the discharge continues until the cavity is obliterated. When in consequence of an impediment the cavity persists, the granular surfaces continue to pour forth pus indefinitely. At first, the pus is laudable, but later there may be an admixture of serum and sometimes of blood. At times it becomes thin, ichorous, acrid, and fetid. Later the pus-globules may diminish in number and finally disappear. When an abscess becomes chronic, and pus is not discharged, it indicates an alteration of the cyst. Gradually the pyogenic lining of the abscess is converted into a cicatricial membrane. At last the granular character of the internal surface is lost, and no more pus is produced. This shining cicatricial membrane possesses the property of exosmosis and endosmosis.

In a paper by Dr. H. Bixley, two cases are recorded in which these changes took place. I am familiar with the progress of these cases. The first was that of Mrs. H. When I first saw her, she had a hæmatocele. The effusion was succeeded by inflammation, which, although not great, persisted until she left for the east. During the latter part of the first year, symptoms of suppuration were present, but before leaving the west she had improved, and for some time there had been no symptoms denoting the formation of pus. There had, without doubt, been a collection of blood, the sac and surrounding tissue had undergone inflammation and an abscess, which had not found its way out, had formed.

About eight years after the accident occurred, Drs. Mack and Bixley drew off three pints of straw-colored serum. The color, consistency, and microscopical character were such as would be expected after the processes which are now known to take place in these collections. I examined this patient one year ago; the change of life had taken place, and excepting a little sensitiveness in the genital organs, there was no apparent lesion. I think that in this case the internal surface became cicatrized, serum was thrown out, and the pus and remaining broken-down blood-clots were absorbed.

Dr. Bixley's second case was similar, and ran a similar course. I first saw it in 1865: it presented the history of hæmatocele followed by inflammation. The peritonitis, which was moderately acute, subsided in a few weeks; in less than a year she was in the enjoyment of good health, and so remained.

The lining wall of a chronic abscess does not completely undergo the changes so described. Masses of granulation from one-twentieth to one-half an inch long often spring from it. I believe that they depend upon circumstances of a peculiar character existing only in certain cases, and that they may exist for an indefinite time and degree. In all the instances which I have seen, they have been friable and easily broken, not firm enough to be considered fibrinous. They are fungous and easily removed with the finger or dull curette. As the above changes take place in the lining of the cavity, a large portion of the inflammatory deposit external to the abscess is absorbed, and finally we have an encysted cystic tumor.

With these remarks in reference to the changes which take place in the lining membrane, I shall proceed to speak of the treatment. If the abscess is recent and the opening into the vagina free, it will require but a short time for the obliteration of the cavity if there is any connective tissue in the walls. It often happens that the abscess opens into the bladder or rectum, and the discharge is imperfect; in such cases there is a strong tendency for the abscess to continue to refill. If the case is seen before the opening has occurred, and the abscess is opened through the vagina, perforation of the bladder or rectum may still take place.

When perforation takes place into the rectum or bladder, I pursue one of three courses in cases where the abscess is at the middle point between being acute and being chronic. First, I pass a bent probe through the bladder or rectum into the cavity of the abscess, turn the point toward the vagina, and press downward until it becomes perceptible in the vagina. An incision is then made upon the end of the probe. The opening should be free enough to receive two or three fingers. This gives a free outlet to the pus, and often will be sufficient. If not, a drainage-tube may be introduced, and daily injections of water will finish the cure.

The second and next best method is to use the aspirator through the vagina. After withdrawing some of the fluid, to make sure that the needle is in the cavity, open the abscess from the vagina in the same manner as before.

The third method consists in finding the opening in the rectum or bladder and enlarging it sufficiently to permit the free discharge of pus and the washing out of the cavity.

When the abscess has become chronic, and there are granular vegetations on the inner surface, I employ scraping with the finger or dull curette, drainage, and the daily ablution of the cavity with disinfectant solutions. If the masses of redundant granulations are not removed, the pyæmic fever will continue. If we depend on drainage, they will fall off slowly, and will be more or less decomposed, giving a strong odor. If they are removed with the curette and washed out of the cavity, the bad odor will at once disappear. There is no danger in scraping with the finger or a dull instrument, for in these old cavities the walls are thick and quite resistant.

I have here the notes of a case reported by Dr. Nelson, in which this practice was entirely successful. The patient was Mrs. F., aged twenty-four, married, but childless. She was a sewing woman, working a machine. She had had previous attacks of peritonitis. The last attack was a severe one. On consulting a physician, she was told that she had a cancer. Early in January, 1877, Dr. B. saw the case and found an opening in the vagina from which pus escaped. The opening was in the antero-lateral wall of the vagina, and was readily found and dilated by the fingers. The cavity was then washed out. Later a larger abscess was found behind the womb opening into the left posterior wall of the vagina. This canal was tortuous. The opening was dilated until two fingers could be introduced. The wall of the abscess was studded with granulations, some of which were an inch in length. These were scraped off with the finger and the cavity washed out. The walls of the abscess were so thick that they did not collapse. The patient kept the cavity washed out with carbolized water and made a rapid recovery.

When the wall of the abscess has been converted into cicatricial tissue, it will only be necessary to keep the cyst open, as it will soon be obliterated by contraction.

When suppuration occurs early in hæmatocele, simple puncture is not enough, the cavity must be scraped, drained, and washed out. It is necessary to keep up the latter process for a long time. The scraping is required to remove the clots.

Mrs. W. was admitted June, 1882, to the Hospital for Women and Children, Chicago. In the retro-uterine pouch, and extending above the brim of the pelvis, was detected obscure fluctuation. The patient was emaciated and presented symptoms of hectic fever. The diagnosis of suppurative hæmatocele was made. The abscess was opened by a free incision, and the cavity imperfectly washed out. The symptoms were mitigated, but were still severe. Later the opening was enlarged to admit the finger, and a digital examination disclosed a number of clots, in process of decomposition, tightly adherent to the wall of the cavity. Many smooth spots were noticeable, showing that glazing had begun. With considerable difficulty all the clots were scraped away. A large drainage-tube was introduced, and the cavity washed out with carbolized water twice a day. The offensive odor and the symptoms of sepsis subsided, and the patient made an uninterrupted recovery.

In conclusion, let me give the following summary of my views: I do not claim to have presented anything new or original. I look upon the inner surface of an abscess as being similar in structure to the surface of an external ulcer. It is covered with the same kind of granulations, producing pus. These are sometimes exuberant, forming masses similar to, but larger than occur in external ulceration. They may give rise to ichorous pus and blood, or produce laudable pus. As the inflammation of the surrounding tissue subsides and the exudation is absorbed, the granulations disappear in cicatrization, the pus is not increased in quantity, serum is mixed with the pus, the pus-plobules break down and are absorbed, and the cavity contains nothing but simple serum. This process finished, there results an encysted tumor of the pelvis.

Dr. T. G. Thomas, of New York, in discussing the paper, said that one of the questions which are constantly occurring in our department of medicine is this—the necessity for always searching for and opening these abscesses. Some years ago Dr. Brittle brought this subject before us, in a paper which I thought might be very dangerous, the Doctor taking the ground that the abscess should be sought for and opened. More recently Dr. Mundé advocated the use of the aspirator. More recently still, Dr. Lyman read a paper to the same effect. There is no more dangerous practice than that of seeking for these abscesses when high up in the broad ligament, when in Douglas' pouch, or when in the retro-uterine areolar tissue, unless we are sure that there is pus, and that we can reach it. When we can ascertain, by conjoined manipulation, that there is pus, and we know where to seek for it, then, and only then, should this exploration be made.

Dr. Byford's second method of treatment is by the aspirator, followed by the knife. I have employed the aspirator only as a means of diagnosis. The method that I like best is by the use of the exploring needle passed upward until it reaches the cavity of the abscess, as shown by the escape of pus along the groove. A sharp-pointed curved bistoury is then passed along the groove of the needle until the abscess is reached and a free incision is made. I use Sim's long knife, cutting out on both sides. I have found it difficult to keep these abscesses open. In order to do this, I use a glass drainage-tube furnished with a flange; both the tube and the flange are perforated with small holes. I carry this into the abscess and sew the flange to the vagina with silver wire. In this way injections can be readily employed.

When the abscess is large, and a sufficient opening cannot be made, I stuff the cavity with tow which has been saturated with iodoform. This is renewed every twenty-four hours until the cure is complete. I have used injections of carbolic acid and iodoform.

There is a class of cases in which the whole areolar tissue is occupied by multilocular abscess. The woman has hectic, and looks like a patient in the last stage of pulmonary consumption. On examining by the vagina, the tissues feel like plaster of Paris. These cases are sure to end fatally unless relieved by surgery. I have adopted the method of cutting along Poupart's ligament, reaching the pelvis from above and opening the abscess with the finger. If possible, I make a counter-opening below. The abscess is then stuffed with tow saturated with iodoform, as before described. The abscess is kept perfectly clean.

Dr. William Goodell, of Philadelphia, said: Dr. Byford's recommendation of the use of the curette is wholly novel to me, but I think that it would be an admirable method. The very great majority of cases which consult me I do not see *ab initio*. They present themselves after a number of fistulous tracks have formed, and often the woman has been greatly reduced in strength and flesh.

My method of operating in these cases is as follows: If there is an opening from above the pubes, I pass in the uterine sound and try to find some point in the vagina where the tip of the instrument can be felt. If it can be felt, I cut down upon it and put in a drainage-tube. I always inject these fistulous tracts with potassium permanganate or carbolic acid. Occasionally I have tried constant irrigation, with excellent effect. On several occasions I have treated these abscesses by opening them from above the pubes, and putting in Keith's glass drainage-tube. The aspirator I use in preference to the knife, when the intervening tissue between the vagina and abscess is thick. I also use it in encysted abscesses of the broad ligament, which often are partly movable. It sometimes disappoints me, but, on the other hand, I have had perfect relief and complete success from one aspiration.

About six months ago, I performed oöphorectomy in a lady who had recurring attacks of pelvic peritonitis and peritonitis at every menstrual period. My object was to stop menstruation and prevent the tendency to inflammation. Since then the patient has greatly improved; but two small abscesses have formed.

With reference to the cases alluded to by Dr. Thomas, in which the patient has run into a condition of great emaciation, I have one under my care at present. I am glad of the light which Dr. Thomas has given me, but I am afraid that my patient is too exhausted to allow of the carrying out of the treatment that he has suggested. She has no fever or chills, but there are great prostration and emaciation, and I would not deem it justifiable to make the suprapubic incision in such a case.

Dr. Thomas, in reply to Dr. Goodell, said that he looked upon the resort as a desperate one, but regarded the condition of the patient as more desperate. He would be unwilling to let a patient die without giving her the benefit of the operation. He would consider it a hazardous proceeding in the case which Dr. Goodell described, and would resort to it only when he felt that it was the last hope that the patient had.

Dr. R. S. Sutton, of Pittsburg, said that in Esmarch's clinic at Kiel, he saw him scraping out abscesses with curettes made especially for the purpose. He calls them aseptic curettes. They are made of one piece, so that there are no crevices in which dirt may collect. He removed everything that he could find from the abscess. He saw no abscesses in females in his wards, but saw pelvic abscesses in the male. He also saw two cases in which Esmarch had passed a rubber tube, three yards long, through the pelvis with one end in a reservoir of carbolized water, and the other end in a vessel to receive the drainage. He thought that the treatment of chronic abscesses by the curette is the established treatment in Esmarch's clinic, and that he is the exponent of the surgical knowledge of Europe.

Dr. Henry F. Campbell, of Augusta, said: I have never used the curette. I keep these abscesses clean by syringing them with water, beginning with tepid water, and gradually allowing it to become colder. I stuff them, but not entirely full, with soft linen. The process of granulation is stimulated in this manner.

I regard the constitutional treatment as very important. I wish to call particular attention to the value of the tartrate of iron and potassium. It lessens purulent formation, and favors the development of healthy granulations.

Dr. Byford, indorsing the discussion, said that it was not his intention to write anything like a special treatise on the subject of pelvic abscess, but only to call attention to a few points in connection with the treatment of some of the changes which take place in the lining membrane. Dr. Thomas has alluded to the danger of producing acute inflammation in searching for the abscess; I did not have such cases in view. At the meeting of the American Medical Association, I presented a paper on that subject. In the old abscess there is not much danger in searching for it, and treating it as I have described.

The last paper read was by Dr. George J. Engelmann, of St. Louis, and was entitled

ERGOT: THE USE AND ABUSE OF THIS DANGEROUS DRUG,

in which he said that he considered the use of the drug entirely unnecessary in the pregnant woman. The only condition in which it would be of service was in post-partum hemorrhage, and then no one would employ it, as it was so slow, and much better means were at hand. He would limit its use to the non-pregnant womb. If it were allowable at any stage of labor, it was in the third stage, but even there it might do harm by causing incarceration of the placenta. The accidents, which may result from the use of ergot in labor are rupture of the uterus, laceration of the cervix, laceration of the perineum, and other injuries to the utero-vaginal tract, and injuries to the child. It should not be used in abortion. He had seen two deaths resulting from the use of ergot and a number of injuries.

Dr. J. T. Johnson, of Washington, did not think that ergot was used so frequently as Dr. Engelmann's paper would indicate. He had, at a former meeting, read a paper in which he took similar grounds, but in the discussion of his paper, Dr. Barker drew attention to the fact that ergot does considerable good in cases where there is a hemorrhagic tendency, and where chloroform has been administered.

Dr. Henry F. Campbell said: I use ergot almost invariably in my obstetric practice. I never give the drug until the mouth of the uterus is well dilated, and hardly ever until after the delivery of the child; but I always give it afterwards to favor the expulsion of the placenta, the contraction of the womb and the removal of clots. In 1836-37, Dr. Milton Anthony published a series of articles in the *Southern Medical and Surgical Journal*, in which he clearly recognized the value and the dangers of the remedy. I never use it to cure post-partum hemorrhage, but it is a powerful agent in preventing hemorrhage.

Dr. Albert H. Smith, of Philadelphia, said: I agree entirely with Dr. Englemann. I believe ergot is never needed, is always capable of doing harm, and often does harm. There is nothing more important in the process of parturition for the welfare of the mother and child, than the intermittency of the pains. Ergot produces a tetanic contraction. There are circumstances where ergot might not do absolute harm in the first stage of labor. These are cases in which we know from previous experience that there is no obstruction in the pelvic canal, but we can never be positive on this point, for while one labor may be easy, the next may be difficult. In the second stage we never have a right to give ergot, for we have in the forceps a much better method of terminating labor. In the third stage, while its use may not be so reprehensible, there are very few cases in which it can be useful. I have seen the uterus thrown into such a state of contraction by the use of ergot, that ether and the injection of opium into the bowel failed to relieve it.

We have been told that ergot is useful in counteracting the effects of chloroform. I have used chloroform for eight years, and have rarely seen its use attended with relaxation. After ether relaxation is often met with; chloroform can be used in much smaller quantities than ether. I have seen less need for ergot after chloroform than after ether.

Dr. Elwood Wilson, of Philadelphia, in discussing the paper said: I formerly used chloroform in labor, but its tendency to favor relaxation and post-partum hemorrhage caused me to abandon it. I have seen the same thing after the long-continued and excessive use of ether. I am astonished to hear it said that ergot should never be given to the pregnant woman. I doubt if any man would approach a case of placenta prævia without resorting to the use of ergot. I consider ergot of immense benefit in post-partum hemorrhage. The difficulty is that in many cases it is given in too large doses, and at too late a period.

I believe that the judicious use of ergot in the third stage of labor is very important. I think that a half a drachm of the fluid extract of ergot, administered after the death of the child, will often result in the expulsion of the placenta and the tonic contraction of the uterus.

During my whole lifetime I have been in the habit of using ergot in abortion. I have only seen one death after abortion, and that was not due to the drug.

Dr. Englemann.—I may have been misunderstood. I believe that ergot is a powerful stimulant of uterine contractions, but I think that we have other and better means of obtaining the same end.

The paper of **Dr. James R. Chadwick**, of Boston, entitled, *A Theory to Explain the Relaxation of the Vagina and Perineum During Labor*, was read by title and ordered to be printed in the *Transactions*.

THANKS TO THE EX-SECRETARY AND EX-TREASURER.

Dr. Albert H. Smith read a series of resolutions expressing the gratitude of the Association to Dr. James R. Chadwick for the faithful manner in which he had performed the duties of secretary.

Dr. William Goodell was requested to draw up a series of resolutions expressing the obligation which the Association was under to Dr. Mundé for the manner in which he had served as treasurer.

The discussion of Dr. C. D. Palmer's paper on *Some Points Connected with the Subject of Dysmenorrhœa*, which had been postponed until the end of the session, was closed by a few remarks from Dr. Palmer.

Dr. Albert H. Smith, the **President-elect**, was now called to the chair and made a brief address.

The meeting then adjourned.

THE WISCONSIN STATE MEDICAL SOCIETY.

Adjourned Meeting, held at Milwaukee, September 4th, 5th, and 6th, 1883.

(Specially reported for The Medical News.)

Tuesday, September 4th, First Day.

The State Medical Society of Wisconsin held an adjourned meeting in the city of Milwaukee on the 4th, 5th, and 6th of September, this meeting, for all business purposes, taking the place of the thirty-seventh regular annual session.

The attendance throughout was very good, and, to more than the usual extent, the time of the meetings was spent in discussions rather than in the reading of laboriously written papers.

The President of the Society, Dr. T. P. Russell, of Oshkosh, being absent, no formal presidential address was delivered, but the Society was very acceptably presided over by the **Vice-President, Dr. D. Mason**, of Milwaukee.

The opening formalities and the report of the Committee of Arrangements having consumed but little time, the Society proceeded at once to business, which was opened by the reading of the

REPORT ON THE PRACTICE OF MEDICINE,

by **Dr. J. S. Walbridge**, Chairman of the Committee. The paper pointed out that the general practitioner of medicine must of necessity work chiefly in the direction of the application of remedies to particular diseases, having few facilities for the finer investigations of physiology or pathology, while the effects of therapeutic agents are matters of daily observation, and the study of these effects his highest duty. The antipyretic treatment of fevers was then dwelt upon at length, and the claim was made that by it the mortality from fevers has been very largely reduced, and many severe and dangerous complications and sequelæ avoided. Quinine and the application of cold water are the chief antipyretics made use of in this country, the sponge-bath being highly commended. The defects of clinical thermometers were pointed out, and a picture drawn of the weary description of continued fevers which was given before the thermometer was used.

The character of the fevers of the Northwest was discussed at some length, whether these were typhoid, typho-malarial, or simple remittent, the conclusion being that they were chiefly of malarial origin, even though there may be intestinal hemorrhage, and post-mortem cases may reveal softened or disintegrated intestinal mucous membrane, or even some form of ulceration of Peyer's patches.

Of recent advances in medicine, those attracting the most attention are in the field of microscopical research, the relation of micro-organisms to disease being the most startling and the most important question now before the medical profession. If it is established that disease is the result of the invasion of the system by bacteria, our therapeutics must conform to that idea, and preventive medicine assumes vastly increased importance, and the study of infectious diseases will be placed upon a scientific basis.

In answer to questions, **Dr. Walbridge** stated that he gave as an antipyretic dose of quinine from twenty to forty grains; had given as high as fifty-five grains—seldom more than thirty to forty grains. He never had seen any bad effects from it, and had often been surprised at the lack of cinchonism from such doses. He generally gave it in the form of a bolus, at one, two, or three doses, and on alternate days, using cold sponging during the intervening day. The reduction of temperature following these doses of quinine is generally one to three degrees, and the effect continues from twelve to twenty-four hours. If, after a few days, the quinine does not have the desired effect, he stops its use, and treats the case expectantly until later, when quinine is again tried. He did not consider antipyretic treatment necessary unless the temperature is over 103°, but with this temperature he would use it in fever of any type.

Dr. Senn referred to the use of kairin as one of the most valuable of antipyretics, the chief objection to its common use being that it is very expensive. He said the temperature in fevers is reduced in one of two ways—either by the direct abstraction of heat, or by checking tissue-metamorphosis. Quinine, salicylic acid, etc., belong to this later class. Koch has demonstrated that bacilli or micrococci exert their baneful influence by changing the character of the white-blood corpuscles, increasing their power of adhesion, and inducing embolism and metastatic abscesses. He believes that typhoid fever is common, and would always put down any case where there is any change in Peyer's patches as genuine typhoid. He believes that there is more danger of mistaking typhoid fever for fever of malarial type than of mistaking the malarial for typhoid. Typhoid is more common in children than malarial.

DR. MANLEY had given a boy of thirteen, with initial symptoms of violent scarlet fever, twenty grains of quinine at night, and twenty grains more in the morning, with the effect of aborting the fever.

DR. STANSBURY agreed with Dr. Senn in classing our common continued fevers as typhoid, though some of them, especially the milder cases, are more or less deficient in the characteristic symptoms of true typhoid. He believed that an expectant mode of treatment produced better results and a smaller death-rate than are found where large doses of quinine are given. He believed that the opinion that these cases are not malarial is sustained by the fact that quinine has little effect in shortening their duration.

DR. WENZEL stated that in this latitude there is but little malaria, the summer heat not being sufficiently powerful or prolonged for the evolution of the malarial germs. The fevers met with are a low, continued fever or a typhoid, and quinine does little good. If they were of malarial origin, quinine would break them up. He expressed doubt of the safety of forty to fifty-five grain doses of quinine. He thinks such doses may cause amaurosis or deafness, or even death from paralysis of the heart. He thought that better results would follow small, frequently repeated doses. He regarded digitalis as the best antipyretic and heart tonic we have in dangerous cases of typhoid or continued fever.

DR. STEELE expressed the opinion that typhoid fever is a *very* rare disease in his section of the State, though there may be a tendency to its increase by the changes incident to increased population and the climatic changes which come from greater cultivation of the soil. The present type of fevers in Northern Wisconsin is of malarial origin, and can frequently be broken up promptly by the daily administration of ten to fifteen grains of quinine, for a few days, in the early stages.

DR. DAY, referring to what had been said about cold sponging, said that he had found the use of warm or hot water preferable, there being no unpleasant reaction following, or congestion, as was liable to be the case after the use of cold water.

DR. FRENCH doubted if cold sponging affects the temperature materially; but he has reduced temperature from 105° to 103° by an hour's bath of cold water, and the temperature did not again rise to its former height. He agrees with Dr. Walbridge as to the infrequency of typhoid as compared with malarial forms of fever.

WEDNESDAY, SEPTEMBER 5TH, SECOND DAY.

MORNING SESSION.

DR. BARNETT, reopening the

DISCUSSION OF FEVER,

said that, while agreeing with Dr. Walbridge in the belief that remittent fevers were of more frequent occurrence than typhoid, he could not agree with him in the belief that typhoid fever was seldom or never met with, nor could he agree with those who would class all or most of our continued fevers as typhoid. He would be unwilling to give much weight to the influence of antipyretics or the rate of mortality in making a diagnosis.

DR. DAVIES expressed the belief that the type of fever is changing. Typhoid fever, which was prevalent fifteen years ago in his section, is now seldom met with, and the remittent type of fever generally predominates. He gives quinine in such cases, but not with the liberal hand mentioned by others as a rule, though, during the remission, he would give in the aggregate as much. He prefers not to give it in doses of over five to ten grains.

DR. BRETT said that at Green Bay, in eleven years, he had never seen but one typical case of malarial fever, but had seen many cases with all the characteristic symptoms of typhoid.

DR. DODSON found in his practice many typical cases of typhoid fever. He uses quinine in antipyretic doses of forty-five to sixty grains, given in two doses one-half hour apart, and repeats this dose on the second day if the fever rises to the point of danger. If it does not, he depends on sponging. He believes nearly all our diseases are modified by malarial influence.

DR. MANLEY thought that we very often do not find well-marked typical cases of disease, but he believes we frequently find true typhoid fever. He has had several cases which he believes to have been caused by infected water, and believes this condition of the water-supply will often be found where typhoid fever prevails.

DR. HOEGH, in fourteen years at La Crosse, had never seen a distinct case of remittent fever, but had seen numerous cases of typical typhoid, identical with those seen in Norway, where there is no malaria, the identity being verified by post-mortem results. He regards the disease as certainly contagious, and has found but limited benefit in it from the use of quinine.

DR. MANN read a paper, giving a report of a case of

PHLEGMASIA ALBA DOLENS FOLLOWING TYPHOID FEVER,

as an after-result of which one leg had been enormously swollen its entire length, with extreme pain and sensitiveness, most marked over the course of the femoral vein, the symptoms being apparently identical with those of phlegmasia alba dolens. The case had been a protracted one, the man having, during his sickness, had pneumonia also. It resulted in recovery.

DR. BARNETT had had a similar case, and he called attention to the fact that Stokes said that these cases were of the same nature as the swelling of the leg following parturition, and had actually called them phlegmasia alba dolens.

DR. SENN believed that the swelling of the leg in these cases was from thrombosis of the femoral vein, caused by deficient *vis-a-tergo*, while in "milk-leg" septic phlebitis is the cause.

THE PATHOLOGY AND MORBID ANATOMY OF TUBERCLE,

being the subject of a paper by DR. SENN before the Society at its session a year ago, was now called up for discusson.

DR. MEACHER said that it was a question whether tubercular disease is inherited, or only a tendency to it. Pathologists, he said, differed on this point, the best clinical observers being in doubt. A recent writer in the *Lancet* says experience does not teach us whether tubercular disease is inherited, or whether there is simply a soil ready for it. In some, after many years, it seems to break out without exposure.

DR. SENN defended his proposition that tubercle is always a product of a specific inflammation caused and incited by bacilli. This has been made plain by the experiments of Koch. Hereditary tendency may exist, but if the general system is robust, it will be thrown off. If the system is debilitated, there is ready for the development of tubercle a fertile soil. The heredity of the disease consists in anatomical predisposition to it, due to peculiar anatomical arrangement of cells. All bacilli or micrococci have a tendency to enter white blood-cells, or to change their character, deleteriously favoring local congestions from emboli, and causing inflammation of a specific type.

Dr. Meacher, of the Committee on Surgery, reported a case of lithotrity, and also read a paper on

ANTISEPTICS,

in which he expressed his belief that the use of the spray was in many cases of serious operations even not necessary, and he personally was generally satisfied to do without it. He believed carbolic acid, iodoform, and corrosive sublimate the best antiseptics known, extolling the virtues of the latter, and called attention strongly to the benefits of absorbent cotton in surgical dressings.

Dr. Binnie reported a case of

STRANGULATED FEMORAL HERNIA,

where an operation had been performed, resulting in the formation of an artificial anus, seventeen days after the operation, and terminating in the closure of this opening and in complete recovery in three months. In subsequent remarks, Dr. Binnie strongly advocated operation for strangulated hernia without prolonged taxis, which he believed made subsequent operation, if it became necessary, dangerous; while an early operation, when the patient was in good condition, was simple and attended with little risk to the patient, at the same time working a radical cure.

Dr. Stansbury and Dr. Reynolds both favored the use of large doses of opiates and of chloroform. After the prolonged use of these remedies, reduction was usually easy.

Dr. Catlin related a case in which he had succeeded in reducing a hernia by the application of an elastic rubber bandage; the uniform equable pressure of which, maintained for an hour, caused the reduction of the hernia, after taxis, opiates, etc., had failed.

Dr. Brett had found great benefit from tapping the hernial sac with a hypodermic syringe, drawing off the accumulated serum, and from tapping the knuckle of intestine, unscrewing the barrel of the syringe and allowing the gas to escape. In one case where all these had failed, he had succeeded by inserting the finger-nail under the constricting ring, and by steady pressure stretching or slightly tearing the same.

Dr. Stansbury, of the Committee on Gynecology, read a paper entitled

REST, THE GREAT ESSENTIAL TO COMPLETE INVOLUTION,

in which he entered a strong plea for prolonged rest after parturition, arguing that the period of involution in healthy women is regulated by as fixed a law as is that of pregnancy, and urging rest in bed for a period of six weeks, that involution might be complete before getting up, and that a train of troublesome uterine diseases might be prevented.

Afternoon Session.

Dr. Barnett read a paper on

MECHANICAL GYNECOLOGY,

entering a plea in favor of the use of the pessary more frequently than it is now used, claiming that mechanical support is indicated in all forms of uterine displacement not complicated by acute or malignant disease, whether attended with discomfort or not—cases of version or flexion which seem firmly fixed by adhesions, should not be abandoned as irremediable until every resource of graduated support and extension has been patiently tried. He had known a chlorotic patient, who had made the rounds of routine medication, to recover promptly upon the mechanical support of a retroversion. He had never known injuries to result from pessaries, always removing them immediately if they produced discomfort.

Dr. Meachem, Jr., Chairman of the Committee on Obstetrics and Gynecology, read a valuable paper on *Pelvic Cellulitis.*

Dr. Wenzel, of the Committee on Pathology, read a paper on

THE RELATION OF DIPHTHERIA AND ERYSIPELAS TO PUERPERAL FEVER,

the following being some of the conclusions of the writer: (*a*) Puerperal fever is of septic origin. (*b*) The poison may be carried from one to another, or, indirectly, by a third person. (*c*) Zymotic diseases affecting the puerperal woman may become virulent or malignant, but they retain their entity, and are the same when under similar conditions in another patient, or in the same patient at a different time. (*d*) There are no grounds to consider the diphtheritic patches appearing as a concomitant of a puerperal disease as diphtheria; diphtheria is a constitutional disease, with local manifestations, usually in the fauces; the diphtheritic patch is only an accidental process in some of the diseases of childbed, appearing only upon or in the organs of generation. (*e*) No dried diphtheritic infection has been observed to produce anything else than diphtheria, and if a parturient patient becomes infected with it, the disease is diphtheria, and not puerperal fever. (*f*) Erysipelas may develop in the puerperal woman, and prove rapidly fatal, without external manifestation. (*g*) The diagnosis between erysipelas and puerperal fever is very difficult or impossible during life.

Dr. Clark, of the same Committee, also presented a paper, bearing the same title. He said that no special micro-organism or germ had yet been discovered as the cause of either erysipelas, diphtheria, or puerperal fever. Until such discovery is made and verified, or some other cause indubitably established, the etiological relation of these diseases to each other will remain a subject of speculative inquiry. So far as is known, each productive germ throughout universal nature, large or small, produces its kind; but there is no fully accepted definition of puerperal fever; its morbid processes have not been accurately measured. Owing to the immensely favorable conditions for bacterial growth and absorption presented by the puerperal state, the invasion of any putrid infection is likely to be in great force, and accompanied by many different kinds of bacteria, especially those of putrefaction.

The puerperal state presents a condition of lowered vital resistance, and, in addition, opens wide gaps in the line of natural defences. Through the lochial discharges and thrombi in the uterine sinuses it provides an abundance of highly nutritious food for the enemy, whether that enemy be erysipelas, diphtheria, or a hypothetical puerperal poison. This poison cannot be expected to advance alone, for there must always be more or less of the virus of putrefying lochia blended with it, thus presenting a clinical picture of profound poisoning of the blood and nervous system, which does not materially differ whether the virus be traced to an offensive autopsy, to a case of phlegmonous erysipelas, or to what is vaguely termed epidemic influence. The fact that the worst cases of puerperal fever begin within two to four days after labor should never be lost sight of. It is then that the internal surface of the womb is in the best possible condition for the absorption of poison. If absorption does not take place until a few days later, the case generally falls short of puerperal fever, and becomes pelvic cellulitis or pelvic peritonitis, pyæmia, mammary abscess, or embolic obstruction of veins, such as is seen in phlegmasia alba dolens.

The entire lochial discharge should be rendered strictly aseptic, and for this purpose dressings of antiseptic absorbent cotton and gauze should be faithfully applied during the first week in every case.

The question whether there is causal relation between erysipelas, diphtheria, and puerperal fever cannot be answered until the special germ or poison of each disease can be ascertained.

Dr. Hoegh read a report of a case of *Sudden Deafness, with Loss of Coördinating Power.*

Dr. E. W. Bartlett read a paper on a *Modification of the Operation for Cataract*, and also a paper showing the

PREVALENCE OF COLOR-BLINDNESS,

and urging proper legislation for the protection of the travelling public from dangers arising from this cause. The following resolution was adopted in reference to this matter:

Resolved, That a special Committee on Color-blindness be appointed, whose duty it shall be to disseminate information in regard to its nature and frequency, and to secure the influence of persons, medical societies, and corporations throughout the State to obtain proper legislation in regard to the employment of the color-blind.

The President appointed Drs. E. W. Bartlett, Hoegh, and Brett as this Committee.

Dr. Bartlett also exhibited various forms of nasal douches, and several forms of magnets and needles for the removal of metallic bodies from the eye.

Dr. Brett reported an interesting case of

POST-RECTAL ENCYSTED TUMOR COMPLICATING LABOR,

it being necessary to remove the tumor before delivery could be effected. In size, the tumor, which was an encysted one, filled with an odorless brown fluid, was as large as a child's head. The recovery was rapid.

Dr. Davies presented a paper on the *Obstetric Forceps and How to Make Traction.*

Thursday, September 6th, Third Day.

Morning Session.

Dr. Catlin reported a case where death had suddenly followed what was supposed to be

BILIOUS COLIC,

to which the patient had been subject for a number of years. A post-mortem revealed an enlarged gall-bladder, impacted with gall-stones, ulcerated, and ruptured. About two hundred gall-stones were found, their aggregate weight being three hundred and sixty grains.

REMOVAL OF THE ASTRAGALUS.

Dr. Manley presented an astragalus which he had removed for disease following dislocation. The wound healed kindly; the foot presented a symmetrical appearance, though slightly inverted; and two months after the operation there was limited motion. The removed bone was examined with interest.

PROPHYLAXIS OF PHTHISIS.

The following resolution offered by Dr. Manley was adopted:

Resolved, That in consideration of the advance made as to a knowledge of the causes of consumption, and of the now known infectious character of the disease, we use all means in our power to have the phthisical members of our families as much as possible separated from the healthy members; and also that we recommend the State Board of Health to take means to have such persons separated from intimate association with the well in our public institutions.

Dr. Epley read a paper on the

THERAPEUTICAL USES OF ERGOT,

claiming for this remedy a place of the same rank as that accorded to opium, quinine, and iron. Its chief action is upon the nerve-centres; not affecting voluntary muscular fibre. It is the most universal and potent internal hæmostatic in use. Is valuable in the night-sweating of phthisis; in congestive headaches; in dysentery, and in various other diseases; but in the opinion of Dr. Epley, its greatest value lies in its power to arrest acute local inflammations, especially in the lungs. It has also proved to be very useful in controlling hacking, irritative coughs where there is a relaxed state of the mucous membrane. The paper concluded with the assertion that ergot would abort ten cases of pneumonia to one pregnancy.

Dr. Manley endorsed from his experience, the use of ergot for controlling the kind of coughs referred to.

Dr. Meacher believed that the claim that ergot will abort pneumonia is fully justified.

Drs. Binnie and Bartlett also spoke in support of the value of this drug in the diseases named by Dr. Epley.

After the transaction of some considerable routine business, and the adoption of an amendment to the constitution, making the office of the Secretary permanent, and fixing the term of office at ten years, the Society adjourned, having had, as is generally conceded, one of the most pleasant and profitable sessions in its whole history. There was no formal social gathering as has frequently been the case, but a general good-feeling pervaded all of the meetings. Several of the papers presented were of a high order of ability, and the discussions elicited by them were highly interesting and instructive.

THE NEXT MEETING

of the Society is to be held in the city of Milwaukee, on the first Tuesday in June, 1884.

THE OFFICERS FOR THE ENSUING YEAR

are as follows:

President.—Dr. N. M. Dodson.

Vice-Presidents.—Drs. E. W. Bartlett and G. W. Jenkins.

Permanent Secretary and Treasurer.—Dr. J. T. Reeve.

Assistant Secretary.—Dr. Wm. Thorndike.

Censors.—Drs. Mason, Senn, and Thorndike.

RHODE ISLAND MEDICAL SOCIETY.

Quarterly Meeting, held at Newport, September 20, 1883.

(Specially reported for The Medical News.)

The meeting was held at Newport Masonic Hall, and was called to order by the President, Dr. Job Kenyon.

The Secretary, Dr. G. D. Hersey, read the records of the annual meeting, which were approved.

Dr. Hersey exhibited several specimens of

BLACK IRON-DYED SILK,

claiming it to be the best kind for surgical use. This silk, he said, was dyed in iron, and finished in acetic acid. It is round, firm, and can be waxed, oiled, carbolized, etc., the same as any other kind. It comes in fourteen sizes, the largest size being sufficiently strong for any surgical use. It is also the cheapest silk in the market.

It is non-irritating to the skin. A case was cited in which sutures of this silk were employed in closing a lacerated wound of the eyelid, and at the end of thirteen days, five of them were still in place, having caused no inflammation. Ordinary white silk, in the manufacture of which *lead* is used, is very apt to irritate. Another important advantage in using the *black* silk sutures lies in their being so *readily seen*, as, for instance, in the operation of circumcision, where œdema is likely to occur and conceal the stitches, especially if white silk is employed.

Dr. W. E. Anthony read a paper on

THE ADVANTAGES OF IMMEDIATE DELIVERY OF THE PLACENTA IN NATURAL LABOR.

Attention was called to the discrepancy between the practice and precepts of teachers on this subject. One author says we may wait twelve hours for the afterbirth—another says twenty minutes. The reader could not see why *one hour* or *one minute* should be allowed to intervene between the so-called second and third stages of labor, he having become convinced by clinical observation and study that no time should be lost. What is known as the third stage of labor may be also subdivided into—1st, the detachment of the placenta; 2d, its expulsion from the uterus; and 3d, its expulsion from the vagina. Of these, the first is most important, for, once it is accomplished, the other two follow readily.

It is best that the second stage of labor be merged into the third, for, during an interval of delay, danger to the patient may arise from hemorrhage, uterine inertia, entrance of air, and, later, septicæmia.

It was the writer's custom to adopt such measures before the birth of the child as should insure this—namely, to employ the method of Credé during the close of the second stage, grasping the uterus through the abdominal wall, with one hand following it down as it contracts, and maintaining the compression until the delivery of the placenta is complete. If necessary, the finger of the unoccupied hand is introduced, and the placenta separated. It is much better to accomplish all this during the severe uterine contraction that comes with the birth of the child; and the Credé squeezing process employed thus early tends to insure both the detachment of the placenta and its folding together, so as to be expelled with its long diameter corresponding with that of the maternal passages. Of course, in case of retained placenta due to calcareous, fibrous, or syphilitic degeneration, the hand must be passed into the uterus, and there is no better time to do this than immediately after the second stage.

The advantages of thus securing an immediate delivery of the placenta were named as follows:

1. The uterus having firmly contracted upon itself will remain so, and post-partum hemorrhage will not occur. 2. No clots remaining in the uterine cavity, septicæmia is not to be expected. 3. The speedy removal of the placenta is a source of relief to the patient. 4. After-pains are less. 5. The lochia are more natural. 6. It saves time; and 7. It is carrying out the natural law of parturition.

In remarking upon the same subject, Dr. D. H. Batchelder said: We meet with very few *natural* labors—*i. e.*, when the placenta is attached centrally to the fundus of the uterus, in which case you will get uniform pains.

When, however, the attachment is on one side, there will be unequal contraction of different parts of the uterus. The so-called severe *frontal* pains are caused by the placenta being attached posteriorly; and *back* pains are due to the attachment being to the front part of the womb.

He had also found, on post-mortem examination, that when rupture of the uterus occurs, the placental site is near the os internum, thus approximating placenta prævia.

It was his practice, when called to cases in which the contractions were not uniform, to call at once for a shawl or blanket, and tie it very tightly around the patient's abdomen. This soon causes the pains to be uniform and effectual by equalizing the force of the contractions, so that the uterus does not become tired out. Since adopting this plan of treatment, he had not had post-partum hemorrhage once in 19 or 20 cases. It was also his practice to secure the immediate delivery of the placenta by measures similar to those described by Dr. Anthony.

THE REPORT OF THE BOARD OF CENSORS

was then presented by Dr. Eldredge. It recommended the following

NEW FELLOWS,

who were then duly elected:

Drs. Arthur H. Harrington, John P. Sweeney, Geo. V. Foster, Henry Arnold, and Ezra Dyer.

Dr. S. W. Francis reported a case of

PROBABLE EPITHELIOMA CURED BY ASTRINGENT WASHES.

The patient was a woman, forty-five years of age. The disease was on the inner side of the cheek, and seemed to have been caused originally by the irritating effects of a carious molar tooth. The writer had no doubt as to the cancerous nature of the ulcerative disease that followed in the cheek; and this diagnosis was confirmed by other physicians.

The offending tooth was first removed, it being the right inferior second molar. The cavity of the sore was then kept packed with charpie, and the following lotion applied to its surface four times daily:

R.—Tinct. opii, ... ℥ss.
Tinct. myrrh.,
Glycerinæ, ... āā ʒj.
Liq. plumb. subsulph., . . . ʒss.
Aq. rosæ, ... ad. ℥iv.—M.

Syr. ferri iodidi in gtt. xx doses, *t. i. d.*, was also given. Under this treatment, the patient has steadily improved, and bids fair to wholly recover.

Dr. O'Leary reported a case of

CONSERVATIVE SURGERY.

A boy's hand was severely injured in machinery last February, the index and middle finger being so far crushed and lacerated that amputation, at first, seemed the only thing to do; but it was decided to simply dress the hand and wait a little. In ten days the first (*i. e.*, next the palm) phalanx of the index finger was found to be detached, and was removed. The case then went on to complete recovery; the lost phalanx being replaced by new bone. The boy now has a perfect index finger with the joints all movable.

Dr. T. W. Perry showed the

SKIN OF THE PALMS AND THUMBS WHICH HAD BEEN EXFOLIATED ENTIRE IN A CASE OF DERMATITIS.

The patient, a man, fifty-three years old, had a chill June 12, 1883, and four days later there was exfoliation of the epidermis over the whole body; that of the palms and soles coming off complete. The patient was then literally as "red as a lobster" from head to foot. This was followed by apparent recovery. July 3d, a second chill occurred, and then came another complete desquamation, the scales being thinner than those first cast off. July 29th, a third chill, with exfoliation on the fourth day after. August 11th, the process was repeated the fourth time. The desquamation took place in no definite form, but in irregular patches, underneath which was a semi-transparent fluid, resembling flour and water paste. There has been no recurrence of the attack since the date last named.

The man had the same disease thirteen years ago. The treatment, both times, consisted of arsenic and iron internally, and cod-liver oil externally. The sulphide of calcium was also given in the recent attack, with the local use of ung. diachylon. The man is a worker in broadcloth. He suffered greatly from itching, but there was no severe pain.

IODOFORM IN CANCER.

Dr. Perry also spoke of a woman who had a sore the size of a silver dollar, with indurated edges, and of eleven years' standing, on the side of her neck. She regarded it as cancerous. Iron and potassium iodide internally, with iodoform locally employed, led to a perfect recovery in two months. Two cases of cancer of the uterus were mentioned which had apparently been cured by the use of iodoform.

Dr. Ezra Dyer, of Newport, exhibited

A NEW PERIMETER

of his own devising. It consisted of a standard of wood, supporting a spiral of wire. Within the spiral an arm of brass is made to revolve by turning a crank on the back of the standard. As the arm revolves, an objective or *traveller* moves correspondingly upon it, towards or away from the centre of the spiral. In the old style of perimeter, both the *arm* and *traveller* had to be moved again and again by the hand of the operator. The exhibitor said that a case of scotoma could be excluded in one minute by means of his instrument. He also said he proposed to make a further improvement by the addition of a small electric light to be used in certain tests.

It was voted that the thanks of the Society be extended to Dr. Dyer.

Dr. H. G. Miller said that he had been treating a case of retino-choroidal disease in a man who was both intelligent and skilful in the use of the pencil and brush. He had thus kept an accurate record of the progress of his own case by a series of charts illustrating his power of vision at the time the tests were employed. These charts, bound into a volume, were shown by Dr. Miller as constituting a most plain and accurate record of the case.

The Chairman then called for the report of the committee consisting of Drs. A. Ballou, J. H. Eldredge, and S. W. Francis, appointed at the June meeting to consider the

PROPOSITION TO ABOLISH THE CORONER SYSTEM IN RHODE ISLAND,

and to substitute, therefore, that of *Medical Examiners*.

Dr. Ballou said that he had not as yet called the committee together, and consequently had nothing to report, but hoped the subject would be discussed freely.

Dr. Storer said that Dr. Francis had sent circulars of inquiry to all the towns of the State. The replies, so far as received, showed that there were only two coroners in the State who were physicians—those two being in Providence.

The remaining coroners were farmers, assessors of taxes, auctioneers, undertakers, station agents, lawyers, firemen, clerks, grocers, etc.

Dr. Storer also said that in Suffolk County, Massachusetts, which includes Boston and Chelsea, where there were, under the old law, forty-seven coroners, there are now two medical examiners—and that the duty of the examiner ceases, for the time being, at least, when he has expressed his opinion in a given case, whether or not murder or crime has been committed. The case, if necessary, then goes into the hands of the trial justice.

Dr. H. W. Williams, of Boston, an honorary member of the Society, was called upon and spoke of the workings of the new system in Massachusetts. He said that formerly the coroner system in Massachusetts was similar to that of Rhode Island, the coroners being chosen from all classes of occupations, and that when doctors were found among them, they were usually disreputable ones or mere pretenders, whose decisions were apt to be made up of the opinions expressed by bystanders, etc.

The Massachusetts Medical Society had used all its influence to secure a change, and he thought the State had been fortunate in the men appointed medical examiners—some seventy first-class physicians now serving in that capacity. The Medico-Legal Society, an outgrowth of the new system, has been of great service to the public.

The Medical Examiner becomes an expert in the matter of autopsies, and far better able to judge as to the cause of death. Hence a large proportion of cases are dismissed as not requiring further investigation, but if it goes on to prosecution, the new system results in giving to the legal authorities a far more satisfactory account of the cases, and with much less notoriety.

When asked as to the comparative expense of the two systems, Dr. Williams replied that the cost in Suffolk County had been reduced to about one-third what it formerly was, and that on political, scientific, and financial grounds, the new system in Massachusetts is proving a grand success.

A draught of a new law for Rhode Island having been framed by a committee of the Newport Medical Society, and submitted to the General Assembly of the State at its May session, 1883, together with a petition that the same become an enactment, Dr. Browning asked Dr. Storer how nearly it corresponded to the present law in Massachusetts.

Dr. Storer said that it resembled the latter in many particulars, but differed in some, and that the advice and approval of Dr. Hossmer (Mass.,) had been sought in framing the present draught.

It was then voted to add the names of Dr. Lloyd Morton, of Pawtucket, and Dr. H. G. Miller, of Providence, to the committee on this subject.

Upon motion of Dr. Turner, of Newport, it was voted to instruct the same committee to ascertain if a law requiring burial permits exists all over the State.

Dr. J. H. Eldredge reported a *Case of Gunshot Wound*, four bullets entering the body—in the jaw, shoulder, side, and back.

Adjourned.

MEDICAL SOCIETY OF VIRGINIA.

Fourteenth Annual Meeting, held at the Rockbridge Alum Springs, September 4, 5, 6, and 7, 1883.

(Specially reported for The Medical News.)

(*Concluded from page 335.*)

Evening Session.

Honorary Fellow Dr. A. M. Fauntleroy, of Staunton, read a report on the therapeutic qualities of

ROCKBRIDGE ALUM SPRINGS WATER.

After giving a chemical analysis of the springs, he showed the therapeutic uses, and gave clinical results of the action of the water. Dr. Fauntleroy specially pointed out the therapeutic value of these waters in scrofulous, tuberculous, and specific diseases. The waters are "alterative" in the therapeutic sense of the word, as well as deobstruent. In dyspepsia of various forms, especially where it occurs in overworked ladies, these waters, properly used, are of peculiar value. They are also particularly recommended for "female irregularities." They diminish the amount of acid secretions, and hence are useful in forms of nephritic gravel, as well as in gastric and hepatic torpidity. The sodium sulphate probably assists in restoring the normal activity of the liver.

The President, Dr. J. Edgar Chancellor, enumerated several cases of severe strumous disease which had occurred in his practice, which had been entirely cured by the use of the water.

LETTERS OF REGRET.

A letter was read from Honorary Fellow Dr. J. Marion Sims, of New York, who had just returned from Europe, regretting his misfortune in not being able to attend. A like letter was received from Dr. Metcalf, of New York.

The subject of

DIPHTHERIA

Again being called for, Dr. J. J. Chisolm, of Baltimore, Md., made some remarks, in which he expressed a doubt whether there was really such a trouble as diphtheria of the eye, as a distinctive disease.

Dr. McLane Tiffany, also of Baltimore, stated that tracheotomy does not cure the disease, while the operation does not kill the patient. Tracheotomy, even when successfully performed, relieves a symptom—that of "want of breath." He thinks it almost impossible to decide where the difficulty of breathing in such cases begins, and in many cases it is impossible to decide when to begin to operate. He has never been able to decide strictly when the obstructing membrane was above the sternum, or when below the usual point of tracheotomy. He related a peculiar case, in which he opened the trachea just before death resulted, but after opening the windpipe, he found it fully plugged with a diphtheritic exudation, through which neither a tracheotomy tube could pass, nor a probe made to enter.

Dr. L. B. Edwards related a case of tracheotomy he had seen performed (and in which he had assisted) by Dr. Hunter McGuire and O. F. Manson. One of the heated blades of the Paquelin thermo-cautery, as modified by Dr. H. P. C. Wilson, of Baltimore, was used as the knife. The operation was successfully performed, and the patient lived for some days. He died, however, of capillary bronchitis. Whether his death was due or not to an extension of the membranous trouble, he had no opportunity of finding out, but he doubts whether or not there is a greater cause for apprehension than the extension of the membrane downwards. Blood-poisoning evidently had much to do with his death. Dr. Edwards fully agreed with Dr. Tiffany that it was impossible to decide *when* or *even where* to operate; but in cases which are sometimes presented he thought doctors, as the only parties upon whom anxious friends depend in such an adversity, should speak plainly and operate boldly. We cannot always save life, but because of popular prejudice against an operation that has saved so few lives, why should we reject that one operation that has saved *some* lives? Is there a better remedy for an obstacle in the windpipe than giving the patient free inspiration? If we fail to reach far enough to let the patient have the necessary respirations, then the doctor is simply unfortunate and the patient is the victim.

Dr. W. W. Parker begged the younger doctors not to become discouraged because they lose some patients who have diphtheria; no physician can save all his cases. In many cases, he had found value in the vapor of lime. Build a sort of tent over the child, and inside of this tent slake lime so as to get the air fully impregnated with its vapor.

Dr. J. N. Mackenzie, of Baltimore, remarked upon the development of adenoid growths as a sequel of diphtheria. They occur especially in the post-pharyngeal space. This is a point not enough studied; but little has been written upon it. He believes the simplest means of treatment to be the best; hence he relies mainly on steaming for local applications. Internally he would advise the use of small doses of the bichloride of mercury, such as a teaspoonful or two, according to age, etc., of a solution of one or two grains of corrosive sublimate in a pint of water.

Dr. R. I. Hicks, of Cassanova, Va., related a peculiar instance where a diphtheritic patient associated with a number of persons in health without conveying the disease to them.

Drs. Patterson, of Monterey; C. T. Whiting, of City Point; James Craddock, and others, reported cases as confirmatory of one point or another that had been made.

Dr. Wm. C. Dabney, of Charlottesville, Va., said he had seen cases where sanitary conditions existed, and yet death had occurred in a few days. He had seen peritonitis, he thought, produced by diphtheria.

Dr. Samuel B. Morrison, of Rockbridge Baths, Va., had never seen a case that was not constitutional in its origin; but he believed in local treatment. His experience had taught him that the poison may remain quiescent for years in one locality, and then suddenly break out. He thought all remedies should be more often employed than is common, and that a person of strong vitality cannot contract the disease. From his experience, he judged diphtheria and typhoid fever to have the same germ, only manifested in different ways. He strongly believed in complete isolation of a diphtheritic patient.

Dr. J. St. Peirre Gibson, of Staunton, Va., believed that peritonitis could be produced by diphtheria, and cited a case in point.

Dr. A. M. Fountleroy, of Staunton, mentioned a number of cases showing the peculiarities of the diphtheritic poison. One instance showed where a servant-girl wiped up the floor where ice had melted from a diphtheritic corpse, and contracted the disease, and he mentioned another case where a boy stopped over night at a house where the disease existed several days before, and not only received the poison, but communicated it to thirty-two other children in an asylum which he entered. He spoke of the difficulty of ingestion of food in the disease, and mentioned a case where he had fed the patient three weeks through a stomach-tube, with ultimate recovery.

CHOLERA INFANTUM.

Dr. Samuel K. Jackson, of Norfolk, Va., by request, described his method of *preventing* cholera infantum, which consisted in the administration of the following:

R.—Sulphite of soda,
Hyposulphite of soda,
Aromatic syrup of rhubarb,
Bicarbonate of soda, . . . āā gr. ij.—M.
S.—Take every two hours, when required.

Malarial fever was selected as the subject for general discussion at the next annual meeting, and Dr. R. B. Stover, of Richmond, Va., was appointed to open it.

ROCKBRIDGE ALUM SPRINGS, VA.

After the introduction and adoption of several complimentary motions as to the excellent management of this place, the following, offered by Dr. Samuel K. Jackson, of Norfolk, Va., was unanimously adopted:

"The Medical Society of Virginia does hereby bear testimony to a thorough examination into the medicinal properties of the Rockbridge Alum Springs water, and from the professional knowledge and information obtained, it unhesitatingly endorses and recommends the same to persons afflicted with the following disorders and diseases: some forms of dyspepsia or indigestion, scrofula, incipient consumption, chronic bronchitis, chronic laryngitis, chronic pneumonia, chronic diarrhœa, chronic dysentery, aphthous diseases, many of the chronic skin diseases, torpidity of the liver, and diseases peculiar to females.

THE COMMITTEE ON THE CONSTITUTION of the Society, appointed last year to suggest what, if any, changes were necessary, presented their report, and most of the emendations suggested were adopted—all to take effect at the next annual session.

The same Committee was continued another year to codify the various resolutions, etc., governing the action of the Society, in matters not involving the Constitution.

Various resolutions of local importance were passed, and the Society then adjourned, to meet next year at the Rawley Springs, at the call of the Executive Committee.

OBSTETRICAL SOCIETY OF PHILADELPHIA.

Stated Meeting, Thursday, September 6, 1883.

THE PRESIDENT, R. A. CLEEMANN, M.D., IN THE CHAIR.

DR. WM. T. TAYLOR read the report of a case of

FACE PRESENTATION WITH ECLAMPSIA.

Face presentations are somewhat rare. Dr. Churchill, some years ago, in recording the statistics, found that in British practice they occurred once in 292 cases, in French practice once in 275, and in German practice once in 130 cases. In my own practice, I have met with about one dozen, and as the last was combined with eclampsia, I will report it to the Society.

During utero-gestation, my patient enjoyed very good health, having no headache, no swollen limbs nor bloated features, no vertigo nor dimness of vision. There was no deficiency of urine, and therefore I did not examine it for albumen. Her appetite was fair, her bowels regular, and she took a moderate degree of exercise, so that I had no reason to expect any trouble when labor began.

On May 14, 1883, I was summoned, at 6 A. M., to visit Mrs. C. Haley, aged twenty-three years, primipara, who was in the first stage of labor, having had a show since midnight. On examination, I found the os very slightly dilated, with the pains "few and far between," and the face of the child presenting, with the chin toward the sacrum. The nurse informed me that the patient had not slept during the night, and was very nervous and irritable. Her skin was moist, her pulse normal, and she had urinated frequently.

I gave her a mixture containing hydrate of chloral, bromide of potassium, and valerianate of ammonia, to compose her, and went home for my breakfast, intending to return in a few hours.

At 8 o'clock, the husband came to my office, and told me that his wife had "had a fit, and could not keep the medicine down." I arrived at the house at 8.30 A. M., and sent immediately for some powdered hydrate of chloral and an injection apparatus. The patient had had two convulsions, which were ushered in by complaints of her head, her face being very red, and her head drawn to one side, with the features much distorted. The first convulsion occurred when the nurse was about to give the first dose of the medicine. Directly after my arrival, a third convulsion occurred, and lasted for a minute or more, her head being violently drawn to the right side, with jerking of her arms and legs.

I dissolved one drachm of the hydrate of chloral in about four ounces of water, and threw it into the rectum. The fit yielded immediately. As she was unconscious, I had an excellent opportunity for examining her. The os was dilated to the size of a quarter dollar, and soft, so that it yielded gradually to the pressure of my fingers, when I discovered the face presentation, with the chin toward the left sacro-iliac junction. I endeavored to push the chin toward the breast, so as to bring down the occiput in the second position of Baudelocque. This I found somewhat difficult, but as the os dilated under the pressure of my fingers, I reached the occiput, and, after several attempts, succeeded in bringing it down to a favorable position, the one aforesaid. My patient, by this time, was becoming restless and uncontrollable, and, fearing another convulsion, I again gave her an injection of chloral, which quieted her. Having placed her on her back, and brought her to the edge of the bed, her limbs being supported by the nurse and a neighbor-woman, the forceps were easily applied, and the head brought down below the inferior strait. I removed the instruments when the head pressed against the perineum, allowing nature to finish the delivery. The child, a boy, was still, the cord being pulseless; in fact, I was apprised of this whilst endeavoring to dilate the os with my fingers, for a significant tremor had passed through the body of the child, assuring me of its death. The placenta was removed quite easily.

During all this time my patient was unconscious and had no return of convulsion from the time I gave her the first injection of chloral.

As her pulse was good and her respiration easy, I applied a binder, and having placed her in a comfortable position left her sleeping. On my return at 5 P.M., she was restless and slightly feverish, but after taking a few doses of chloral and valerian, she was quieted to sleep. On the next morning, May 15th, she was perfectly conscious, pulse 80, temperature 99°, and respiration normal. She had urinated freely, and with the exception of some slight soreness over the abdomen, was very comfortable. She inquired for the babe, knowing from her condition that it had been born, but the preceding twenty-four hours were, to her, a perfect blank. From this time she had no further trouble and soon recovered. This case certainly showed the beneficial effect of injections of hydrate of chloral in controlling puerperal convulsions when they are of a nervous form.

DR. ALBERT H. SMITH remarked that face presentations and puerperal convulsions presented a large field for discussion. Dr. Taylor was very fortunate to be able to bring around the occiput and keep it so until the forceps could be applied. In this operation a man needs three hands, one to hold the head while the others manipulate the instrument. The mechanism of a primary face presentation, as reported in this case, is difficult to understand. It may occur secondarily from obliquity of the uterus and a sudden free gush of waters, causing a sudden engagement of the head before flexion could be secured. In such cases it is very difficult to secure and maintain flexion until the forceps can be applied. In the majority of cases of face presentation, even with the chin posterior, nature is best able to terminate the case satisfactorily. It is to this class that the aphorism "meddlesome midwifery is bad" is most applicable. The natural forces work slowly, and the neck of the child becomes accustomed to the extreme extension which it has to undergo; while it is very bad to bring, by means of the forceps or otherwise, a sudden strain on the vertebræ and other tissues of the neck by too rapid forcing of the chin into violent extension. The consequence of the hasty proceeding is a still-born child. The only ground for interference is an alarming condition of the child's pulse. If the child's heart is beginning to fail, we must take the risk and give it the benefit of the chance. The child's head cannot be born in face presentation until the chin has engaged under the pubis. The old teaching was that the chin posterior could not be born, but he was very early undeceived on this point, one of his earlier cases having been of this character. He had sent for his preceptor to come and bring perforating instruments, but while awaiting their arrival, nature proved equal to the task, rotation occurred spontaneously and a living child was born.

Dr. B. F. Baer inquired if version by the feet would not be much preferable to waiting for nature to deliver in chin posterior positions.

Dr. Smith did not mean that we should never interfere in a case of this kind, but that a large majority, if left to nature, would terminate spontaneously by anterior rotation of the chin, with safety to both mother and child. He would decidedly negative the proposition of version by the feet, because the amniotic sac having been necessarily ruptured by previous efforts to bring down the vertex, the waters would have been completely drained off, the uterus would be in a condition of spasmodic contraction, and an attempt to turn would involve great danger of rupture of the uterus. The introduction of the hand always increases the risk of septic absorption, two terrible risks against the mother, while the child is exposed to all the dangers of head-last delivery. He would consider chin posterior presentations natural labors, and would allow them to terminate spontaneously, unless there was some complication demanding version.

Dr. J. G. Allen coincided with Dr. Smith in his conservative principles. The risks of version to the mother are great, too great to allow it to be performed for the sake of the child. The operation of version is not looked upon in as serious a light as it should be under all circumstances. In some instances it may be very easy, and may terminate well, but in others, apparently similar in conditions, the results to the mothers are bad. He would not lose one mother to save ten children. He would never resort to version unless the labor was impossible under other measures. Even after it is skilfully performed the child is often still. The increased risk to the mother is followed by no corresponding gain in safety to the child.

Dr. R. P. Harris thinks the ideas of Dr. Smith are the same as held by most eminent obstetricians, and agrees with their practice as expressed to him in private correspondence.

Dr. Baer was willing to be taught. The views expressed this evening did not harmonize with the teaching of even the present day in Philadelphia. He had been taught that version would be proper if the case was diagnosticated early, and the operation could be performed before the waters were evacuated, and it seemed to him that the rational thing under such circumstances would be to turn. It was entirely a new light to him to consider chin posterior cases as easy natural labors. He had been taught to look upon them as impossible, and that rotation never took place, the forces in action not being great enough to compel it. His own recent experience had led him to doubt this dictum; with one blade of the forceps used as a vectis, he had without difficulty secured anterior rotation. His idea of the impossibility of rotation under the circumstances made him doubt the correctness of his diagnosis of the position, but the principles put forth this evening reassured him. May not the death of the child, causing relaxation, be the cause of the face presentation?

Dr. Allen does not expect others to accept his opinion, but in his denunciation of turning, he alludes to the complete transposition of one extremity of the fœtal ellipse for the other, and does not include the changing of one part of the head for another, but in the first class the poor chance of saving the child will not compensate for the increased danger to the mother.

Dr. Smith does not consider chin posterior an easy natural labor. On the contrary it is the most difficult of natural labors. The chin strikes upon the posterior inclined planes and is rotated to an anterior position, in which it engages under the arch of the pubis exactly as the vertex would. In multiparæ nature is able to accomplish this result, but in primiparæ assistance in rotation may be required, and even traction may become necessary. In contrasting the dangers incident to version by the feet and those involved in trusting to nature in this condition when the waters have been discharged, as they necessarily have, in the attempts to bring down the vertex, which would be first tried, we must remember that the child will be tightly grasped by the uterus, and that it must be twisted upon its long axis as well as turned, to bring the nape of the neck under the arch of the pubis, and that this procedure will greatly enhance the danger to both mother and child.

Dr. Taylor, in closing the discussion remarked that the death of the child occurred after it was fully engaged, and was not a factor in causing the face presentation. When he made his diagnosis of position the head was high up, and the child being small he had no difficulty in bringing down the vertex.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting September 12, 1883.

The President, Wm. M. Welch, M.D., in the chair.

Dr. Charles M. Seltzer read a paper on

DIETETICS FOR THE SICK.

The methods of dietetic treatment of diseases are as various as are the ills that flesh is heir to, but all of them contain some of the following principles as essential features. In acute diseases, *rest* is of primary importance; it is the fundamental principle of their medical and surgical treatment, and the same idea must be carried out in dietetics by remembering what part each organ serves in absorption, assimilation, and excretion, and by avoiding such food as would cause the performance of that function. Of course, this plan is only to be pursued while the disease is advancing, and as soon as recovery begins there must be a gradual return to a promiscuous diet, very little at first, just enough to slightly exercise the crippled organ, using as great care as we would in instituting passive motion in a limb that has been fractured. Nature enforces this principle by the loss of appetite that marks the onset of nearly all acute diseases. The dietetic rest of an organ does not necessarily imply a depletory diet, for while it is non-active, other organs may be made to perform a compensatory amount of work, and thus sustain or even increase the patient's vitality. It is upon this idea that we must act when we obey the command of Graves to feed fevers. In chronic diseases food should be administered as frequently as assimilation and proper amount of organic rest will allow; the appetite should be kept active, by using food prepared in such a variety of ways as to allow no charge of monotony or disgust. A valuable aid, usually lost sight of, is condiment. Many of the bitter tonics and carminatives of our materia medica are the same as are used in cookery, and are none the less efficacious in a palatable dish than in the nauseous pill or draught. Therefore let the delicate aroma of herbs, celery, and bay leaves pervade the soups; use India curry on starchy foods, and when desirable add *Capsicum*, *Piper nigrum*, etc., to animal broths and substances.

Some articles of diet may be administered simply for their curative effect. A five-ounce cup of strong coffee contains about sixty-six grains of extract, or an equivalent of about two grains of *Caffeine* -quite sufficient to relieve a neuralgia, or a headache and sick stomach after a dose of opium. Beef-tea, made red-hot with red pepper, is the very best treatment for delirium tremens. Mucilaginous teas and drinks made from gelatine, isinglass, Irish moss, and flaxseed are very soothing to any inflammation within the digestive track. Green vegetables are necessary to cure as well as prevent scurvy.

In the science and art of preparing sick diet there is a most lamentable lack of knowledge, especially among physicians, and the only way to acquire this knowledge is to don the apron and take a practical course from a practical and scientific cook. Such a course was inaugurated last winter in this city and in Boston with a very satisfactory result. It is the only way to learn.

DR. L. TURNBULL, in opening the discussion, said: Physicians should learn how to make beef-tea, extract, etc., and similar articles. The important preparations of mush, of Indian and oat-meal, for instance, are rarely properly made. They should be prepared over night, so as to be thoroughly gelatinized; if made in the morning just before being served, they will not be digestible. In cases of very weak stomachs, many articles of diet may be peptonized with great benefit by using a small amount of a mixture of sodium carbonate and pancreatin, these being allowed to act for a short time at a temperature of about 80° F. Such peptonized foods are like the old-fashioned preparations made with rennet and warm milk, and will be well borne by delicate stomachs. An article that is often wrongly prepared is barley. It may be softened and extracted with water, or it may be torrefied, so as to make a sort of malt extract. In the latter form it is very suitable as a substitute for the diastase-like principle of the saliva in cases where that secretion is deficient. It can easily be given mixed with other food, as in puddings, for instance.

This summer we have been very successful in relieving the irritability of the stomach and bowels of both children and adults, due to temporary indigestion, by substituting first barley-water alone, and after a time a wineglassful of barley-water, with half a tumbler of milk, or its equivalent of condensed milk.

Beef-tea contains often but little nourishment, and in debilitated conditions, such as most cases of typhoid fever, beef-essence, made, not from the round of beef, but from the neck, in which blood is found, will be much more nourishing. A valuable form of beef-juice can be prepared by cutting up in pieces fresh beef, and placing it under a block of ice until, by the pressure, all the blood has been extracted. With the addition of a little salt it has been found to be retained by the most delicate stomach, and is very useful in cases of great exhaustion.

DR. ALBERT H. SMITH said: The older we get the less disposed we are to rely on medicine and the more on diet. The remarks in the paper in reference to the importance of teaching physicians the art of cooking, are deserving of full endorsement. On one point, however, I cannot agree with the author of the paper. He seemed to advocate the use of highly stimulating food in acute diseases. In cases of disease attended with high temperature, we only add fuel to the flame by the use of stimulating food.

The use of a low form of diet, with refrigerants and depressants, may often be of the greatest benefit. I can look back on my early experience, and recall cases in which, after operative measures, patients have been treated on the theory that plenty of pabulum should be furnished to the system, but such patients have perished. A strong patient will in such cases do much better on a low diet. Adhesive inflammation will be secured more satisfactorily on the low diet system.

DR. HENRY LEAMAN reported the following

CASE OF AMPUTATION OF THE BREAST.

Mrs. J. J. W., æt. 48, in September, 1882, complained of a tumor in her breast which she had noticed three months previously. At that time a small pimple upon the surface of the skin served to call her attention to the swelling that lay beneath in the substance of her breast. Examination showed a tender enlargement, the size of an English walnut, situated deeply in the inner, lower quarter of the left breast. She stated that during the past week she had experienced for the first time frequent, sharp, retracting pain shooting through the nipple. Menstruation had ceased six years before, without giving rise to any trouble. She had no *cachexia*, and was apparently in her usual health

On the twenty-third of April, 1883, the tumor then was of an oval shape, and about four inches in length. From its inner anterior surface were extending two cornua, slightly ulcerated, about three-fourths of an inch in length. The skin over the tumor was deeply congested, red and inflamed, as was also the skin for several inches around. The tumor in front rested upon the cartilages of the rib, but was movable. The glands in the axilla were slightly involved. The breast was removed under the spray on April 26, 1883, and Lister's dressing applied. One nodule of hardness was removed from the axilla. At the sternal end the cut surfaces could not be approximated within two inches, owing to the necessary ablation of tissue.

The case did well, and the temperature never rose above 99½°.

On and after May 10th, the wound was dressed with iodoform, cosmoline, and salicylated cotton, under which treatment the wound rapidly healed. Dr. Brubaker made a histological study of the growth, and pronounced it carcinoma.

As soon as the cicatrix was complete, neuralgic pains began to be felt in the left arm, right leg, and body. At first the cicatrix remained perfectly healthy in appearance. Subsequently, however, a nodule appeared in the lower part of the neck behind the left sterno-clavicular articulation. Next, the left axilla, the posterior and healthy part of the cicatrix began to show hardening. At present there is a chain of nodules along the whole cicatrix—one large and painful is felt over the cartilage of the third rib on the left side. The left axilla is one hard pyramid. The left hand and arm are swollen. A pain of a lancinating, burning character is referred to the left scapula, arm, and axilla, occasionally shooting in the course of the incision.

The apparent freedom from involvement of the axillary glands at the time of the operation, and the rapid development of the disease after the healing of the cicatrix, would seem to point to the idea that the original tumor was but a local nidus for a constitutional trouble, and that this having been destroyed, a general efflorescence of the disease ensued.

DR. BALDWIN said: I remember that the late Dr. Atlee spoke of the effects of arsenic in carcinoma, and gave a number of cases in which he used it with the apparent effect of preventing the return of the tumor. I employed it in a case on which operation was performed in 1875, the patient being put on the use of Fowler's solution, continued until 1876, when the growth redeveloped and a second operation was done in 1878; no return has occurred to this time. The use of arsenic was discontinued after the second operation. During the formation of the second growth some trouble occurred in the lung, and cancer of that organ was feared, but it disappeared after operation.

Dr. Forbes said: Dr. Leaman speaks of a period of efflorescence after operation, by which I understand a general development in different organs; this, as he remarks, does not always occur after the first operation. In 1864 I removed a cancer from the breast of a lady. In 1867 a hardened growth appeared in the cicatrix. It was not removed at once, as it was then giving no pain. In a short time, pain having developed, it was removed. It returned a number of times and was each time removed until it developed in attachment to the interosseous cartilage and the muscles, and then I declined to remove it, although the patient earnestly urged me to do so. It continued to increase, and in eighteen months it involved the integument on the clavicle and sternum. Its condition was much aggravated by various caustic applications. Finally some irregular parties attempted to remove parts of the diseased mass, and this was followed by an efflorescence and a number of organs in the thorax and abdomen became involved. The patient died eighteen months after the last attempted operation.

I have heard Dr. Geo. W. Norris speak of this condition of efflorescence and its likelihood to occur in patients upon whom the cauterizing and escharotic treatment had been practised. After such treatment he advised non-interference with the knife.

Dr. J. M. Barton said: Even when the knife does not cure, it may prolong life. Operation offers us ten per cent. of recoveries. In Dr. Leaman's, the almost immediate return in the axilla is suggestive of the possibility that some affected gland had escaped removal. The removal of the entire breast in the earlier stages gives chance of total recovery, and in the later stages, with ulceration, operation is also useful; but in the intermediate periods, when the tumor is extensive and adherent to the adjacent structures, non-interference is best.

Dr. Albert H. Smith said: I am glad to hear the repeated use of the knife advocated; I believe in attacking the tumor every time it appears, for, at the least, life may be prolonged and made comfortable, and the patient may be spared the suffering and loathsome discharges of the advanced stages of the disease, conditions which make her a source of misery to herself and to those around her. Cancer is doubtless a local disease, although a constitutional taint or tendency is probably inherited. Yet, if the tumor be removed early, a cure can be obtained. Removal of the breast should be complete; every reappearance should be met by operation. I recall the case of a patient from whom, at the first operation, no axillary glands were removed, but at the second twelve were taken out. Two more operations were subsequently performed; at the last one a very large amount of tissue was removed, but perfect union was obtained. Operation should cease when the condition is such that union by first intention cannot be obtained. In this particular I cannot agree with Dr. Gross, who pays no attention to the size of the cicatrix or the question of union by first intention. The patient just referred to has been well during this summer, but is now beginning to manifest infiltration, and the condition is such that primary union cannot be obtained, and I do not consider operation permissible. Under the modern advances in antiseptic surgery, operative interference in cases of cancer becomes simple and entails little suffering, and the after-treatment is not difficult.

Dr. Barton said: The important point in operation is to make a complete cleaning out of the affected glands, and the obtaining of this must not be interfered with by consideration of the amount of tissue to be removed, or by the desire for primary union. Where much tissue is removed, the after-treatment is more simple than where flaps are made; no counter-openings are needed; no drainage-tubes; no pockets of pus are formed; but little, if any, fever occurs; the wound usually goes on uninterruptedly to full cicatrization. In hospital practice I rarely have to see a case after operation, from which the breast has been thus removed. I cannot recall a case in which the disease returned in the cicatrix so formed, though it often returns in the axilla. I remember a case in which three operations were performed upon secondary axillary growths in a period of four years—the last operation being amputation of the arm, ligation of the axillary artery, and removal of the growth—yet the resulting cicatrix from the first thorough breast operation remained perfectly soft and healthy.

Dr. Leaman said: In my case the axilla was opened, and no glands were affected except the one removed. The first symptoms of return were shooting pains in the fingers, referable to a nodule near the insertion of the sterno-cleido-mastoid muscle, behind the left sterno-clavicular articulation. Subsequently the axillary glands were involved. A few small nodules have since appeared over the seat of the first tumor.

In my experience arsenic has not been of use in carcinoma.

A NEW USE FOR AN OLD INSTRUMENT.

Dr. Leaman called attention to the fact that he had found the hooked end of Dr. Gross's ear and nose instrument the best and safest means of rupturing the membranes in labor.

Dr. Wm. R. D. Blackwood then made some

REMARKS ON THE CHICAGO BEEF WIRE SKEWER.

He alluded to a report in the daily papers of a case of swallowing of one of the barbed skewers employed to fasten the labels on the Chicago slaughtered beef sold in this market. He exhibited one of these skewers, and it was readily seen that it would be well-nigh impossible to gulp down a morsel of meat large enough to hide this fastener.

The labels which are attached—one to each quarter only—are removed by the butcher before cutting up the meat, and could, even if allowed to remain, scarcely fail to attract the attention of both cook and eater.

NEW YORK COUNTY MEDICAL SOCIETY.

Stated Meeting, September 24, 1883.

The President, David Webster, M.D., in the Chair.

(Specially reported for The Medical News.)

The Secretary read a communication from John T. Metcalf, M.D., tendering his resignation of membership.

The next business in order was the

NOMINATION OF OFFICERS.

Dr. Austin Flint, Jr., said: At the request of a number of gentlemen, all of whom are interested in sustaining the National Code of Ethics, I am authorized to place before you the names of certain gentlemen, every one of whom will be an uncompromising supporter of the Code of Ethics of the American Medical Association.

The names have been selected carefully and with great deliberation. This ticket represents the Code of

Ethics of the regular profession. I wish all my friends to understand what it means. I wish them to comprehend what we believe an election of this ticket to mean, and I firmly believe it will be elected, viz., that an election of this ticket means a reversal of the action of the State Society, which has abolished, as you well know, the Code of Ethics of the American Medical Association, and made a Code of its own. These remarks are not made in a spirit of malice, and with no imputation to gentlemen who differ with us in this contest. As a matter of interest we cannot fail to understand what we believe to be a serious encroachment upon the honor of the profession.

I now nominate for *President*, Dr. T. Gaillard Thomas.

Dr. Frederick R. Sturgis said: The nominee is opposed to this Society, not being in affiliation with it. It remains for us to carry out the wishes of the State Society, and it will not be well to place ourselves in opposition to that Society. I therefore nominate for *President*, Dr. S. Oakley Vanderpoel to carry out a principle that the State Society has a right to control the County Society, and the County Society has a right to carry out the wishes of the State Society.

Dr. D. B. St. John Roosa said: We are perfectly well prepared for the organization from whose chief we have heard to-night, and with the consciousness which the gentleman gives us credit for, we are sure of being quite as regular as any member of the profession, and quite as much in sympathy with its defence; and our organization is not for any personal aggrandizement, and from only pure motives we set up a ticket of those who are opposed to the Code of Ethics of the American Medical Association. I therefore nominate for *Vice-President*, Dr. Andrew H. Smith; and for *Secretary*, Dr. Wesley M. Carpenter.

The complete list of nominees is as follows:

NATIONAL CODE.

President.—T. Gaillard Thomas.
Vice-President.—Charles A. Leale.
Secretary.—E. A. Judson.
Assistant Secretary.—P. B. Porter.
Treasurer.—Henry D. Nicoll.
Censors.—Charles McBurney, Charles S. Wood, Richard H. Derby, Charles Hitchcock, and Thomas H. Burchard.

NEW CODE.

President.—S. O. Vanderpoel.
Vice-President.—Andrew H. Smith.
Secretary.—Wesley M. Carpenter.
Assistant Secretary.—C. H. Avery.
Treasurer.—O. B. Douglas.
Censors.—David Webster, Daniel Lewis, F. R. S. Drake, Joseph W. Howe, and F. R. Sturgis.

The paper of the evening was read by Dr. R. B. Swinburne, and was on *Fungoid or Adenoid Growths of the Vault of the Pharynx.* The paper was discussed by Drs. Bosworth, Pomeroy, Curtis, and others.

CORRESPONDENCE.

TESTING URINE FOR ALBUMEN.

To the Editor of The Medical News.

Sir: Having been much interested in your recent editorials on the improved methods of examining urine, I beg to be allowed to add to them a description of an easy and quick way of performing the Heller test for albumen, with its modifications. A few lines on page 293, Vol. xliii., No. 11, of The Medical News, suggested to me the importance of mentioning it. As the sole objection to the picric acid test, you speak of the difficulty of overlaying a urine specimen of low specific gravity with the acid solution. When resident physician in one of the city hospitals, where I was called upon to make frequent and numerous tests for albumen in urine, my preference was for the Heller test, but owing to the difficulty of underlaying the urine with nitric acid, the sore trial of patience, and the time involved, to say nothing of the waste of acid, the staining of fingers, and sometimes of carpets, when in a hurry, I experimented for an easier way than the ordinary test-tube method. My plan at present—and it would do admirably, I should think, for the picric acid test—is to use in place of the test-tube a pipette of about twenty-eight mm. circumference; this is plunged into the urine; a small quantity taken up; then, while the free end is closed by the finger, it is plunged into the nitric acid, and the finger gently removed. As soon as a small quantity of the acid has entered, the end of the tube is again closed, and the whole removed and held over a test-tube while the ring is examined. Another advantage in favor of this method is that, while in the old way the thickness of the ring depended very much on the size of the tube and the delicacy with which the admixture was made, in this the standard is uniform.

Respectfully yours,
Granville Faught, M.D.

142 North Fifteenth Street,
September 27, 1883.

NEWS ITEMS.

CINCINNATI.

(*From our Special Correspondent.*)

The Medical Colleges of Cincinnati have taken a step in the interest of reform by commencing their regular sessions earlier than in former years. The experiment is well received, especially by advanced students, and it is hoped that a greater lengthening of the courses will be the result.

At the Medical College of Ohio, lectures began on Tuesday morning, the 18th inst., with nearly two hundred matriculants. The introductory address was delivered in the evening by Prof. J. G. Hyndman, of the Chair of Chemistry. His subject was "Medicine as a Science and a Profession." He showed the students that even in the present advanced state of medical science, there remains a wide field for investigation and research. Referring to the objection that certain branches now taught are too theoretical, and not sufficiently practical, he said that nothing is more certain to retard the advancement of science than the search for that only which promises immediate practical results. The utility of pure science is constantly cropping out at unexpected places. In conclusion, he urged the students to make diligent use of the facts collected by their predecessors in the profession, in order to be the better prepared for original work; for the physician who utilizes the past will be more instrumental in saving life than the one who contents himself with making a living out of the afflictions of humanity without the will or the power to advance the standard of his profession.

There was no preliminary course at the Ohio this fall, but the histological, pathological, and chemical laboratories have been in operation, with fully a hundred students at work, for about three weeks before the opening of the regular session.

The Miami College also opened its sessions on the 18th, and with encouraging prospects. The introductory address was delivered on Monday evening by Prof. J. C. Mackenzie, of the Chair of Theory and Practice; his subject, "Biology, or the Science of Life." The speaker considered briefly the various forms of life, and the difficulty of defining what we know as "life." In regard to the origin of life, he favored the Darwinian theory, believing it to be the best supported by scientific evidence, and the view adopted by the greatest scientists and naturalists of the time. In conclusion, he said that, while "The proper study of mankind is man," the student should not confine his studies to man. All life and all nature must be his teacher.

A New Medical School (?) has recently been granted a charter in this city. Its name is, The Medical University of Ohio. Its founders are some dozen men, as yet, to fame unknown. The charter grants remarkable latitude in the branches of instruction, but where the infant is cradled has not yet been revealed.

Counter-prescribing.—At a recent meeting of the Academy of Medicine, the Secretary was instructed to request the Cincinnati Medical Society and the Pharmaceutical Society to appoint a committee to confer with a similar committee from the Academy, with reference to counter-prescribing, advertising patent medicines, and other irregularities among the druggists of our city. The evils referred to are constantly practised by a majority of them, and, in some instances, with the most remarkable openness.

Yellow Fever.—Eighteen deaths from yellow fever occurred at Havana during the week ending September 15th.

Yellow fever is reported among the foreign residents at Ponce, Porto Rico.

One case of yellow fever is reported from the city of Mexico—an imported case.

Cholera.—At Calcutta there were eleven deaths from cholera during the week ending August 4th, and twelve for the week ending August 11th.

One death from cholera, during the week ending August 10th, is reported from Flushing, Netherlands.

The Sanitary Service in Panama.—The climate of the Isthmus of Panama has been frequently urged as an objection to the building of the canal, but the numerous reports concerning it appear to have been very much exaggerated. An official bulletin on the sanitary service of Panama says: "It is true, and we have never hesitated to declare it, that the climate of the Isthmus requires especial laws for the preservation of health, unrelaxed attention and great moderation in diet. Our agents have understood it, and healthfulness has been greatly improved, notwithstanding the number of employés has largely increased. Since the commencement of our work no real epidemic has appeared, the illnesses have been few and the cases seldom severe." In the month of May, 1882, when the number of employés was 2852, there were but 6 deaths, and in August, when there was the greatest mortality of any month in the year, and the number of clerks and laborers had increased to 2895, there were but 20 deaths; and in December, when the number reached 3898, but 9 deaths occurred. In January of the present year, there were employed about the canal 4901, and during the month the deaths numbered but 6, while in February, when the help aggregated 7804, there were but 11 deaths. In March, out of a total of 6131 persons employed, the mortality was 19; and in April, 14 out of a total of 6812. In order to meet any emergency a central hospital was erected on a well-selected site near the city of Panama, containing 275 beds. It consists of a group of buildings, the wards, each of 24 beds, being well separated and abundantly supplied with water. At Colon there is a hospital of 80 beds on the sea-coast. The administration of these hospitals has been confided to a benevolent commission, of which Monseigneur Paul, the Bishop of Panama, is president. The solicitude of the members of this commission and the devotion of the French Sisters of Charity secure to the sick the best of care. This main organization is supplemented by an infirmary at each post or section. In addition, on the Island of Taboga, in the harbor of Panama, an establishment has been erected for convalescents.

Medico-chirurgical College of Philadelphia.—Dr. William S. Janney has been elected Professor of Practical Anatomy and Clinical Surgery in this institution.

American Pork Investigation.—The New York Chamber of Commerce has named Prof. Charles F. Chandler as the most suitable expert for the purpose of investigating the pork packing interests of the country, with special reference to the dangers from trichinous pork.

An International Veterinary Congress was held at Brussels on September 10th–16th inst.

Dr. Brown-Séquard.—Dr. Brown-Séquard, who will be remembered as having been some years ago resident for a time in London, and as having delivered courses of lectures at the Royal College of Physicians and St. Bartholomew's Hospital, is now a candidate for the seat in the Académie des Sciences left vacant by the death of M. Cloquet. His varied and valuable researches prove that he merits the honor, though he cannot command it. They have, perhaps, contributed more than those of any other experimental physiologist to establish that proper appreciation of pathological phenomena which leads naturally to accurate diagnosis. Dr. Brown-Séquard is the first physiologist who demonstrated the constriction of bloodvessels when the nerves that innervate them are submitted to the influence of electricity, and who explained vascular dilatation and increased local temperature by paralysis of the parieties of the vessels. This explanation was verified by Claude Bernard, who discovered that on dividing the cervical branch of the sympathetic, these phenomena are present on the corresponding side of the head. Neither must it be forgotten that Dr. Brown-Séquard has especially elucidated the question of the pathogeny of epilepsy by his researches, and has furnished evidence that it is hereditary; also that spontaneous lesions may be inherited. Latterly, Dr. Brown-Séquard has especially studied phenomena manifested by the nervous system. It is to these researches that science owes the discovery that when a portion of the nervous system is irritated, or in a state of lesion, it exercises on distant organs an influence which Dr. Brown-Séquard calls inhibition. Thus, a lesion of the encephalon can determine an arrest of the functions of the spinal cord, or a lesion of the cord may arrest the functions of the brain. Before mentioning Dr. Brown-Séquard's investigations in another field of research, we must call attention, though they are well known, to those on the transmission by the spinal cord of sensory impulses, from which the principal conclusions to be drawn are that sensory impulses pass along the posterior and lateral columns, and are transmitted by the gray matter to the brain, which is the principal conductor of sensory impulses. Dr. Brown-Séquard's interesting researches on generalized anæsthesiæ resulting from irritation of the mucous membrane of the larynx by carbonic acid or chloroform, also those on a special kind of syncope resulting from the application of anhydrous chloral to the skin, may be classed among many others he has made with successful results, and will tend to solve many pathological problems, as they earn for him the right to all honors his French brethren can bestow on him.—*British Med. Journal*, September 15, 1883.

The Foot and Mouth Disease in England.—A correspondent of *The London Times* says that the foot and mouth disease is spreading alarmingly in Derbyshire, and that within the past week the returns for that county have almost doubled. Nine out of every ten farmers in Derbyshire are convinced that the disease is not carried in the air, but that the poisonous germs are conveyed by animals from herd to herd. In the treatment of the disease, careful and judicious nursing and attention seem to answer better than medicinal remedies. A diet of hay tea, oilcake, gruels, or linseed tea, varied with mashes and pulped roots, has been tried by some, and others, when the mouth of the animal is sore, place it in pieces of oilcake and slices of roots. Especially successful has been the simple process of washing the mouth of the cattle twice daily with a mixture of water, nitre, and tincture of myrrh. Complete rest on a dry floor and clean litter has, perhaps, superseded all remedies for the feet. There has been an increase of 39 in the number of places infected, and of 393 in the number of cattle attacked by the disease within the past week. *The Times* has also received discouraging accounts of the rapid spread of the disease from Cheshire, Denbighshire, Yorkshire, Lincolnshire, Leicestershire, Buckinghamshire, and other counties.

Health in Michigan.—Reports to the State Board of Health for the week ending Sept. 15, 1883, indicate that influenza, remittent fever, and tonsillitis have increased, and that cholera morbus, typhoid fever, and diarrhœa have decreased in area of prevalence.

Including reports by regular observers and by others, diphtheria was reported present during the week ending Sept. 15, and since, at fourteen places, in Argentine, Berrien Springs, Bingham, Detroit, Grand Rapids, Hastings, Holly, Hobert, Ida, Kalamazoo, Lansing, Mt. Pleasant, Pontiac, and Somerset. Scarlet fever at fifteen places, in Detroit, Charlotte, Elk Rapids, Grand Rapids, Howard City, Ithaca, Lansing, Middleville, Morenci, Nashville, Negaunee, North Adams, Port Huron, Sunfield, and Woodland. Measles was reported at three places, in Detroit, Ithaca, and Jerome.

Obituary Record.—Prof. Ritter von Rittershain, editor of the *Prager Medizinische Wochenschrift*, and Professor of Diseases of Children in the University of Prague, has recently died in that city. For many years he has been known as an authority in diseases of children, and especially in rickets, to the literature of which subject he was a valuable contributor.

OFFICIAL LIST OF CHANGES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM SEPTEMBER 17 TO SEPTEMBER 24, 1883.

Campbell, John, *Lieutenant Colonel and Surgeon, Medical Director, Department of the South.*—Granted leave of absence for fifteen days.—*Par. 2, S. O. 94, Department of the South*, September 13, 1883.

Alexander, Charles T., *Major and Surgeon.*—On being relieved from duty at the U. S. Military Academy, October 1, 1883, to report in person to the Commanding General, Department of the Missouri, for assignment to duty.—*Par. 7, S. O. 211, A. G. O.*, September 14, 1883.

Gibson, Joseph R., *Major and Surgeon.*—Relieved from duty in the Department of the East, October 1, 1883, and to report by letter to the Commanding General, Department of the South, for assignment to duty.—*Par. 7, S. O. 211, A. G. O.*, September 14, 1883.

Alexander, Charles T., *Major and Surgeon.*—Granted leave of absence for four months, from October 1, 1883.—*Par. 1, S. O. 213, A. G. O.*, September 17, 1883.

Horton, Samuel M., *Major and Surgeon.*—Relieved from duty in the Department of the Platte, October 1, 1883, and to report in person to the Commanding General, Department of the Missouri, for assignment to duty.—*Par. 7, S. O. 211, A. G. O.*, September 14, 1883.

Meacham, Frank, *Major and Surgeon.*—Relieved from duty in the Department of the East, October 1, 1883, and to report in person to the Commanding General, Department of the Platte, for assignment to duty.—*Par. 7, S. O. 211, A. G. O.*, Sept. 14, 1883.

Smith, Andrew K., *Major and Surgeon.*—Relieved from duty at Willet's Point, New York, October 1, 1883, and assigned to duty at U. S. Military Academy, West Point, New York.—*Par. 7, S. O. 211, A. G. O.*, September 14, 1883.

Taylor, Morse K., *Major and Surgeon.*—Relieved from duty in the Department of the East, October 1, 1883, and to report in person to the Commanding General, Department of the Missouri, for assignment to duty.—*Par. 7, S. O. 211, A. G. O.*, September 14, 1883.

Wolverton, William D., *Major and Surgeon.*—Relieved from duty in the Department of Dakota, October 1, 1883, and to report in person to the Commanding General, Department of the East, for assignment to duty.—*Par. 7, S. O. 211, A. G. O.*, September 14, 1883.

Appel, Daniel M., *Captain and Assistant Surgeon.*—Relieved from duty in the Department of the Missouri, October 1, 1883, and to report in person to the Commanding General, Department of the East, for assignment to duty.—*Par. 7, S. O. 211, A. G. O.*, September 14, 1883.

Munn, Curtis E., *Captain and Assistant Surgeon.*—Relieved from duty in the Department of the Missouri, October 1, 1883, and to report in person to the Commanding General, Department of the East, for assignment to duty.—*Par. 7, S. O. 211, A. G. O.*, September 14, 1883.

Merrill, James C., *Captain and Assistant Surgeon.*—Relieved from duty in the Department of Dakota, October 1, 1883, and to report in person to the Commanding General, Department of the East, for assignment to duty.—*Par. 7, S. O. 211, A. G. O.*, September 14, 1883.

Maus, Louis M., *Captain and Assistant Surgeon.*—Relieved from duty in the Department of the Missouri, October 1, 1883, and to report in person to the Commanding General, Department of Dakota, for assignment to duty.—*Par. 7, S. O. 211, A. G. O.*, September 14, 1883.

Price, Curtis E., *Captain and Assistant Surgeon.*—Relieved from duty in the Department of the East, October 1, 1883, and to report in person to the Commanding General, Department of Dakota, for assignment to duty.—*Par. 7, S. O. 211, A. G. O.*, September, 14, 1883.

Patzki, Julius H., *Captain and Assistant Surgeon.*—Relieved from duty in the Department of the South, October 1, 1883, and to report in person to the Commanding General, Department of the East, for assignment to duty.—*Par. 7, S. O. 211, A. G. O.*, September 14, 1883.

Shannon, W. C., *Captain and Assistant Surgeon.*—Assigned to duty at Fort Bridger, Wyoming.—*Par. 3, S. O. 102, Department of the Platte*, September 19, 1883.

Vickery, Richard S., *Captain and Assistant Surgeon.*—Relieved from duty in the Department of the Platte, October 1, 1883, and to report in person to the Commanding General, Department of the Columbia, for assignment to duty.—*Par. 7, S. O. 211, A. G. O.*, September 14, 1883.

Weisel, Daniel, *Captain and Assistant Surgeon.*—Relieved from duty in the Department of the East, October 1, 1883, and to report in person to the Commanding General, Department of the Platte, for assignment to duty.—*Par. 7, S. O. 211, A. G. O.*, September 14, 1883.

Appel, Aaron H., *First Lieutenant and Assistant Surgeon.*—The leave of absence granted July 20, 1883, extended one month.—*Par. 10, S. O. 211, A. G. O.*, September 14, 1883.

Brewster, William B., *First Lieutenant and Assistant Surgeon.*—Granted leave of absence for two months, from October 1, 1883, with permission to apply for an extension of four months.—*Par. 1, S. O. 107, Military Division of the Missouri*, September 15, 1883.

Strong, Norton, *First Lieutenant and Assistant Surgeon.*—Now on duty in the field near Fort Thornburgh, Utah, to accompany command to Fort Douglass, Utah, and there await further orders.—*Par. 2, S. O. 101, Department of the Platte*, September 17, 1883.

ORIGINAL LECTURES.

BLOODLETTING.[1]

A Clinical Lecture.

BY PROF. DUJARDIN-BEAUMETZ,

MEMBER OF THE ACADEMY OF MEDICINE, PHYSICIAN TO THE HOPITAL ST. ANTOINE, PARIS, FRANCE.

GENTLEMEN: From a medical point of view there is no history more interesting alike to philosopher and physician than that of bloodletting. It is a history replete with useful lessons. We see there illustrated the truth that when the spirit of system and of routine takes possession of a philosophical or medical doctrine, the results are distorted and misinterpreted, and the practical outcome is barren of good fruits and baneful. If, moreover, the word of the master is worthy of respect, hot-headed enthusiasts who urge to riot and madness every good measure are always to be distrusted; finally, enlightened observation and the true scientific spirit ought continually to submit to the test of the experimental sciences the data furnished by tradition.

We are ignorant of the origin of bloodletting; we only know that it was in use at the dawn of our historical era. Eleven hundred years before Christ, Podalirius is said to have practised it at the siege of Troy. It is probable that it was already in vogue among nations where civilization was more advanced, and that in Egypt, India, and China bleeding was a recognized therapeutic measure.

However this may be, Hippocrates, in his writings, speaks of bloodletting and its indications. Afterwards Aretæus and especially Galen insist on the importance of bleeding, and thenceforth down to the seventeenth century venesection was practised in accordance with the principles which Hippocrates and Galen had laid down. It was as much as ever, if during this long space of time certain opponents, Van Helmont and Porcius in particular, dared lift their voices in protestation against the abuse and the uselessness of bloodletting.[2] They were, however, little heeded, and the majority ranged themselves on the side of Botalli, who compared diseased blood to stagnant water in a well, which becomes more and more pure the more you take out. It is precisely so, said Botalli, with the blood and with bloodletting.[1]

It was, however, in the seventeenth century that phlebotomy attained its zenith, becoming in France, as in England, the unique system of treatment of all diseases—children and old men alike were bled; the new-born babe was not even spared, and blood was taken by *quarts*. Guy Patin bled his *confrère* and friend Mentel thirty-six times in succession, and caused himself to be bled seven times for a simple cold. Pitcairn drew more than five kilogrammes from a rheumatic patient, and Gregory, for a pleurisy, gave issue to more than six kilogrammes. Medicine at this epoch was reduced to these three great elements: purgings, bleedings, and clysters; and the response of the bachelor in the immortal comedy of the *Malade Imaginaire* is in exact conformity to the prevalent practice of the epoch, when he replies to all the questions propounded to him by these three lines—

Clysterium donare,
Postea seignare,
Ensuita purgare.

When one thinks of the prodigious number of purges ordered, the enormous quantity of lavements administered, and the sanguinary floods which phlebotomy produced in this and the succeeding epoch, one can but exclaim with Bouley, physician to the Hôpital Necker, in view of such heroic medication: "A sick person has more vital resistance than one would think!"

---

[1] Translated from advance sheets by E. P. Hurd, M.D., of Newburyport, Mass.

[2] The following passage from one of the writings of Hippocrates makes particular mention of bloodletting: "A patient had borborygmi and pain; had taken emetics without relief; was bled by turns from each arm to syncope, and got well."

From the time of Hippocrates, bloodletting has given rise to very many discussions; nevertheless, owing to the influence of Galen and Celsus, who were for ages the teachers in medicine, bleeding was adopted as a treatment applicable to a great number of complaints. Galen made the following reservation: not to bleed children under four years of age, and rarely to bleed old people.

It was in the seventeenth century that the contest between the adversaries and the partisans of venesection took on the most vehemence, and a perfect furor for letting of blood seized certain physicians. Guy Paton was the most ardent of these enthusiasts. He bled his *confrere* Mentel thirty-two times consecutively, and bled himself seven times for a cold. He would bleed infants at the breast, and even aged people.

Chirac went further, if possible, than Guy Paton, and to him is ascribed that celebrated utterance, "Smallpox, I will make you used to the lancet."

Pitcairn boasted of having drawn twenty English pounds of blood from a patient affected with acute articular rheumatism.

Tweedie, in a case of pericarditis, took first 421 grammes, then 720 grammes, then 960, then 1200, and finally 1440, before the patient was relieved.

Gregory caused a pleuritic patient to lose 5520 grammes in the course of several days.

There was a revival of excessive bleeding under the influence of Broussais at the beginning of this century, and Bouillaud, with his bleedings, "blow after blow" (*coup sur coup*), was the last representative of this period, which Schneider has characterized as the period of *hæmatomania*.

The ancients practised phlebotomy with various instruments; generally, a spear-pointed fleam, called *fossorium*, was thrust into the vein. This instrument is still used by veterinary surgeons when they bleed horses. One of these *fossoria* was found in the ruins of Pompeii.

They also used an instrument called *scalpellus*, with which they opened the vein. Galen employed a cutting implement which he described under the name of *phlebotomon*. Albucasis made use of all three kinds, the *scalpellus*, the *fleam*, and the *phlebotomon*.

The words *lance* and *lancet* were not introduced into surgery till about the year 1200 (Journal, Considerations Relative to General Bloodletting, 1867; Brichetan, Bloodletting, Its Physiological Effects and Therapeutic Indications, Bull. de Thér., lxxv. p. 261, 1868; Article, Saignèe, in Dict. Encyclop. des Sciences Méd.; Sanceritte, Bull. de Thér., li. p. 145).

[1] Botalli was a physician of the University of Paris; afterwards (from 1571), physician to Charles IX. His controversy with the faculty, and in particular with Donatus, has become famous. The latter reproached him with the hardihood of his bloodlettings. He was one of the greatest partisans of phlebotomy. He bled all his patients to excess, basing himself on the principle which he enunciated to his friend Etiénne Pasquier: "The more you withdraw of stagnant water from a well, the more of pure water flows in to take its place. The more the wet-nurse is sucked by the infant, the more milk she has; the like holds good with blood and bloodletting." (Etiénne Pasquier, Lettres liv. xiv., lettre 19.)

This mania for bloodletting, after having abated for a number of years, burst forth with new ardor at the commencement of the nineteenth century, and Bosquillon with his humoral ideas, Broussais with his physiological doctrine, Bouillaud with his system of bleedings, *blow upon blow* (coup sur coup), gave a new *eclat* to the practice of phlebotomy. Then the zeal by degrees died away again, and it may be truly said that to-day the prescription of a phlebotomy is an exceptional thing in the practice of our hospitals, and it is as much as ever if I order one or two bleedings a year. Peter has indeed made some attempts the last few years to show the evil consequences of so complete an abandonment of this therapeutic measure. We will now see by the most recent data of experimentation if the favor which bloodletting once found and its present abandonment are susceptible of justification.

We ought here to divide our subject into two parts, and study in particular the action of general bloodletting, and that of local bloodletting. We ought also under each of these heads to examine successively the operative procedure, the physiological effects, and lastly the indications and contra-indications of general and local bloodletting.

General bloodletting (called also venesection, phlebotomy) is practised, as you know, at the bend of the elbow; and although in my audience there are doubtless many who have never bled a person, or seen one bled, I need not now take up your time in describing the operation, which you will find in full detail in any text-book on minor surgery. This ignorance of the manual procedure is quite pardonable in anybody, considering how very seldom bleeding is practised in even our large hospitals.[1]

What are the physiological effects of bloodletting? Here we have to study the effects of bleeding on the circulation of the blood, and on the blood itself, and the modifications which supervene in the functions of the different organs of the economy.

The blood is profoundly altered by bloodletting, and we must examine successively the modifications of the globules, and of the serum. In treating the globules, we are to consider the changes in the red corpuscles, the leucocytes, and the hæmatoblasts.

Hayem has shown us in his admirable work on the modifications of the blood, from which I derive the principal data of this lecture, that every loss of blood, however trifling, and though not exceeding 1.75 per cent. of the weight of the body, produces a diminution in the number and quality of the globules which persists from ten to twenty days. When the hemorrhage is large, or when the bleeding is often repeated (*coup sur coup*), the diminution of the globules continues and even augments during the eight days which follow the operation. But that which it is important to note, is that in proportion as the globules are destroyed, others are produced with extreme rapidity. The number of the hæmatoblasts also augments after each bleeding, and in a marked manner; this it is which has led Hayem to say that every hemorrhage inevitably causes a *hæmatoblastic crisis*. This reproduction is even so rapid in certain animals, as the dog, that it is difficult to produce in them a persistent anæmic state by bleedings of moderate intensity, even if frequently repeated.

As for the leucocytes, Weber and Bauer maintain that they augment with losses of blood; Hayem affirms, on the other hand, that it is not so, and that their number remains the same after as before the emission of blood.

The modifications effected in the blood-plasma are less known than those of the globules. Thus, while Prévost, Dumas, and Jürgensen allege that there is augmentation of albumen, Becquerel and Rodier maintain that there is diminution. There is the same dispute with regard to the fibrin; White, Andral, Gavarret, Schutzenberger, Nasse, Sigmund, Mayer, Jürgensen, assert that fibrin is increased; Magendie, Coze, Hirtz, Brücke, affirm a decrease; Hayem is of the opinion of the first-mentioned experimenters, and according to his numerous researches there is a positive increase of fibrin after each bloodletting.

As for the plasma, note that Arsonval has always found peptones in the serum after copious bleedings; this is a fact of great importance, and shows the modifications effected in nutrition by phlebotomy, the peptones being the result of a veritable *autodigestion* provoked by each bleeding.[1]

This same modification in the nutrition is still further indicated by the diminution in the quantity of gases dissolved in the blood. Lothar, Meyer, Mathieu, Urbain, Vinay, and Noil, have in fact observed a decrease in the quantity of carbonic acid, and especially in that of oxygen.[2]

Bleeding has also an influence on the circulation. It at once modifies the pulse, and here, too, Hayem has shown us these modifications in the frequency, force, and form of the pulse. We must here distinguish the effect of one bleeding from that of several, and this distinction should always be made when the physiological effects of blood emissions are to be studied. When there has been but one bleeding, the pulse, half an hour afterward, becomes slowed; when on the contrary there have been repeated bleedings, the pulse augments in frequency in a sensible manner; in augmenting in frequency it diminishes in force, and its form takes on that which is observed in cases of anæmia or aortic insufficiency. The ancients attached great importance to this action of bloodletting on the pulse; they maintained that bleeding *raised the pulse*. One can readily understand, to-day, that this increased amplitude of the pulse results not from the greater energy of the circulation, but from the diminution of the vascular tension in consequence of the loss of blood.[3]

---

[1] Phillipart, of Tournay, has protested against the abandonment of bloodletting. He insists that the profession, in forsaking venesection, have gone too far, and that it is needful to return to this ancient mode of treatment in acute diseases. *Apropos* of the neglect of bloodletting, he cites some curious facts—namely, that the physicians of hospitals attached to the Central Bureau in the year 1867 prescribed bleeding but twice out of 8000 consultations, while in 1852 it was prescribed 1259 times. (Phillipart, on Bloodletting in the Treatment of Acute Diseases, Bull. de l'Acad. de Méd. de Belgique, 1883, t. xvii. p. 128.)

Vinay, On Bloodletting in Acute Diseases (Thèse de Paris, 1880, etc.).

[3] Hayem has remarked, after one bleeding, increase of pulsations during the operation, but this increase ceases half an hour afterward. When the hemorrhage is mortal, the pulsations increase at first, then diminish, and become irregular at the moment of death.

In the case of repeated venesections, the augmentation of pulsations becomes more and more marked with each bleeding, as is seen by the following table.

Before first bleeding, . . .	122	pulsations	per minute.
During " " . . .	164	"	"
One-half hour after first bleeding, .	149	"	"
Immediately " " " .	180	"	"
Before second bleeding, 24 hours later,	148	pulsations	per minute.
During " " " "	204	"	"
Immediately after second bleeding, 24 hours later, ...	189	"	"
One-half hour after second bleeding, 24 hours later, ...	209	"	"

These modifications of the pulse are subordinate to the disturbance occasioned in the blood-pressure. For it is now admitted by all experimenters—Volkmann, Navrotky, Gatzirck, Vorm-Muller, Vinay, Hayem—that hemorrhages diminish the blood-pressure; but in order that this diminution may be effected and maintained, considerable losses of blood are required, for as Vinay and Arloing have shown, these circulatory depressions disappear with great rapidity. This diminution in pressure is accompanied with a swifter blood-current, but on condition always that the hemorrhage has not been too considerable.[1]

These circulatory modifications give rise to troubles more or less profound in the functioning of the different organs. The respiratory movements, at first slowed, become more frequent, and more tumultuous in proportion as the hemorrhage becomes more considerable. Nevertheless, when the blood loss is moderate in amount, the dyspnœa is diminished, and this it is that explains the relief experienced by most patients affected by pulmonary diseases after bleeding. These respiratory troubles are connected with the perturbations caused in the functions of the nervous system by bloodletting.[2]

This *rôle* of the nervous system renders more complex than one would suppose the question of the physiological effects of bloodletting. Since we have learned the existence of the vaso-motors we are obliged to assign to the nervous influence modified by the hemorrhage, a part quite as important as we ascribe to the direct effect of the loss of blood on the mechanical and physical conditions of the circulation.

We ought also to attribute to this double influence the action of bleeding on the temperature.[1]

Bleeding lowers the animal heat, and this in the normal as well as in the pathological state. It even seems to me that we have not of late years insisted enough on the therapeutic value of this powerful antithermic means. I know of none more active or more efficacious, and in contemplating what sometimes takes place in certain pyrexias, as typhoid fever, one is tempted to ask if it would not be well to return to the practice of bloodletting, after the manner of our fathers. This is what happens with our typhoid patients; when in the course of this disease a moderate hemorrhage appears, you see immediately the thermometric curve fall, and this lowering of temperature long persists. I know that this benefit is obtained at the expense of a convalescence often long and painful, but the fact none the less remains that, placing ourselves exclusively on the stand-point of hyperpyrexia, bleeding is a powerful depressant of this high temperature, and I am astonished to see an attentive observer like Lorain consider this fever-fall as transient and illusory.

Bleeding acts not only on the circulation, on the respiration, on the nervous system, on the temperature; it modifies the organism in its entirety, and the conditions of nutrition even.

Every abstraction of blood, as Lepine, Bauer, Claude Bernard, and especially Hayem, have shown, energizes the nutritive movement; but this activity produces, if the bleedings are prolonged, a fatty transformation of the different organs, and particularly the heart, and this is a point which must not be lost sight of.[2]

If, then, I were to sum up the physiological effects of bloodletting, and with special reference to its pathological applications, I would say: Sanguineous losses of medium intensity diminish the number of globules and raise the pulse, while they enfeeble the blood-tension; they also lower the temperature; their effects, however, are generally temporary, for the reason that they provoke a hæmatoblastic crisis, which tends to bring back the blood to the state in which it was before the hemorrhage, and if the latter be often repeated, the hæmatopoietic formations exhaust the organism, and speedily produce grave disorganizations in the different viscera.

Local bloodletting has general effects analogous to general bloodletting, but it has local effects quite different. The mode of performance of these local abstractions of blood is very variable; sometimes we open the vein directly, sometimes we have recourse to mechanical means, as wet cups, or we employ leeches.

Before third bleeding, 3 hours later, .	188 pulsations per minute.
During " " " " .	240 " "
Immediately after third bleeding, 3 hours later, ...	220 " "
One-half hour after third bleeding, 3 hours later, ...	220 " "

As for the force, Vinay from his experiments concludes that the force of the pulse diminishes with acceleration of the pulse, and this is the rule in bleedings of moderate intensity. In fine, as to the form, after abundant hemorrhages the character of the pulse is like that observed in aortic constriction and insufficiency. (Hayem, Modifications du Surg., p. 177. Vinay, Des Emissions Sanguinés dans les Maladies Aiguës, Thèse de Concours, 1880, p. 25.)

[1] According to Volkmann's table, the normal vascular pressure being 155, a bleeding of 2 per cent. of the weight of the body reduces the blood-pressure to 56, and one of 3 per cent to 30. Vinay and Arloing have established the following laws:

1. That venesection produces immediately a considerable lowering of blood-pressure in the arteries.
2. That equilibrium is reëstablished with great rapidity.
3. That copious bleedings effect great oscillations of pressure.

According to Hayem, the lowering of pressure is not progressive. Scarcely appreciable in the first fifth of a mortal hemorrhage, it is between the first and second fifth that the diminution takes place the most rapidly. It is inappreciable in the last stages of the hemorrhage.

According to Vinay, small or medium sized hemorrhages are accompanied with a more marked irrigation of the tissues, but when the loss becomes more considerable the course of the blood changes, and is slowed. (Volkmann, Hemodynamik, 1850; Vinay, op. cit., p. 21; Hayem, op. cit., p. 162; Gatzirck, Centralbl. f. d. Med. Wissensch., No. 53, p. 883, 1871.)

[2] Lichtenstein has remarked a diminution in the number and profundity of the respirations following medium hemorrhages. Bauer has arrived at the same results, but when the hemorrhage is more considerable, this diminution gives place to augmentation. In the experiments of Hayem the respiratory movements augment and become more and more irregular in proportion as the hemorrhage continues.

These modifications result from the anæmia of the spinal cord produced by the loss of blood. (Lichtenstein, Zeitschrift f. Biologie, Bd. vii. 2 Hft. Bauer, Geschicht des Aderlasses, München, 1870; Hayem, op. cit.)

[1] In animals a lowering of temperature is observed after hemorrhage. The experiments of Marshall Hall, of Bœrensprung, of Gatzirck, and of Hayem, were absolutely demonstrative of this; in man the pathological temperature falls also. At the same time Thomas and Lorain have considered this fall as transient and illusory. (Gatzirck, Centralbl., 1871, p. 53; Bœrensprung, Müller's Archiv, 1851, p. 126; Hayem, op. cit.)

[2] Experimentally, under the influence of bloodlettings, instead of obtaining a slowing of the nutritive exchanges, there is an acceleration; the experimental researches of Lepine prove this. According to Claude Bernard, bleeding has a constant effect to accelerate and provoke the organic exchanges. Bauer has studied experimentally on animals the action of bloodletting on nutrition, and he proves by the examination of the urine, as well as by that of the gases of respiration, that there is exaggeration of the phenomena of denutrition and accumulation of fatty matters. He insists especially on the augmentation of urea, which is produced immediately after the bleeding, and which persists for several days. According to him, bleeding causes not simply a loss of fluid pabulum, but a real alteration of the organs and tissues. There is also a perturbation of nutrition under the influence of repeated bleedings, characterized especially by fatty transformation of the organs, and in particular of the heart, as Perl has shown. (Lepine, Soc. de Biologie, 1880; Perl, Virchow's Archiv. 1873, pp. 39-51; Bauer, Zeitschrift f. Biologie, viii. Bd., 4 Heft, Munich, 1872.)

Local bleeding, properly so called, that is, the opening of certain veins by the lancet, has fallen into greater desuetude than venesection at the bend of the elbow. Nevertheless, latterly, Arango, Chaparr, Mestivier, and especially Aran, have endeavored to revive the old practice, vaunted by Hippocrates, Galen, and Alexander, of Tralles, of bleeding from the ranine veins of the tongue, while Seutin, Cruveilhier, and Denucé have proposed to take blood from the nasal mucous membrane, thus going back to another ancient practice. At the present day, despite these tentatives, local venesections are abandoned, and we have recourse only to leeches and wet cups.[1]

Cupping is to day very much in use, in spite of our repugnance to let blood, and you see it employed in a considerable number of affections, and in particular in ocular therapeutics.

Here, as in the case of venesection, I refer you to your manuals of minor surgery for the details of the operation, reminding you only that under the name of *pneumodern*, Montain, of Lyons, and, under the name of *terabdele*, Damoiseau, have devised cupping apparatus similar to those which Heurteloup and, more recently, de Wecker devised and use in inflammatory affections of the eye, and which are veritable artificial leeches.

As for leeches, they render us daily great service, although we have much restricted their usage. The application of these leeches, the hemorrhages which result, the means of augmenting the flow of blood, or of arresting it—these are points with which you are all familiar, and which you learned at the commencement of your medical studies.

I will now show you what are the physiological and therapeutical effects of local bloodletting—effects which, in some respects, surpass those of general bleeding.

Local bloodletting, whether by scarifications, by cupping, or by leeches, has a double action—a general effect and a local effect. When it results in an abundant loss of blood, it produces the same modifications as general bloodletting; the pulse rises, the blood-pressure falls, and the temperature is lowered. The most marked effect, however, and the one most often sought, is the local action, and this is determined in part by the hemorrhage, and in part by a revulsive influence provoked by the local pain.

As for the hemorrhage, the anæmiating action takes place not solely at the point where you apply the leeches or the cups, but it extends more or less far. Despite the affirmations to the contrary of Binz and Struthers, I persist in thinking with Johnson that a considerable area may be exsanguinated by the local bleeding, and this owing to the vascular communications which unite certain organs to certain points of the skin; owing also to the intimate connections of the cutaneous nervous filaments, which hold under their dependence the vaso-motor innervation of organs situated more deeply.

The *rôle* of the local pain determined by the punctures is as important as that of the hemorrhage. We have here, first of all, a substitutive effect, then a vaso-motor action. We know, in fact, and on this point I insisted when considering the revulsive method in its application to the treatment of diseases of the spinal cord, that revulsion produced in any point of the skin causes anæmia of organs more or less deeply situated. Hence it is that local bloodletting has remained one of our most powerful therapeutic agents to combat the element congestion and the element pain, and especially the association of these two elements.

I come now to the most delicate and difficult part of my subject—namely, the indications for bloodletting, general and local. We will begin with the first.

If you reconsider the physiological effects of bloodletting, you observe that these effects are very transient, and cannot be persistent, except on condition either that your bleeding be exceedingly abundant, or frequently repeated, *coup sur coup*, after Bouillaud's fashion and that of the ancient phlebotomists. While, therefore, these repeated venesections undoubtedly do produce durable results, it is necessary to keep in mind that, despite the hæmatoblastic crises which they determine, they are followed by a persistent anæmia, and, what is especially worthy of being remembered, by a tendency to fatty degeneration of different viscera; and one may well ask if the inconveniences and the dangers which result from this double pathological state do not far more than counterbalance the feeble benefits which are obtained from these abstractions of blood, so that to-day, all these facts being well weighed, every body is agreed to solicit from phlebotomy only the transient effects which it can produce, and to resort to it only for relief of active and passive congestions of different organs.

There is especially one pathological condition where this depletion—temporary as it may be—of the circulatory system, by bleeding, may render us some service. It is when we have to do with those pulmonary congestions which are accompanied with asystolism, and especially those which are not linked to fatty degeneration of the heart. You understand how, in these asphyxiating periods of cardiac affections, a temporary depletion is sufficient to enable the heart to recover its habitual rhythm.

In the phlegmasiæ, properly so called, after the congestive period has gone by, and the exudation has formed, bloodletting can have little or no influence, as I explained to you when on the treatment of inflammation of the lungs.

Impotent to arrest the march of an inflammation, bleeding may nevertheless act the part of a prophylactic in these phlegmasiæ, and if experimentation in animals does not sufficiently explain these facts, clinical experience, and especially clinical surgery, shows us again and again the happy influence of general bloodletting in averting the inflammatory accidents which traumatisms determine. Hence it is that bloodletting, seldom employed in clinical medicine, is still utilized in clinical surgery.

In the treatment of the essential fevers, bleeding can have only antipyretic effect, and I shall have more to say of this when I come to fevers. This antithermic action is purchased at the cost of a profound trouble inflicted on the economy, nor, for all that, is the course of the febrile phenomena affected thereby. The doctrine of microbes which, in our day, plays so important part in the pathogeny of the infectious diseases, explains for us sufficiently the impotence of bloodletting in these pyrexiæ, since the removal of blood can in no way prevent the development of these micro-organisms in the mass of the circulating fluid.

Bleeding is indicated much more in the inflammatory fevers, or, at least, in those which accompany local inflammation—fevers which present often a great elevation of temperature, as pneumonia. When we refer to the physiological effects of bloodletting, it is easy to understand the ancient popularity and universality of this therapeutic measure, since, directed to an affection which, by its normal evolution, tends toward recovery, it relieves the oppression of the patient, lowers the temperature, and gives a marked elevation to the pulse. But our predecessors were ignorant of the price which they paid for this passing amelioration.

---

[1] Mestivier, On Bleeding from the Ranine Veins in Diseases of the Pharynx (Bull. de Thérap., t. 52, p. 12, 1857); Arango, Treatment of Quinsy by Bleeding from the Ranines (La Union, Jan. 1883); Chaparr Gaz. hebd. de Méd., April, 1855); Aran, Bleeding from the Ranine Veins in Diseases of the Larynx and Pharynx (Bull. de Thér., t. 52, p. 105); Denucé, Bleeding Practised from the Nasal Mucous Membrane (Journ. de Médicine de Bordeaux, August, 1856).

Nevertheless, in certain cases of blood-poisoning, obscure in their nature, bleeding has a happy influence. Thus in the eclampsia of puerperal women general bloodletting, practised heroically, has arrested the convulsions, and all authorities seem unanimous in recommending venesection in these cases, although we are unable to explain the curative action of this spoliative treatment. You see then, gentlemen, that general bloodletting is indicated only in eclampsia and in certain congestive states, especially such as arise from temporary perturbations of the cardio-pulmonary circulation, and that even here the relief obtained from the depletion is only momentary.

Local bloodletting, by its double action in producing revulsion and opposing congestion, has applications to therapeutics which are much more numerous, and it is a very common practice to resort to this method in painful congestive affections. Thus in the pain which accompanies pneumonia and pleurisy, cups and leeches may give relief; in congestions of the spinal cord, of the kidneys, of the liver, and of the uterus local depletions often prove useful. As in local bloodletting the revulsive effects are more powerfully remedial than those resulting from the loss of blood, you understand the superiority of wet cups over leeches, and they are therefore more in use.

Such are the considerations which I wished to present relative to bloodletting, and which show the mediocre but useful *rôle* which this therapeutic means is destined in the future to fulfil. They will, moreover, help to convince you that, notwithstanding the opposition which we have been called to witness against bleeding in all its forms, and the decadence into which it has fallen, it ought not to be completely abandoned.

ORIGINAL ARTICLES.

THE INTRA-PERITONEAL METHOD OF TREATING THE PEDICLE IN OVARIOTOMY,

WITH A REPORT OF SOME EXPERIMENTS MADE BY

J. EWING MEARS, M.D.,
GYNECOLOGIST TO JEFFERSON MEDICAL COLLEGE HOSPITAL, SURGEON TO ST. MARY'S HOSPITAL, ETC.,

AND

MORRIS LONGSTRETH, M.D.,
PHYSICIAN TO THE PENNSYLVANIA HOSPITAL, PATHOLOGIST TO JEFFERSON MEDICAL COLLEGE HOSPITAL, ETC.

[*Read before the American Surgical Association.*]

I wish to call the attention of the Fellows of the Association to some experiments which I have made, in connection with Dr. Morris Longstreth, on the intra-peritoneal method of treating the pedicle by the ligature after ovariotomy, and to make a few remarks upon the various methods of treating the pedicle.

As is well known, the first operation for the removal of ovarian cyst was performed by Dr. Ephraim McDowell, of Kentucky, in 1809. In this operation the pedicle was secured by a ligature, one or both ends of which were drawn through the incision in the abdominal wall and placed outside. In this way the pedicle was drawn up and placed in contact with the abdominal incision.

In 1821, Nathan Smith, of New Haven, Conn., according to the statement of Peaslee and others, ignorant that the operation of ovariotomy had been performed, ligated the pedicle in this way, *i. e.*, he ligated all the vessels of the pedicle separately, using for that purpose animal ligatures in the form of strips of kid-glove. He ligated the vessels, cut the ends of the ligatures close to the knots, and returned the pedicle to the abdominal cavity. This is the first instance of ligation of the vessels of the pedicle, and also the first instance in which the ligature was cut close to the knot and the pedicle returned to the abdominal cavity with the ligatures in position.

Torsion was afterwards performed—torsion of the vessels separately, torsion of the pedicle *en masse*.

Later, in 1860, Mr. Simpson, of Edinburgh, suggested the use of the acupressure needle for the purpose of constricting the pedicle. In 1858, John L. Atlee, of Lancaster, Pa., used the écraseur in that way, dividing the pedicle and crushing the vessels. Baker Brown, of London, in 1864, used the actual cautery—divided the pedicle with the actual cautery, and thus seared the stump of the pedicle. Spiegelberg, of Breslau, used the galvano-cautery in 1868. McCloud, of Glasgow, twisted off the pedicle by means of two pairs of strong forceps, and in that way controlled the hemorrhage. In 1869, Dr. Miner, of Buffalo, N. Y., enucleated the pedicle. In 1869, Peaslee, of New York, introduced a method which consisted in the introduction of a tube into the abdominal cavity, around which the pedicle was secured by double ligature. At the expiration of two or three days these ligatures were divided by a peculiarly shaped knife passed into the tube, and the ligatures, with the tube, were then withdrawn from the cavity.

These are in brief the different plans which have been adopted since 1809 in the treatment of the pedicle after ovariotomy in the intra-peritoneal method. All these forms can be divided into two classes: 1, those which include the application of ligatures to the pedicle; 2, those which dispense with ligatures. The first includes the method of McDowell, Nathan Smith, and of the other operators, in which the ligature is applied either to the vessels separately or to the pedicle in two or more portions or *en masse*. The methods which dispense with the ligature are torsion, the acupressure needle, the écraseur, the cautery in both forms, and the method of Dr. Miner, of Buffalo, *i. e.*, enucleation. It will be seen from this that the first method adopted was the intra-peritoneal.

I wish to mention another intra-peritoneal method, termed the sub-peritoneal method, in which the pedicle is constricted beneath the layer of peritoneum. It was suggested by Dr. Hayes, of Dublin, and consists in entering the needle beneath the peritoneum, carrying it around the pedicle, and bringing it out at the point of entrance.

The intra-peritoneal method was practised until Mr. Hutchinson, of London, introduced the clamp. Then the pedicle was treated outside of the abdominal cavity, being brought between the lips of the abdominal wound and clamped. There are some modifications of this method, but not many. They consist in securing the pedicle between the lips of the wound by acupressure needles, hare-lip pins, or some other method.

Spiegelberg and Waldeyer were the first to investigate the changes which take place in the pedicle after its ligation and return to the abdominal cavity. These experiments were made in 1868, and they were corroborated by Masllowsky, of Russia; he, going further in his investigations, endeavored to show what changes occurred in the pedicle after the application of the actual cautery. So far as I know, no experiments which show the changes occurring in the pedicle after ovariotomy, have been made in this country. Therefore, as a matter of interest, I exhibit to the Fellows of the Association the results which we obtained.

We propose to continue this series of experiments on the lower animals, and hope to present further results at the next meeting of the Association.

We selected rabbits as the animals upon which the experiments were to be made, and used ligatures of various kinds.

In the first experiment, we removed both ovaries. On one side we used a simple catgut ligature of the ordinary size employed for the ligation of vessels after operations. On the other side we used a chromatized catgut ligature, *i. e.*, a ligature which had been submitted to the action of chromic acid (one part of acid to five of water) for three weeks. This mode of preparation has been instituted for the purpose of hardening the ligature so that it will last longer; the fear being that the ordinary catgut ligature would so soon disintegrate that hemorrhage might thus occur after its application. This ligature was prepared in St. Mary's Hospital, as are all of the antiseptic dressings which are there used. It was of large size, and had been prepared for the purpose of uniting the fragments of bone in an ununited fracture, in which case it was proposed to apply the ligature and allow it to remain *in situ*. At the end of two weeks the rabbit was killed, and a post-mortem examination was made. On opening the abdominal cavity, there were no evidences of inflammatory action in the general peritoneal cavity. It was found that the ligatures (both the simple catgut and the chromatized catgut ligature) were completely encapsuled.

These specimens will show distinctly the conditions which existed. I also exhibit a drawing of a microscopical section showing this to better advantage than it can be seen in the specimen. In applying the ligatures, very little force was used. Only sufficient force was used to control the hemorrhage. This is a point to which I wish to direct particular attention as an important point in the discussion of this subject. The ligature was cast around the pedicle *en masse* with sufficient force to control the hemorrhage, and the ovary was removed. In applying the ligature to the pedicle it was embedded in the tissues, and at the point of application the two portions of the pedicle came in contact and became adherent. A layer of lymph covered the ligature—even the knots were covered. The layer of lymph passed over the divided ends of the ligature. Thus a bridge was projected between the proximal and distal portions of the pedicle. What had occurred in the distal—in the free portion—the raw surface? We found that it was also covered with a layer of lymph, and on one side it had become adherent to the adjacent portion of the broad ligament. On the other side the stump was free and covered with a layer of lymph.

An interesting point in connection with this is to ascertain, especially on the side on which the stump was free, how the stump was nourished. I think there is no doubt that it was nourished in two ways. In the first place, by this bridge conducting nutrition from the proximal to the distal portion; and in the second place by interstitial nutrition, *i. e.*, by nutrition passing through the tissues beneath the ligature which was sufficient to nourish the distal portion. On the side where the stump had become adherent to the broad ligament, no doubt the distal portion formed vascular connections, and in this way was nourished.

The specimens taken from the first rabbit, which I herewith present, make it very evident that the ligature is encapsuled.

Here are the specimens removed from another rabbit, in which a silk ligature and an ordinary linen thread were used. These ligatures had been soaked in a solution of carbolic acid (one part of acid to twenty parts of water). This rabbit was killed at the end of four weeks. We found on examination of the specimens that the ligatures had not disappeared, although not completely intact. Between the meshes of the ligature cells had wandered and the ligature was in a process of disintegration. This was also seen to a certain extent, in the catgut ligature in the first experiment. This indicates the manner in which the ligature disappears—by disintegration and by the development of cells which get into the meshes; in which way absorption takes place.

In these specimens at the end of four weeks we have a layer of lymph not so voluminous, showing that there have been some absorption, shrinking, and development; and after a time we should find only a thin, fully developed layer of lymph covering the ligature and also the distal portion of the pedicle.

Mr. Spencer Wells has objected to the employment of the intra-peritoneal method of treating the pedicle. He feared that the distal portion of the pedicle would slough off and would be thrown into the abdominal cavity and thus increase inflammatory action, leading to a fatal termination. He has, however, been convinced to a certain extent by the experiments of Spiegelberg and Waldeyer, although he still adheres in great measure, I believe, to the extra-peritoneal method of treating the pedicle. He had in one of his cases a fatal termination after the employment of the intra-peritoneal method, in which he found that the distal portion had attached itself to a coil of intestine; this portion was found in a sloughing condition and lying in a pool of pus.

In the second rabbit we found that adhesions had taken place between two portions of the intestine; adhesions between the abdominal wall and the intestine. We are just as liable to have adhesions of the intestine to the abdominal wall in the line of the incision, as we are to have adhesion of the pedicle in the extra-peritoneal method. What might occur also if the pedicle became adherent to the intestine is this: The stump might attach itself between two coils of intestine, and, suppuration occurring, the pus would accumulate as in a pocket and escape possibly through the intestine.

The conclusions which we may deduce from one or two experiments may be of little value; still they may be taken for what they are worth. I think that they show that the intra-peritoneal method is in every way a safe method; that nature takes care of the ligature, and that it takes care of the stump of the pedicle; a point of importance to which I think that attention ought to be called, is in regard to the amount of force which is used in the constriction of the pedicle. It is desirable to simply control the passage of blood through the vessels. It is very desirable to permit the so-called interstitial circulation, nutrition being maintained beneath the constricting ligature through the connective-tissue interspaces.

Subjoined is the report of Dr. Morris Longstreth upon the appearances presented post mortem:

Rabbit No. 1.—Right ovarian pedicle tied with carbolized catgut; left side tied with chromatized-carbolized catgut—large sized.

Operation, April 10th. Autopsy, April 25th, two weeks after operation.

The animal was killed with chloroform, and the body immediately opened. The specimens removed for microscopic examination were placed in Müller's fluid.

At the autopsy, no evidence of inflammation of the peritoneum was found. All the organs of the body were healthy.

At the seat of the operation, the extremities of the uterine horns were found attached to the adipose tissue embedded in the lateral or broad ligaments, by which the uterine extremities, their fimbriated terminations, and the ovaries are held in place. This adipose tissue formed a cap over the free end of the pedicle made by the removal of the ovary. The adhesions were firm and well organized, but the adjacent parts showed no evidences of inflammatory changes or lymph.

The bloodvessels behind the seat of the ligature were enlarged and very full of blood, and in the new tissue, over and at the point of operation, were seen fine red lines resembling newly formed capillaries.

The ligatures on both sides were thoroughly covered by either the old or the newly formed tissues. The catgut was entirely concealed, except on the left side, where the heavier strands had been employed; here the ends of heavy, blackened strands could be seen and felt protruding from the crease or furrow behind the tip of the pedicle, formed by the circle of the knot. These projecting ends of catgut were, however, completely covered, although visible through the layer of semi-transparent lymph, and thus they presented a smooth surface to the surrounding peritoneal membrane in contact with them.

The process by which the ligatures were covered, as seen by the naked eye, and in the sections under the microscope, was as follows: The compression of the pedicle, at the moment of tying the ligatures, caused a deep sinking-in of the tissues at this line, and on cutting away the ovary and its attachments, the parts on both sides of the ligatures well up over its strands, nearly covering it, but not completely. The opposed surfaces of the peritoneum, thus brought in contact over the ligature, adhered, and their union was cemented by a thin layer of lymph. By this process, the parts *beyond* the point of ligation were placed, probably very rapidly, in organic or vital relations with the parts *behind* the ligature.

The free extremity of the pedicle and all portions beyond the pedicle, though deprived immediately of blood circulating in the normal channels, received a measure of nutrient material, sufficient to maintain its vitality. This material could find its way into the tip of the pedicle through connective-tissue interspaces in the part compressed by the ligature. This compression was sufficient to prevent the passage of blood in the vessels, and thus control the hemorrhage, but was not firm enough to stop the penetration of the nutrient fluid derived from the blood. The nutrition was maintained, and rapidly increased by the route of the peritoneal surface newly adherent over and around the ligature.

The almost immediate effect of the partial strangulation on the tip of the pedicle is that the tissues of this portion become infiltrated with small cell-elements, derived partly from the cells of the part, partly from an immigration of white blood-cells. This portion, hence, becomes filled with material capable of covering the free extremity with a granulation tissue or a plastic lymph. If this material is well nourished, its capacity for rapid organization is very great, and the newly capped raw extremity may heal almost immediately. In this rabbit, however, the free extremity coated with lymph came in contact with the adjacent peritoneum, and adhered to it; between these two surfaces the microscopic sections show that union has taken place.

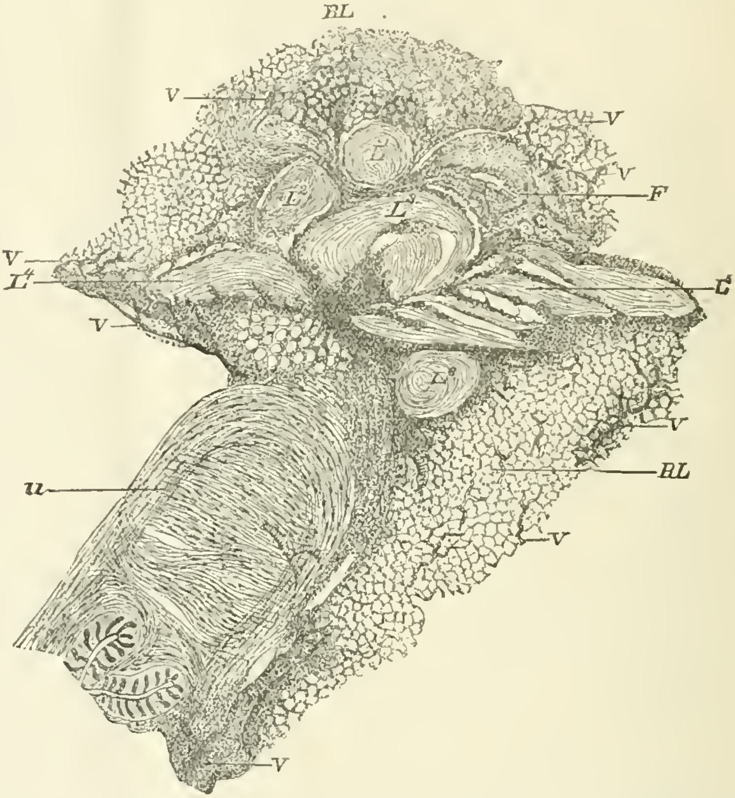
The ligature at the end of two weeks is well preserved, the knot well tied, and the whole firmly enclosed by a covering of organized or organizing materials. In portions there is presented the appearance of a vascular protrusion between the strand of the ligature. And if this foreign body is ever removed, the object is probably effected after the vessels have been well developed around and through its strands.

Rabbit No. 2.—Right ovarian pedicle tied with silk; left ovarian pedicle tied with linen ligature.

Operation, May 1st. Autopsy, May 29th, four weeks after operation.

The animal was treated in the same manner. The autopsy showed no form of disease, except several hydatid cysts attached to the omentum just below the transverse colon. The microscope showed the presence of living echinococci.

The uterus in this animal was probably nulliparous, and its tissue, as well as that of the surrounding parts, was less voluminous. No adhesions were found in the abdominal cavity around the seat of the operations.



U. Uterus. V. Vessels. F. Fallopian tube or uterine cornu. $L^{1, 2, 3, 4, 5, 6}$. Ligature. B L. Broad ligament.

The broad ligament arises from the uterus, and passes up between L^4, ^{5}, and ^{6}, and under L^3. The parts of it to the left (in contact with the uterus) are loaded with cells and inflammatory material. To the right is seen its fatty structure, somewhat inflamed, and containing small vessels, V. It has been caught also by L^6, adheres to L^4 and ^{5} by lymph, cells, etc. The upper portion of the broad ligament has been caught between L^1, ^{2}, and ^{3}. Its cut extremity has fallen over to the left, over L^1, ^{2}, and ^{4}, to which it is adherent by inflammatory material, just to the left of L^4. The upper and lower portions of the ligament here come into contact and adhere. At this point, the vessels V probably anastomose. The stump of the Fallopian tube, or uterine cornu, F has been caught between L^1 and L^3. Its cut portion has fallen down and to the right: the lower portion rests upon, and is adherent to L^5.

Some peritoneal adhesions of the intestines existed which were very possibly due to the introduction of the hypodermic needle in the administration of the solution of curare at the time the abdomen was opened. The points of the two pedicles presented about similar conditions.

The healing process had taken place without the intervention of adhesions to the surface of the broad ligament. The end of the pedicle was covered by a layer of organized material, and was much less in bulk than the same parts in the former animal. The ligature of silk with which the right ovarian pedicle was tied, remained in position.

STIGMATA OF MAIZE AS A DEMULCENT, ANÆSTHETIC DIURETIC.

By E. STUVER, B.Sc., M.D.,
RAWLINS, W. T.

For the last three or four years stigmata of maize has been used, especially by French physicians and surgeons, in irritated and catarrhal conditions of the bladder and kidneys, with most gratifying results.

Prof. Castan, at Montpelier, first called attention to the remedy and spoke highly of its beneficial effects in gravel and nephritic colic; in the latter disease its administration produced a marked amelioration of the painful symptoms, from which he inferred that the stigmata acted less as a diuretic than as a local anæsthetic. Prof. Denucé, of Bordeaux, obtained most favorable results in vesical catarrh, the remedy appearing to possess an elective action on the mucous membrane of the bladder. These statements are corroborated by a number of other eminent practitioners; of whom, Dr. Landrieux, from a considerable number of observations, has arrived at the following conclusions:

1. The various preparations of the stigmata of maize are of use in modifying the secretions of the urinary tracts. They may also be considered to possess a distinctly diuretic action. 2. Diuresis is rapidly produced, and the increase of urine is very marked after three or four days. 3. The diuretic effects are observed not only in diseases of the organs concerned in the urinary secretion, but also in the affections of the vascular system (diseases of the heart, bloodvessels, etc.). 4. The pulse is regular, the arterial tension is increased, while the venous pressure is diminished. 5. The remedy produces no disturbance of the nervous or digestive system. The tolerance of the drug is complete and absolute, while in chronic cases its administration may be continued for three to six months without inconvenience.

In *L'Union Médicale*, April 6, 1880, Dr. Dassum summarizes a number of reported cases of chronic cystitis, dysuria, and retention of urine of many years' duration, requiring catheterization, in which, after all the ordinary means, including washing out the bladder, had been tried and failed, stigmata of maize was used, and produced prompt and permanent relief.

In corroboration of the above-mentioned results, and in view of the fact that the merits of corn silk are not widely known, or, if known, are not fully appreciated by the profession, I submit brief reports of the following cases, taken from quite a large number treated during the last two years.

Case I.—February 9, 1883, was called to see Mrs. M.; married last autumn, and menstruated the last time on November 15, when she had some irritation of the bladder, with frequent micturition. This subsided in a short time, however, without treatment. About two weeks ago, she began to have pain in the lumbar region, pelvis, bowels, and bladder; micturition very frequent and painful, so much so, indeed, that her rest was broken at night, and she became very nervous and depressed. Pain is more severe when up and around than when remaining quiet. Gave fluid extract of stigmata of maize, one teaspoonful three times daily. Relief was experienced after the first dose, and in a couple of days the trouble had disappeared, and has not returned.

Case II.—April 13, 1883, was asked to prescribe for Mrs. B.; pregnant about seven months; first child. For some time she has been troubled with very frequent and painful micturition and pain in the bladder, which caused her a great deal of suffering. Gave fluid extract of stigmata of maize, teaspoonful three times daily, which soon relieved the frequency of and pain attending micturition, and enabled her to sleep well at night, which previously she was unable to do. The remedy had to be continued regularly until her delivery (June 6, 1883), however, as the painful symptoms invariably returned if a few doses were omitted. It never had any unpleasant effect, and promptly relieved the painful symptoms. After the birth of the child, the symptoms subsided without any medication.

Case III.—June 30, 1883, Mrs. L., strong, healthy, woman; married last January; menstruation has always been quite irregular; has not menstruated for seven weeks; never had any bladder trouble before the present attack. About ten days ago noticed some pain in the bladder, with frequent micturition, but only small quantities of urine were voided, and this on three or four occasions contained blood. The symptoms increased in intensity, and the frequent attempts to empty the bladder were attended and followed by a severe burning pain, which rendered her very miserable. Gave fluid extract of stigmata of maize, forty-five minims, every two to four hours. On July 2d, she called and stated that the bladder trouble had almost entirely disappeared, and she was feeling first rate.

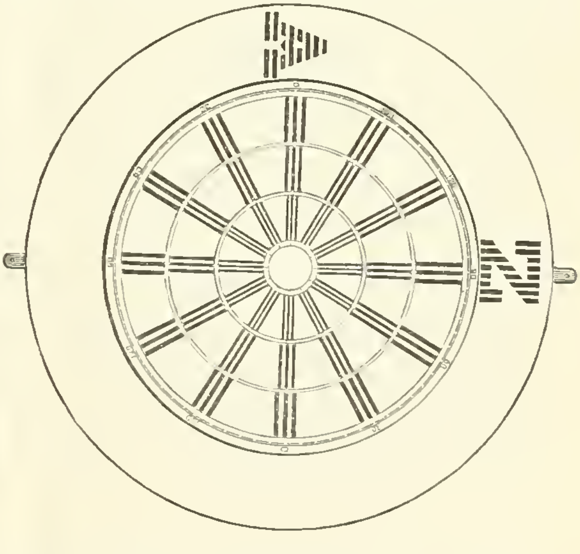
Case IV.—June 14, 1883, P. N., æt. twenty-five years, painter, consulted me with regard to bladder trouble, and gave the following history: Yesterday was engaged all day in painting the inside of an engine-boiler, and, as a consequence, was exposed to the fumes of lead and turpentine without adequate ventilation. In the evening felt badly, but retired as usual, and, being exhausted, slept very soundly until about two o'clock (A. M.), when he was awakened by a severe pain in the bladder, and an imperative desire to urinate; the act, however, was followed by a very small quantity of bloody urine. After this, micturition occurred every few minutes, was very painful, and only a few drops of bloody urine voided at each act. Saw him at seven o'clock A.M., and found him very restless, nervous, and suffering severely. Temperature somewhat elevated, and pulse slightly accelerated.

Gave fluid extract of stigmata of maize, teaspoonful every two or three hours. On the evening of July 1st he reported that he had suffered all day yesterday, but in the evening the pain subsided, and he got a good night's rest; after this the recovery was rapid and uninterrupted.

DESCRIPTION OF A REVOLVING ASTIGMATIC DISK.

By CHARLES A. OLIVER, M.D.,
ONE OF THE OPHTHALMIC AND AURAL SURGEONS TO ST. MARY'S HOSPITAL, PHILADELPHIA.

THIS instrument consists of three distinct parts: A flat brass rod, thirteen millimetres wide and fifty centimetres long, perforated at each end by a small hole. The rod is immovably fastened at its centre to a circular disk thirty-three centimetres in diameter, bearing on its face three concentric series of short test-lines, similar to those of Becker, each being representatives of a certain distance, width, and angle. Upon the periphery of this card are numbers representing five degree differences of angle, commencing at 0° on the left-hand side of the horizontal meridian, running on the under half up to 180° at the right-hand side of the same meridian. This is repeated in the opposite direction upon the upper semicircle, thus making the angles correspond, similar to the ordinary test-glass frame. Between the front card and the re-



taining rod there is a rotating disk forty-seven centimetres in diameter, having two of Pray's letters placed at a quarter angle to each other (ninety degrees apart), each having a small arrow so fixed as to meet the number of degrees on the outer card, showing the exact angle reached.

The primary principles in this instrument are in no way new, and for them no originality is claimed, as this as well as all other forms and contrivances are mere modifications of Thomas Young's original optometer. The placing of two lines of equal width and blackness at right angles to each other, which, to be seen with equal distinctness, must be set at different distances in reference to each other, if there be any asymmetry in the dioptric system of the eye.

The disk is to be fastened to a wall by the retaining rod, in a good light coming over the head of the observer placed at six metres' distance, and at a height so arranged as to bring the centre of the card on a level with the patient's eye.

If we find him able to see the 6 D. type with the eye under examination, he is to have his attention confined to the lines of the inner circle. If the sight of the eye be defective, he is to look at the outer circles. By now making him closely watch, we ask him to designate the clearest, sharpest, and blackest radius; after this has been chosen, we wheel the striped letter Z to the angle named, or to a point between, and ask which letter is the darker and clearer. He will then answer that the Z appears the plainer; now wheel the A into the place occupied by Z, and if it becomes the darker and the clearer, he will have verified his assertion, and the angles of astigmatism be obtained.[1]

Its employment in the estimation of ametropia, whilst the eye is under the influence of a mydriatic, is also of much value. I have several times, without the use of any test-types whatever, made experimental determination, and found that the results were identical with those obtained during the use of the letters. Yet it is no more than fair to state, that it was done with subjects of more than average intelligence, as really, although forming a most delicate test, it is harder to appreciate and keep in mind the slight observable changes of difference in the distinctness of the lines.

As an adjuvant in the verification of a corrected case of ametropia, it is of incalculable advantage. I always endeavor, after the selection of the correcting lenses, to have the two letters appear equally black and distinct in their entire revolution of the primary card, and that every spoke in the inner wheel (or those of the concentric widths, if I cannot bring vision up to normal) shall be of the same clearness, by these means getting the amount and angle of astigmatism almost to a dead certainty.

These disks can be obtained from Mr. John L. Borsch, optician, No. 221 South Ninth Street, Philadelphia.

1507 LOCUST STREET, PHILADELPHIA.

REPORT OF A CASE OF DISLOCATION OF THE FEMUR UPON THE PUBES.

BY WESLEY C. STICK, M.D.,
OF GLENVILLE, YORK CO., PA.

IF Prof. Henry J. Bigelow has never met with pubic dislocation in the living subject, and Mr. Timothy Holmes with but one case, it seems to me such cases are sufficiently rare to make reports of them both interesting and profitable.

Mr. J. J., a strong, muscular man, aged twenty-three years, was working in a drift in an iron-ore mine picking ore, with his body bent forwards and standing on loose, muddy ground. While in this position earth and ore caved upon him, covering him up to his neck. After he was released he was able to stand only on his right leg, his left leg being exceedingly painful. He was removed on a spring wagon to his boarding place, a distance of nearly two miles, where I saw him two hours after the accident, lying in bed and suffering with intense pain in his left hip.

His left hip was considerably swollen, and painful to touch, and the corresponding limb was slightly flexed, abducted, rotated outwards, and advanced. The trochanter was sunk inwards, and a line drawn parallel to the femur would have pointed towards the umbilicus. I could not feel the head of the femur rotate, on account of the intense pain caused by touching the groin. I could flex the leg, rotate it outwards, and adduct it, but could not rotate inwards, nor adduct the limb.

I made an attempt to reduce, without an anæsthetic. The leg was brought to a right angle with the thigh, and the thigh flexed to more than a right angle with the body, the whole limb being still in the position of abduction and outward rotation. An attempt was now made at traction and rotation inwards, but the pain was so great that I was forced to desist.

I placed the patient on the floor, under ether. I could now feel the head of the femur rotate on the pubes. Standing between the patient's limbs I first took hold of the dislocated limb, which was very large and powerful; by placing the palm of my left hand under the knee and grasping the foot with my right hand, the limb was still further rotated outwards. Second, the limb was abducted, without any force, to nearly a right angle with the body, when a soft snap was produced, audible over the room, no doubt caused by the head of the femur slipping down from the pubes. Third, the leg was flexed to a right angle with the thigh, and the thigh flexed to a little more than a right angle with the body. Fourth, just as I began to adduct the thigh and rotate inwards, a soft snap took place and the limb fell upon the table, parallel with its fellow. I could now move the limb into any position with the same ease that I could the sound limb. The entire procedure did not consume one minute. A pillow was placed between the knees, the legs loosely tied together, and the patient removed to bed.

---

[1] If the patient's sight is so bad that he cannot make out any of the lines at six metres' distance, he must gradually approach the test, and watch for the first angle brought out. We note the distance and angle, and place the letter Z at the chosen meridian. He is then to walk nearer and nearer until the letter A and the lines at its meridian become as distinct as the letter Z and its lines. We accurately register this new distance, and calculate the difference.

In about one week the patient could walk across the room and move his limb into any desirable position, but the effect of the contusion of the soft parts had not entirely disappeared. The patient left for his home in New Jersey, and I have not heard from him since.

MEDICAL PROGRESS.

THE ACTION OF IRON AND ARSENIC IN ANÆMIA.—In a recent paper on "Some Points in the Pathology of Anæmia and on the Action of Iron and Arsenic," DR. FREDERICK WILLCOCKS, after giving minute details of seven observed cases in which systematic examination of the blood-corpuscles was made, concludes with some very instructive remarks on the subject.

Large and Small Doses of Iron in Chlorosis.—A careful consideration of the facts suggests the inference that large doses of iron usually act in chlorosis by simultaneously increasing both the number and relative color of the corpuscles, the latter being always in excess; while small, or possibly less easily absorbed doses act chiefly by increasing the number, the relative hæmoglobin value remaining constant, or even undergoing diminution at first. If the number of the corpuscles has fallen but slightly below normal, the hæmoglobin increase may alone be noted. The ultimate effect, however, of *all* iron treatment in chlorosis is to increase the hæmoglobin value out of all proportion to the numerical, and this increase continues long after the corpuscles have regained their average numerical standard. These points fully bear out the well-known clinical fact of the great value of administering large doses of iron in all cases of chlorosis from the outset.

Mode of Action of Iron.—In chlorosis the majority of the red corpuscles are young and undeveloped, and never attain their full hæmoglobin value. There is no reason to suppose that there is any impairment of corpuscle formation in this affection, since in many cases their number is but slightly reduced, and even in cases in which the number is much diminished, probably the excessive vulnerability of the young new forms accounts for the diminution.

In the severest forms of anæmia—the so-called pernicious or essential—in which the normal power of globule regeneration appears to be at a standstill, or almost entirely abolished, iron has no influence in increasing the number of the corpuscles. For, since the natural addition of young forms is almost entirely suspended, iron cannot, on our present hypothesis, indirectly increase their number by improving their vitality and hæmoglobin value. Iron not only does no good, but is actually harmful by acting as an irritant to the stomach, and thus promoting and keeping up the incessant vomiting. The concentration of the coloring matter in a very few large corpuscles, which appears to be the most prominent feature in the severest forms of anæmia, is probably due to a natural process of compensation, by which the respiratory function can still be carried on, even though the corpuscles are reduced ten or twelve times below their normal number.

In chlorosis, however, the supply of young, feebly colored corpuscles is abundant, and the number of red disks per cubic millimetre may fall in many cases but slightly below normal. The average hæmoglobin richness per corpuscle is greatly reduced, and the curative effect of iron is very rapid. A low average hæmoglobin value per corpuscle is not, however, peculiar to chlorosis, but is present in the large majority of anæmic cases from all causes. It is in these cases that iron is indicated.

Arsenic was given in two cases of chlorosis, but it had no influence either in preventing relapse on the cessation of iron, or in improving the number or value of the red corpuscles. On the other hand, in the most intense forms of anæmia, with great diminution in the number of the corpuscles and a high relative hæmoglobin value, iron is practically useless, or even harmful, while arsenic may produce a considerable rise in the number of the corpuscles, as well as great improvement in the general symptoms.—*Practitioner*, August, 1883.

PREMATURE GENERAL PARALYSIS.—In an article on this subject, *à propos* of a remarkable case observed in a young man, nineteen years of age, DR. E. RÉGIS draws the following conclusions:

1. General paralysis is an essentially *climacteric* disease, that is to say, narrowly confined to the middle period of life, during which it habitually manifests itself.
2. The real, immediate cause of this affection appears to be a deviation of the normal anatomical process, which extends, at this time, into the minute cerebral structure; most frequently the general paralysis is attributable to no other material cause.
3. Besides this general paralysis which becomes developed in its own time, and which is the true general paralysis, there are other cases which occur unexpectedly, some before, others after the ordinary period, which may be said to range between the ages of twenty-five and sixty-five years. The first may be designated as *premature general paralysis*, the second as cases of *late general paralysis*.
4. Cases of premature general paralysis, or paralysis before the age of twenty-five years, are very rare, and only a few cases are recorded. Paralysis coming on before the age of twenty is still more rare, only one case being reported (beside the one recorded by Régis).
5. General premature paralysis, contrary to true general paralysis, has habitually a powerful etiological factor, such as heredity, syphilis, traumatism, saturnism, or general or local diathesis. These causes appear to determine in these cases an early predisposition, and to prematurely place the brain in those conditions in which it is found in mature life.
6. Premature general paralysis has, habitually, a slower progress and a longer duration; it is more frequently subject to remissions; and is susceptible of a more or less permanent cure, thus according with the possible curability of general paralyses developed under the influence of a material or specific cause.—*L'Encéphale*, No. 4, 1883.

TOXIC PROPERTIES OF HUMAN SALIVA.—From numerous experiments on animals, GAGLIO and DI MATTEI conclude that fresh human saliva has no toxic action in itself, but that it may and does acquire toxic properties when mixed with decomposing material, or kept long in the mouth.—*Lo Sperimentale*, August, 1883.

INOSURIA IN DIABETES.—M. LABOULBÈNE, from a number of observed cases, is inclined to believe that inosuria occurring in the course of diabetes mellitus is a favorable sign, and believes that it may be regarded as a symptom of recovery.—*Revue de Thérap.*, September 1, 1883.

TOTAL EXTIRPATION OF THE UTERUS THROUGH THE VAGINA.—DR. LUIGI GUALA performed this operation on September 6th on a woman, æt. about forty-six years, on account of carcinoma. On the fourth day the patient was doing well.

Case of Neuro-fibromatosis.—Dr. J. W. Barrett exhibited a patient to the Medical Society of Victoria on June 6th. The patient is a sailor, who has noticed tumors growing for the last two years in almost every part of his body. None of them is larger than a walnut, and they are painless except when injured. Of late he has had several epileptiform fits.

The tumors can now be felt on almost every nerve of his body that can be examined with the finger, and vary in size from that of a walnut to that of a pin's head. They number thousands, and cannot be counted accurately.

The nerves obviously affected are the median, ulnar, musculo-spiral, radial, posterior interosseous, internal cutaneous, intercostals, posterior spinals, spinal accessory, lumbar, saphenous, femoral cutaneous, external and internal popliteal, and musculo-cutaneous nerves, together with a few of the branches of the superficial cervical plexus.—*Australian Med. Journal*, June 15, 1883.

The Third Corpuscle of the Blood.—Dr. Richard Norris, in his concluding paper on the development and coagulation of the blood, gives the following as the reasons why the invisible, colorless disk must be regarded as a constant and normal constituent of the living blood: 1. It is present in the absence of every condition which has been speculatively put forward as capable of producing it, such as solution of hæmoglobin, pressure or compression, violence, contact of two glass surfaces, removal of serum, post-mortem change, mere shedding of blood, etc. 2. It is present in its usual numbers when the blood has been diluted (as for blood-counting) with a five per cent. solution of sulphate of soda, a liquid universally held to be the best known preservative of the blood. 3. It is present as usual when that special preservative of the red disks—viz., osmic acid—is used in proportions and strength the same and also greatly exceeding those held to be necessary. 4. It holds no relation to increase or diminution of hæmoglobin in the liquor sanguinis, and is present in its usual numbers when the surrounding liquid can be shown by the spectroscopic and photogenic tests to contain a mere fraction of the amount of hæmoglobin necessary to account for its presence on the hypothesis that it is a decolorized disk. 5. It is present, and is seen in a few seconds, when a method is employed which appears absolutely to prevent any exosmosis of hæmoglobin, even though the specimen be kept for eighteen or twenty hours (colloid method). 6. It is present when the blood is diluted with a solution made by adding five grains of sulphate of soda to 100 grains of a two per cent. solution of osmic acid, thus combining the preservative powers of the two substances in their recognized strengths. 7. It is present when the blood is diluted with a solution made by dissolving hæmoglobin in water to saturation, and then adding an amount of sulphate of soda sufficient to make it into a five per cent. solution. It is scarcely conceivable that the corpuscles could yield up their hæmoglobin in such a diluent. 8. The colorless disks possess the chemical and physical characteristics of lymph-corpuscles, and have scarcely anything in common with the stromata of red disks. 9. They are present in the contents of the blood-glands, and in the lymph-fluids, before these are poured into the blood, and therefore necessarily in the blood itself. 10. Their analogue in the ovipara can be detected by means of its nucleus in the living circulating blood.—*Lancet*, August 25, 1883.

Nephrectomy.—The second nephrectomy in Naples, and the sixth in Italy, was performed by Dr. D'Antona on June 10th for hydronephrosis. The field of operation was first washed over with a five per cent. solution of carbolic acid. The abdomen was then opened in the middle line by an incision 4.8 inches long. When the peritoneum was opened, the descending colon was found fixed, a little to the left, by two folds of the mesocolon, which covered the tumor in front and behind. The tumor was then exposed, and a trocar plunged in, a large quantity of thin, serous pus, mixed with a turbid, urinous liquid, flowing out. The tumor was found to consist of four sacs containing this liquid. The sacs were separated from their connections with the surrounding tissues, the ureter and renal vessels ligated, and the kidney removed. A large drainage-tube was inserted through an incision about one inch long in the lumbar region. The abdominal wound was then closed by eight deep and four superficial sutures. The operation lasted one hour. The temperature did not rise above 100.4° (on the first day). The discharge from the drainage-tube was never great, and consisted principally of a bloody fluid. Some sutures were removed on the seventh day, and the remainder on the ninth. The patient was discharged on July 1st, well. Microscopic examination of the fluid showed pus and mucous corpuscles almost entirely in a state of fatty degeneration; a few blood globules; groups of cholesterine crystals; no renal cylinders, and uric and oxalic acid crystals.—*Gaz. degli Ospitali*, September 5, 1883.

Jequirity.—Dr. A. A. Foucher, from a study of fifty-one cases in which jequirity was used, concludes that: 1. Jequirity inflammation has different degrees of intensity according to the state of the patient and the manner of using the drug. 2. The type of inflammation appears to be measured by three factors: abundant secretion of a liquid resembling muddy water; a grayish glazing of the conjunctiva, and palpebral œdema. 3. Jequirity inflammation has more of a croupous than a purulent character. 4. It tends to spontaneous cure when the applications are discontinued. 5. In the majority of cases it passes off in from fifteen to thirty days. 6. Corneal or other complications are only to be feared in the bad cases in which the drug is left in substance in the eye, or when the infusions are very concentrated and too frequently employed. 7. It does not appear to have any evident influence on the progress of corneal ulcers or abscesses. 8. Fresh solutions are preferable to old. 9. Cold infusions appear to be most active. 10. Powdered jequirity placed on the palpebral conjunctiva has a prompt and efficient action, provided it is not left in the eye after the lids are washed. 11. Jequirity cures true granulations, pannus, and papillary hypertrophy following chronic inflammations. 12. It is more efficacious in the non-inflammatory and chronic, than in the acute stages of these diseases. 13. The curative effect may be appreciable after a few days, but usually does not appear for a month or two. 14. It rapidly cures old and inveterate cases of trachoma and pannus. 15. It is easily used, and exempt from danger in prudent hands; and is rarely painful. 16. In some cases it is necessary to make several successive attempts to use it. 17. Cicatrices of the conjunctiva are very hard to deal with under its use. 18. It is not necessary to place the patient in a dark room during the treatment. 19. An eye which has already been subjected to jequirity ophthalmia, may be again attacked and more severely than the first time. 20. Inflammation should be produced at once; else the drug may be inefficient. 21. The acute stages of corneal and conjunctival inflammation may be benefited by its use. 22. The powder contained in macerations heated to boiling, lose their effect when subjected to a second maceration at a low degree of temperature. 23. Salicylic acid grs. ij to f℥j of water, does not appear to decrease the effect of jequirity. 24. The preparation most preferable, seems to be very fine powder applied to the conjunctiva, and then immediately removed; and cold macerations of grs. vij to f℥iv of water.—*L'Union Méd. du Canada*, No. 9, 1883.

Coca as an Antidote to Opium.—Dr. Pahuer recommends coca for persons habituated to the use of opium, citing a series of cases in which it gave decidedly good results. It is an excitant of the nervous system, and antagonizes the terrible depression which follows opium-eating. In some cases the habit was discontinued after a week's use of the coca; in others it was gradually abandoned.—*L'Indipendente*, July 5, 1883.

Value of determining the Primary Lesion in Joint Disease as an Indication for Treatment.—In a paper read at the late meeting of the British Medical Association, Mr. George Arthur Wright, in regard to treatment, asks the questions: Is erasion more or less dangerous than excision? Does it give as good or better results? And to what cases is it applicable? By erasion he means freely laying open a joint, exposing the whole articular surface to view, and dissecting out all diseased structures with the greatest care and thoroughness.

In answer to these questions, he says that in proper cases, erasion is less dangerous than excision, because it does not open up bone-tissue. It has two great advantages in its results: first, a movable joint may be obtained; and, secondly, there is no shortening, except such as may subsequently arise from less perfect nutrition of the limb, and this his cases show not to occur.

Lastly, it is applicable to the following cases: To the knee it may be applied in all cases of well-developed chronic synovitis (pulpy disease), which do not improve under treatment, and in which the disease has not gone on to suppuration or deep excoriation of bone. To the tarsus and carpus it may be applied in a few cases of localized disease; but neither there nor in the ankle is the prospect of success good. To the elbow, it could not be, he thinks, applicable, if a movable joint be expected, unless it is done very early and in special cases, but he has not tried it. To the hip it is never applicable, and probably never to the shoulder. It is never applicable where there is extensive bone disease; where there is suppuration, unless very limited, or a great amount of caseation; nor where there is advancing tuberculosis. To be successful, it must be very complete.

Thus, of the eleven cases of erasion of the knee, in two extensive suppuration had taken place, and in two tuberculosis existed. All of these failed. At the time when he began to erase, he had not much basis to go upon in deciding what cases were suitable, and he was obliged, therefore, to ascertain for himself. He does not think a case which has been erased is much the worse for it, should it come to excision afterwards; but he would urge strongly that the erasion must be most complete and thorough, not a mere scooping out, but such removal as will, if possible, leave simply a healthy incised wound, as it were, to heal rapidly, and allow early passive movement. Hence it is only possible, when the joint is actually opened, to decide whether it is a case for erasion, or whether excision is required. It is chiefly the difficulty of removing all the morbid tissue completely that renders the operation unsuccessful in the ankle, and probably in the elbow.

His conclusions, therefore, are these: In the case of the hip, excise very early. In the knee, if seen early, and general treatment with splints, and so on, does not speedily cause improvement, erase; if too late for that, excise. In the ankle, erasion and excision are alike unsatisfactory, and, if non-operative treatment fail, he advises amputation. Pirogoff's operation, if possible, gives the best results; though, for the tarsus, gouging, in many cases, is successful. In the elbow, failing treatment otherwise, he does not yet know about erasion, but he thinks excision is generally necessary to obtain a movable joint.—*British Medical Journal*, Sept. 1, 1883.

The Cholera Microbe.—Dr. Stephan Kartulis, physician to the Greek Hospital in Alexandria, reports the discovery of a microbe in the water of the canals and river. A drop of this water showed, under the microscope, a mass of micro-organisms which he had not been able to find in former researches (this examination was made on July 18th, after cholera had broken out in Alexandria). The water contained two or three kinds of algæ and desmidæ which moved vigorously in the water. Beside these, he found two or three kinds of monads, with vigorous motion, such as euglena, hæmatococcus, and monas guttata. The protoplasm of all these, including the algæ, was colored with chlorophyll. There were also infusions of different kinds. But the greater part of this water contained a great quantity of amœba, the colloid substance of which was filled with vibrios or zoöglæ which moved briskly. There was also seen a species of torula, one-fourth to one-half as large as a red blood-corpuscle.

But the smallest of these organisms could not be distinguished without coloring; they were, therefore, colored by Koch's method, partly with fuchsin and partly with gentian-violet, and swarms of sphæro- or oval cocco-bacteria were found colored an intense red; there were also found separate rods of the size probably of one-fourth the periphery of a red blood-corpuscle. Amongst these swarms of micro-organisms were many rows of bacteria with ramifications. Each of these bacteria had the length of the diameter of a red corpuscle, and was colored an intense red by fuchsin. Beside the bacteria, there were a few examples of a bacillus two or three times larger than a red corpuscle, and twice as thick as a tubercle-bacillus, of a slightly curved and wavy shape, and colored a beautiful red by fuchsin. These then were the organisms found in the Nile water.

The blood and stools of seven patients were examined. Swarms of micrococci and spores or bacteria were found in the first two cases, some of which were isolated. A species of torula was also found in a few cases. When colored, these bacteria appeared as very small rods. Examination of the blood of the remaining five showed many cocci, colored red by fuchsin and violet by gentian, while the red corpuscles were pale. The greater part of these cocci were round, while some were of a slightly elliptical form, and were about $\frac{1}{20}$ to $\frac{1}{15}$, some $\frac{1}{10}$, the diameter of a red corpuscle. Between these were seen single spores. In one case there were seen, in the field, five or six round bodies $\frac{1}{20}$ or $\frac{1}{15}$ as large as a red corpuscle, with movement to the right and left. Noteworthy also was the abnormal fibrine formation under the microscope, which took a form resembling that of a urine cylinder. In a third case, seven hours before death, examination of the blood showed micrococci with similar movements to those above described. In a colored preparation hundreds of micrococci were seen, many in masses, others in groups of four to six, others again dispersed singly.

There was no doubt of the nature of the disease in these cases as shown by the clinical symptoms and *post-mortem* examination.—*Berlin. klin. Wochensch.*, September 3, 1883.

Antagonistic Action of Atropine and Pilocarpine.—M. Morat has recently studied the mechanism of the antagonism of atropine and pilocarpine on the movements of the heart. It is already known that atropine accelerates the heart-beats and that pilocarpine retards them, and also that atropine renders inexcitable the moderating elements of the pneumogastric. M. Morat has established the fact that pilocarpine paralyzes and renders inexcitable the excito-motor elements of the cervico-thoracic sympathetic.

It seems rational, then, to conclude that atropine and pilocarpine are specific poisons, the one as regards the vagus, the other acting on the sympathetic (cardiac filaments), and that this specific action makes the two substances antagonistic. This was shown by the following experiment: The cardiac accelerator nerves were excited in an atropinized animal; the frequency of the beats was not increased. It may be argued that this frequency being already at a maximum, a new irritation causes no increase. But the parallel experiment of irritating the vagus of a pilocarpinized animal shows that the number of beats is not diminished. In other words, atropine and pilocarpine act simultaneously on the two orders of cardiac nerves, and in the same manner, in diminishing their excitability. The difference of their action shows that these two orders of nerves are unequally paralyzed, sometimes in the interest of one, sometimes of the other. The two nerves are acted upon in inverse order, and unequally, by equal doses. The antagonism resides, then, not in the substances themselves, but in the nervous elements upon which they act.—*Revue de Thérap.*, September 1st, 1883.

Gummata of the Penis.—M. Ozenne, in an article on this subject in which the details of nine cases are given, concludes that gummous syphilides may develop at the expense of different parts of the organ, and occupy four situations: the mucous membrane of the glans and the prepuce, the sheath of the penis, the urethral canal, and the corpora cavernosa. When arising from the mucous membrane, they are ordinarily situated at the level of the corona in the glando-preputial groove. Whatever may be their origin, these gummata present, when situated on the penis, the same evolution as when arising in other portions of the body; when recent, a solid tumor, when old, ulceration exists. At the beginning there is found a small nodule, very hard, forming a slight projection, rounded or hemispherical, sometimes flattened and circumscribed. Completely indolent, this callus of the penis, as it is sometimes called, presents no inflammatory character. In some cases it does not commence by a nodule; it extends widely over the surface, infiltrating the tissues to a variable depth, and then constitutes an induration in the skin (*en nappe*). It has been known to invade the entire organ and form a sort of cuirass.

When no attention is paid to the affection, the second or ulcerative period appears. The ulceration is limited and generally not deep, but sometimes burrows to such an extent as to merit the name of gummatous cavern. The edges are perpendicular, its floor uneven and contains a suppurating spot, a very adherent eschar. It is surrounded by a red and indurated zone, contrasting with the softness of the sound parts. Under specific treatment, complete cure often results; but in certain cases, it is only obtained at the price of a cicatricial deformity. A gumma situated at the meatus may produce urethral atresia; and when situated at the frenum may cause perforations and urethral fistulæ.

Subcutaneous gummata of the sheath are not particularly noteworthy; sometimes they leave an adherent cicatrix which may incovenience coitus and incurvate the penis at the time of erection. Urethral gummata are not frequent; sometimes they invade the canal by the extension of ulceration developed primarily in the neighboring tissue; and again, but more rarely, they arise primarily in the urethra. The second form is revealed by a yellow purulent discharge, of blenorrhagic appearance, and an induration of the canal, forming a sort of pipe with hard and thickened walls. According to Veale, a certain number of strictures have this origin and are not amenable to ordinary mechanical treatment.

Gummata of the corpora cavernosa are but little known, and their histological characteristics ignored. Circumscribed, disseminated in various numbers in the two corpora, or, more often, in one only, they develop—as all tertiary lesions—in an indolent manner, and are situated toward the posterior third, on the dorsal surface or lateral parts of the organ. By their situation and numbers, they cause functional troubles more marked than when they attack other parts of the penis; at the time of erection, which is partial and asymmetric, they give it a more or less irregular form, and produce various incurvations.

As to their treatment, though local medication has caused them to disappear, it is always preferable to use general specific treatment. Cure may be complete, or cicatrices, causing more or less deformity, may persist indefinitely.—*Revue de Chirurgie*, No. 7, 1883.

The Heredity of Insanity.—Dr. E. Marandon de Montyel, of Dijon, in a paper on this subject, in which forty families are reported and followed up for several generations, draws the following conclusions:

1. Families with the hereditary taint of insanity are distinguished by (*a*) sterility of far more than ordinary frequency; (*b*) exaggerated fecundity in case of fertile unions; and (*c*) excessive mortality of early infancy, twenty-six per cent. instead of twenty per cent.

2. The concurrence of these three peculiarities in one family authorizes, to a great extent, the diagnosis of hereditary insanity.

3. The influence of hereditary insanity on the fecundity of married persons and the mortality of the children varies in the same family in different generations.

4. The primary influence of hereditary insanity is to increase the fecundity: this decreases more and more in succeeding generations.

5. By the excessive infant mortality and increasing sterility, these families tend to become extinct.

6. The foregoing conclusions are confirmed by the fact that, if the marriages of early generations produce a considerable number of children, succeeding marriages produce children more and more feeble, which will ultimately end in sterility.

7. It is probable that the mortality of early infancy increases with generations, and that their vitality diminishes with their number.

8. Paternal and maternal hereditary insanity, considered in themselves, confirm the general laws laid down above.

9. Paternal hereditary insanity is more powerful than maternal in influencing fecundity and sterility of married persons, as well as in the influence upon the mortality of early infancy.

10. The preponderating influence of the mother on the development of insanity in the descendants, demonstrated by Baillarger, is only diminished by the preponderating influence of the father on the mortality of early infancy, and does not exist in a larger proportion than ten per cent.

11. From this it may be concluded that paternal hereditary insanity is especially influential in the early years of life, and that of the mother later.—*L'Encéphale*, No. 4, 1883.

THE MEDICAL NEWS.
A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

Communications are invited from all parts of the world. Original articles contributed exclusively to The Medical News will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

Subscription Price, including Postage,
Per Annum, in Advance, ... $5.00.
Single Copies, ... 10 cents.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

Address, HENRY C. LEA'S SON & CO.,
Nos. 706 & 708 Sansom Street,
Philadelphia, Pa.

SATURDAY, OCTOBER 6, 1883.

EPILEPTIFORM CONVULSIONS OF CORTICAL ORIGIN.

The first experimental studies of the functions having their seat in the cerebral cortex appeared to have no practical application. After a time, Dr. Hughlings-Jackson came to the conclusion, from pathological evidence, that the cerebral cortex was concerned in certain voluntary movements, and that some epileptiform attacks were induced by irritation of these "motor areas" or "centres."

At the outset, we must define "epileptiform," although by so doing we may embarrass our learned readers with merely elementary observations. Not to embrace other topics, it will suffice to say that convulsions of the type epileptic may be a substantive disorder—true or essential epilepsy—or they may be a merely symptomatic condition—epileptiform. In the latter case, the convulsions merely signify the existence of some "coarse lesion"—a tumor, for example. G. Fritsch and E. Hitzig ("Ueber die elektrische Erregbarkeit des Grosshirns," Reichert u. DuBois-Reymond's *Archiv*, 1870) demonstrated the electric excitability of the cortex, before denied, and proved the existence of motor centres, irritation of which by the electric current induced movements in the associated muscular groups. Simultaneously, Ferrier engaged in the same course of investigation, with the view to test the accuracy of Dr. Hughlings-Jackson's opinion. It is a most interesting fact that the experimental research confirmed the theory based on pathological observation. Ferrier demonstrated that localized epileptiform convulsions occurred in muscles in connection with the motor centre excited, and that the general convulsions began in these muscles, and thence extended to the whole body. It proved to be a question of the degree of the local irritation: slight excitation caused localized muscular spasms; strong irritation, general convulsions. We owe to Luciani the demonstration of the important fact that the epileptiform seizures produced by cortical irritation are transmitted by heredity. Brown-Séquard has since demonstrated similar facts in the case of epileptic seizures in Guinea pigs, induced by nerve injuries.

Not all animals are affected in this way by cortical irritation. Localized epileptiform attacks are readily enough induced in the dog and cat. Dogs even vary in their impressionability, and Albertoni thinks some are wholly unexcitable. François-Franck and A. Pitres ("Recherches Expérimentales et Critiques sur les Convulsions Epileptiformes D'Origine Cortiçale," *Archives de Physiologie Normale et Pathologique*) hold that the same degree and kind of stimulation applied to the brain of different dogs do not always develop the same degree of reaction, but none are entirely wanting in the power of response to irritation of the cortex. Young, fully-grown, and vivacious dogs of good stock are better subjects for the production of epileptiform attacks than are common, old, low-bred, and stupid animals. Cats are good subjects for these experiments.

The kind of irritation employed to incite convulsions is electrical—galvanic or faradic; but mechanical or chemical excitation may produce the same effect, although much less promptly and certainly. Thus, given a wound of the cerebrum of a dog, the epileptiform seizures are not likely to occur at once, but at a variable period after cicatrization of the wound, and then without any appreciable immediate excitation.

At what point must the irritation of the cerebral cortex be applied to develop partial epileptiform attacks? It is perfectly well known that when the cerebral convolutions are irritated in certain animals, convulsions follow; but is there a limited epileptogenic zone, as there is a well-defined motor zone? It seems to be definitely established now that, in the dog, at least, excitation of any part of the motor area may produce epileptiform attacks. MM. François-Franck and A. Pitres believe that convulsions may be caused by electric irritation of almost any point on the exterior surface of the brain, and have, indeed, developed them by very intense and prolonged faradic stimulation of the sphenoidal and occipital convolutions, which are placed considerably without the extreme limits of the motor zone. They explain this result by the *diffusion* of the current, and hold that it is only excitation of the motor zone which really produces epileptiform seizures. Here a very weak current and consequently feeble irritation will cause a prompt explosion of an epileptiform character; but in other situations, only currents sufficiently intense to insure diffusion through the cerebral mass will produce this effect.

When the cortex of the epileptogenic zone is removed, it is found that excitation of the subcortical white substance produces simple movements of the muscles on the opposite side in anatomical connection therewith, but never convulsions. That the experimental observations on which this statement is based may not be vitiated, it is necessary to remove or destroy every part of the cortex. It is the failure to appreciate this essential condition that caused the fallacy in the negative observations of MM. Bubnoff and Heidenhain ("Ueber Erregungs- und Hemmungs-Vorgange innerhalb der motorischen Hirncentrum," *Pflüger's Archiv*, Band xxvi.). These physiologists caused convulsions by irritating the white matter of the *centrum ovale*, because, as asserted by Franck and Pitres, they had not entirely removed the associated cortex.

Galvanic or faradic stimulation of the highest intensity, acting on the corpus striatum, and optic thalamus causes neither muscular movements nor convulsions. When, however, even weak excitation is applied to the internal capsule, muscular contractions of a tetanic character occur, chiefly on the opposite side of the body, and somewhat on the same side, but they cease promptly on the removal of the irritation, and do not have the convulsive character.

Various conditions affect the excitability of the cerebral cortex, and are, therefore, concerned in the production of epileptiform seizures from irritation of the epileptogenic zone. The excitability of the brain may be increased or lessened by the influences to be considered presently. First, as to the conditions under which the excitability is lessened: the brain of a new-born animal is unexcitable, and continues so for from fifteen to twenty days after birth. The anæsthetics—ether and chloroform by inhalation, and chloral by intravenous injection—when carried to the point of complete insensibility, abolish absolutely the excitability of the brain. Bromide of potassium possesses the same property if its administration is carried to a sufficient extent. Albertoni has, indeed, made use of this method, as our readers are informed, for demonstrating the nature of the therapeutical property possessed by the bromides. Secondly, the excitability of the brain may be increased. Of all the causes acting thus, the most powerful is congestion of the cortex, especially inflammatory afflux of blood. Indeed, it appears from some experiments of MM. François-Franck and A. Pitres that simple congestion, such as may be caused by section of the cervical sympathetic, does not affect the excitability of the cortex, but a slight degree of inflammatory congestion renders it, in a high degree, responsive to irritation. Certain medicines have the power to increase the excitability of the brain, notably strychnine, atropine, and, probably, picrotoxine, cinchonidine, and some others. The result of the action of these influences is to promote the readiness of response of the cortex to various forms of irritation. We have thus an immediate and striking illustration of the value of these researches in promoting our knowledge of morbid states, and of the effect of remedies on them.

THE TREATMENT OF VESICAL CATARRH.

No one who has had much experience in the treatment of catarrh of the bladder can have failed to realize the difficulties in the way of its cure, and the extreme annoyance on finding, at the daily visit, that the patient is still unrelieved.

Heretofore, our armamenta have consisted in the use of the numerous infusions, of which those of uva ursi, triticum repens, buchu, and pareira brava are typical examples, and of which none appear to be of any value except as diluents; of the numerous alkaline mineral waters, which are sometimes useful for the same reason, and sometimes harmful because they render the urine more alkaline when it should be acid; of balsam of copaiba, which is more frequently beneficial, but which not more than one stomach out of ten can bear beyond a few doses; of sandal-wood oil, which is nearly, but perhaps not quite, as efficient as copaiba, but is much better borne by the stomach; and finally, of the exclusive skim-milk diet, which we have known to answer when all else has failed, although by no means always successful. Then there are the topical applications, of which warm water carefully injected into the bladder is about as useful as any, although injections of weak solutions of nitrate of silver and of bichloride of mercury, of the mineral acids, and of carbolic acid are recommended. All of these measures have been used in every sort of case, without any constancy of result, although any one of them may, at times, have been found useful.

Among these resources, we should not omit to mention drainage of the bladder through the forcible dilatation of the urethra in females, and through a perineal opening in males, which have been of service in not a few cases.

This being the unsatisfactory state of our therapeutics of this troublesome malady, any suggestion which promises to be efficient will, of course, be gladly received. Two measures, of comparatively recent suggestion, seem to demand further trial. These are the internal and topical use of chlorate of potassium, and the internal exhibition of salicylate of sodium.

The administration by the mouth of the former remedy was recommended by Edlefsen several years ago (*Deut. Archiv f. klin. Med.*, Bd. xix., Dec. 1876), and its use in three per cent. solution as an injection into the bladder, more recently (*Deut. med. Woch.*, Jan. 1882) by Boegehold. Still more recently this same surgeon (*Ibid.*, Aug. 29, 1883) has brought forward salicylate of sodium as a specific in certain forms of acute and subacute vesical catarrhs. Salicylic acid was suggested by Fürbringer as long ago as 1875 (*Berl. klin. Woch.*, No. 19), for a catarrhal state of the urinary tracts attended with ammoniacal urine, and by Maas, in König's *Text-book of Surgery*, on account of its antiseptic and antifermentative properties. Boegehold tried it at that time with inefficient results, which he now ascribes partly to insufficient doses, and partly to the fact that it was not used in cases to which it was adapted.

In no disease is it more important that treatment should be based upon a correct appreciation of the cause than vesical catarrh. At least three distinct forms may be recognized, 1st, that due to cold; 2d, that resulting from extension of a gonorrhœal inflammation; and 3d, that caused by decomposing urine due to obstruction, and the introduction of decomposition bacteria whether through unclean catheters or otherwise. The latter can only be relieved by measures which will cleanse and disinfect the bladder as well as remove the obstruction. Such are solutions of salicylic acid, carbolic acid, and corrosive sublimate, together with the cure of stricture and of enlarged prostate by catheterization and parenchymatous injection with iodine.

On the other hand, in catarrh of the bladder from cold or by extension of a gonorrhœa, which affect usually only superficial layers of the organ, the two remedies referred to, the chlorate of potassium and salicylate of sodium may be used with every expectation of success. Of the former a five per cent. solution may be ordered, and a tablespoonful given every two hours, as originally suggested by Edlefsen. To this may be added, if necessary, but not until after the acute stage is passed, injections into the bladder of a three per cent. solution of the same remedy.

Of salicylate of sodium, half a gramme, or seven and a half grains, may be given in solution or in a wafer every two hours, for from three to four days, when the acute symptoms will generally be found to have abated; after which the same dose may be continued for eight days longer. Should the extraordinary advantages claimed by Boegehold for this remedy be sustained by experience, we shall have a powerful adjunct to our means of treating cystitis. Because he says of it that, for certainty, promptness, and convenience, it is equalled by no other.

DIGITAL DIVULSION OF THE ORIFICES OF THE STOMACH.

On the 9th of July, 1883, Prof. Loreta, of Bologna, divided the cardiac orifice of a girl of twenty years of age who had suffered from stenosis for four years, and who, although of average height, was reduced by slow starvation to a weight of seventy-five pounds. Various therapeutic measures had been tried in vain upon the case, and it was decided to forcibly open the stenosed orifice, in the hope that a result such as had been attained in operations on the pylorus might be obtained. The operative process was different in this case from that of the original, performed by Prof. Loreta in a case of pyloric stenosis, as the location and direction of the abdominal and gastric wounds were quite different. The operation was followed by no unfavorable symptoms, in the form of fever, peritoneal inflammation, or vomiting. The abdominal wound healed by the first intention, and in seven days the woman was in a fair way to recover.

The fifth digital divulsion of the pylorus, and the fourth done by Prof. Loreta, was performed on July 15, 1883, the subject being also a woman, the disease of the stomach having existed for three years. She had vomiting attacks daily, and was very much reduced by the gradual starvation. The operation occupied but twenty minutes, there being no adhesions, and no difficulties other than those naturally belonging to the method. As in the other case, there were no febrile or inflammatory sequelæ. On the eighth day, when the dressing was removed, the abdominal wound was found united by the first intention. In ten days the immediate cure was secured, there having been no vomiting or other disturbance of the stomach since the section was made.

Time alone can test the result of the four cures effected by this method of forcible dilatation, and determine whether, and to what extent there exists a danger of a return of the stenotic condition. Thus far we have heard nothing unfavorable of the cases operated upon, and it is possible that they may be permanently benefited. Forcible dilatations in other parts of the human body are so liable to be followed by contraction that we shall hold the operation of Loreta in doubt until we have positive evidence that its cures are permanent. The demand for the operation in Italy shows that malnutrition must prevail to a large extent, and that ulcerative states of the stomach ending in stenosis are not at all uncommon. Such a condition is very rare in the United States, as we have a generally well-fed peasantry, with no pellagra or malacosteon. Possibly there may be a demand for this operation even here, but the cases must be of very infrequent occurrence.

CONTAGIOUS DISEASES OF ANIMALS.

The action of the German Government as to American pork and the frequent discussions in the French Chamber and the English Parliament of questions relating to American meat, both alive and dead, make it incumbent upon this Government, in the interests of trade, not only to guard against contagious diseases of animals, but to have some system of inspection for meats and for live stock sent abroad. While there is much that is sensational in the reports as to epidemics of contagious pleuro-pneumonia, its occurrence is too frequent.

A few cases of it have recently occurred in Salem, Connecticut, but not, as was reported, derived from New Jersey. Long Island and Staten Island are not rid of the disease. In New Jersey there are at present no known cases. Several herds were affected in the vicinity of Newark early in February last. Inoculation was commenced in accord with the modifications and improvements of methods advised by Wilhelms, Rutherford, Williams, and Fleming. In these cases, the inflammation confines itself to muscles and connective tissue, and does not attack the lung. But the most interesting asserted fact is that the inoculated animal will not communicate the disease. It is a comparative study of great interest to the epidemiologist. These inoculations have been under the charge of the New Jersey State Board of Health.

Some valuable inquiries into this and other kinds of communicable diseases of animals are being conducted by the Agricultural Department at Washington under the care of Dr. Salmon.

COLLECTIVE INVESTIGATION OF DISEASE.

Apropos of the editorial in our issue of Sept. 22d, on "The Collective Investigation of Diseases," we would state that at its last annual meeting held at Norristown, in May of this year, the Medical Society of the State of Pennsylvania passed a resolution providing for a committee of three members on each of the following branches: Medicine, Surgery, Diseases of Women and Children, Ophthalmology and Otology, Nervous Diseases, Insanity and Idiocy. It is the duty of the committee to prepare a series of questions calculated to obtain the history, symptoms, and treatment of the different forms of disease. When these questions are prepared, they are to be sent to the members, with the request that they fill out, in full, one case of the disease specified in the list of questions, and return the same to the chairman of the committee on that branch; so that by this means a collective investigation of the different forms of disease may be made, and a more thorough account obtained of all the facts bearing on the disease in its different stages. When these answers have been received, the different committees shall arrange the facts thus procured for presentation to the Society.

The resolution was offered by Dr. Curwen, and, we presume, it was suggested by the invitation of the Committee of the British Medical Association. Since, however, the State Society of Pennsylvania appears to be the only one which has taken any action, and as there will be no opportunity for others to take similar action for nearly a year, we reiterate our suggestion that the chairman of the American Medical Association Committee select at once from the members of the Association a number of physicians in each State, who can make a beginning; using, at first, the sets of questions prepared by the English Committee. In the case of Pennsylvania, the existing committees might be reappointed and enlarged, if necessary.

THE PRESENT STATUS OF THE CODE CONTROVERSY.

The Code controversy in New York has now reached the stage in which argument has ceased, and the strength of the respective parties is being carefully computed prior to the appeal to the ballot in the New York County Society—the birthplace and stronghold of the New Code—on the 29th proximo, and in the State Society next February.

A poll of the 1661 physicians whose names are in the New York City Medical Register shows that 764 adhere to the National Code, 404 are advocates of the New Code, and 54 of no code. The remainder are uncommitted. In the New York County Society, we are reliably informed, the advocates of the National Code are largely in the majority.

The canvass of the State, which is still in progress, shows that there are 2405 physicians who adhere to the National Code, 924 to the New Code, and that there are 215 who advocate having no code.

These figures are extremely gratifying. They show that the profession of the State has been completely misrepresented in the State Society at its last two meetings, and they unerringly point to the speedy revocation of the New Code.

The City of Newark has recently constructed an open sewer over the Newark meadows, for a large ward of the city. It has a very imperfect fall, but by an open canal alongside, which catches the incoming tide, it seeks a flush which shall carry out the sewage to the bay. We shall see whether salt water will not precipitate a part of the sewerage, and, after a time, the open sewer fill and become a nuisance.

SPECIAL ARTICLE.

DOES VIVISECTION PAY?

Two chief objections are urged against vivisection—its cruelty and its uselessness.

That American experimentalists (and we only have to do with them) avoid all possible pain by the use of anæsthetics is positive truth; and it is done equally in the interest of science, to avoid pain as a disturbing factor in their problem, and on the score of humanity. But, to say the least, the charge of cruelty comes with ill grace from those who cage ill-fated birds for the pleasure of their song; who cause the sacrifice of thousands of birds and fur-bearing animals for mere ornament in dress; who "boil alive" lobsters and terrapin for the pleasure of the palate; who "torture" fish by the hook, and look with equanimity upon their painful gasps and convulsive struggles to escape from suffocation; who maim birds and inoffensive beasts in the pleasure of sport; who, without anæsthetics, torture and mutilate cattle, horses, sheep, swine, and poultry to make them a little less annoying while alive, or a little more tender when dead; who ruthlessly wound and kill wolves, wildcats, and snakes to promote the safety of man, and who poison, or otherwise "torture," by dog or cat or trap, with more than the persistence of science, rats, mice, and all sorts of vermin, solely to promote man's comfort, and yet object to a comparatively few scientific experiments for the promotion of his comfort, and beyond that to prevent his sickness, to cure his maladies, to prolong or even to save his life.

Vivisectors do *not* delight in cruelty. Their sole aim is the increase of knowledge, and of knowledge that will be useful to man and animals. That students do all sorts of cruel experiments merely for amusement, or to obtain dexterity in operating, is neither probable nor true. It is not probable, for vivisection requires a deal of time and large outlay for instruments and animals, and students have neither a surplus of time nor of money; and, as a matter of *fact*, students rarely ever perform any vivisections at all. The atrocious misrepresentations by the anti-vivisectionists (not to use a shorter and more vigorous word) are simply amazing in women and men otherwise honest and truthful.

But the second is the more important point; for if it can be shown that vivisection gives us knowledge which could not be otherwise obtained, and which is of immense good to man and beast, and, on the whole, lessens suffering and saves life, it must be granted by any one whose reason is not warped by sentiment that it should be promoted instead of being abolished.

That Harvey discovered the circulation of the blood and Sir Charles Bell the functions of the two nerve-roots by vivisection has been denied by the anti-vivisectionists; but any one who will read their works, and see their experiments on living animals *described in detail*, and then deny the fact that they did such experiments, must be adjudged incapable either of understanding facts correctly, or of reporting them truthfully. And upon the two facts they demonstrated hang well-nigh "all the law and the prophets."

Again, the medical uses of electricity, the modern methods of artificial respiration in resuscitating the nearly drowned, the present operation of transfusion, and our knowledge of the sounds of the heart, and therefore of valvular diseases, have all been developed by older experiments on animals and recent researches founded upon them.

But it is more the modern progress by research that we wish to draw attention to. John Hunter's famous experiment of tying the artery which fed the antlers of the stag, the growth of which he was studying, led to his operation for aneurism—an operation that saves hundreds of human lives every year. But its brilliant results have been quite equalled and its beneficence increased by modern researches upon the action of the ligature, and upon various materials for ligature. Animal ligatures, which are non-septic, and which are cut off short and absorbed, are as great an advance in the treatment of hemorrhage and of aneurism as was Hunter's operation. At the opening of this century, ninety per cent. of the cases of aneurism died, and ten per cent. were cured. At present, ninety per cent are cured, and ten per cent. die.

Along with this vast improvement have come others, which are no less striking and beneficent. Physick and McClellan and Mott and Mütter would stand amazed at a modern operation, "painless, bloodless, feverless, and almost [and in many cases entirely] without suppuration," as compared with those forty years ago. The last two gains are due directly to vivisection. Founded partly on previous acquisitions, but chiefly on his own vivisections Lister showed us how to operate in such a way as to obtain union by first intention without fever or suppuration, and has consequently enabled us to do operations, which twenty years ago were Utopian, both in their desirability and their impossibility. And this means *human life saved and human happiness increased*. While anæsthetics and Esmarch's bandage are not wholly due to vivisection, their use is largely the direct result of knowledge so derived. Indeed, vivisection will before long, we suspect, reveal to us the ideal anæsthetic that will enable us to abolish pain, retain the consciousness, and therefore the coöperation, of the patient, and this too with safety. Even now, Bert is showing us by vivisection how to give anæsthetics with less danger than heretofore.

Our exact knowledge of Nature's methods of repair in fractures, and of the *rôle* of the periosteum in diseases of bone, is directly due to experiments on animals, and our practice has improved amazingly as a result—a direct gain to every patient with a broken or a diseased bone.

In medicine as well as surgery only a few of the advances due to vivisection can be named. The classical experiments of Virchow, by which he showed the effects of small solid fragments—emboli—broken off from blood-clots, or from diseased valves of the heart, have thrown more light on these processes of disease than the post-mortems of a century. The experiments of Bernard on the origin of diabetes have changed midnight darkness to morning dawn, and some time the noon will come and with it the cure of the disease. The same may be said of the researches of Klebs and Tommasi-Crudeli on malaria, of Wood and Formad on diphtheria, and many others like them.

Nearly all our modern knowledge of the processes even of inflammation, are due to vivisections by Cohnheim, Stricker, Norris, Klebs, and their co-workers. Intelligent and accurate acquaintance with the processes of disease is the first step in the correction of errors of past treatment and in establishing a wiser course in the future.

In the cruel experiments by disease on man, which the anti-vivisectionists insist shall be the only ones we shall use, wide-spread agony and frightful slaughter of human beings by thousands replace the far less painful sacrifice of a few of the lower animals. Thiersch experimented on 56 mice by inoculating them with cholera discharges. Of the 56, 44 sickened, and 14 died with choleraic disorders. So much for the vivisectionist. Two water companies in London experimented on 500,000 human beings by inoculating them with cholera discharges by impure water during two epidemics. By one epidemic alone, and by one company alone, 3476 human beings were killed, of whom over 2000 would have escaped had the lesson of Thiersch's 14 mice been heeded. So much for the antivivisectionists. Which was the most cruel? Which the most useful? Yet, while Thiersch, were he a Pennsylvanian, might, with impunity, poison his 14 mice with arsenic to abate a nuisance, it is soberly and seriously proposed that he should be prohibited from poisoning them by cholera discharges, in order to abate, and if possible abolish, a dreadful pestilence!

Nor is this the only pestilence to be abated. Cholera has slain its thousands, but consumption its tens of thousands. Familiarity deadens our horror of ordinary diseases, but it does not change the mortality returns. A more intelligent hygiene, thanks to Villemin and other vivisectionists, now saves many a life; and though with doubts, as if we can scarce believe it to be true, we do seem to be possibly on the eve of the discovery of the causes of consumption and many of the zymotic diseases. Nay, more; the time may not be far off when we shall be able to eradicate or neutralize their poisons. The whole study of the effects of microscopic organisms is but in its infancy. Their effects can only be studied by means of experiments upon animals. To prevent them means to postpone life-saving discoveries for many years. Twenty thousand persons die annually of snake-bite in India alone. If, by preventing experiments with snake-poisons on animals, we postpone the discovery of an antidote for five years, at a cost of untold suffering, and of one hundred thousand human lives, instead of one-hundredth that number of dogs, have we done wisely? Nay, have we not acted cruelly?

The whole natural history of the trichina in pork, its danger to man, and the modes of making it harmless even if eaten, is due to vivisection. Yet all such beneficent progress the Anti-vivisection Society will *stop*. They mildly propose at present only to "regulate;" they mean—we know what we allege—they mean to *suppress all vivisection*.

Thanks to vivisection, we are beginning to understand the localization of function and of disease in the brain and spinal cord, and this has given us an accuracy of diagnosis and of treatment heretofore impossible.

As to the use of various remedies, almost the whole of our accurate scientific knowledge of their actions are due to vivisection. We may experiment with them, it is true, on man, but we suspect that the president of the Anti-vivisection Society himself would probably dismiss his doctor if he did. Asking for his cur or cat, the doctor would, of course, be denied. What then must the doctor do? Give his remedies with the best light he has. And pray what is this but an unsatisfactory experiment, as unwise as it is unscientific? Besides new drugs, such as carbolic acid, physostigma, chloral, pilocarpine, pepsin, pancreatin, nitrite of amyl, and others added to our stores by experiment, there is scarcely a drug of importance that has not been investigated experimentally, its actions demonstrated both in moderate and in dangerous doses, its alkaloid, if any, made useful, and its proper applications to disease determined with a scientific accuracy (which means again the saving of human life and the lessening of human suffering) utterly unknown thirty years ago. Such experiments *cannot* be made on man.

In disease the experiment is so complex that we cannot say with precision what the effects of the remedy are. In healthy animals we can. And we can vary the conditions under which the drug is used so exactly as to eliminate possible errors. We can also give doses dangerous to life; discover the reasons for the dangers and so learn to avoid or to neutralize them in man. The rational treatment of disease to-day owes more than one-half to vivisection.

The argument that drugs do not act alike on man and animals has been used by many. But while it is true in a few exceptional cases, any one familiar with the facts would smile at the ignorance or prejudice of any who to-day seriously advance such an argument. If evolution has given animals "equal rights" with man, as Mr. Tait maintains, among them is the right to be poisoned by the same drugs and cured by the same remedies as his master.

In not a few medico-legal cases, as has been well shown by Gamgee, the physiological tests—*i. e.*, experiment on the lower animals—are among our most accurate methods of detecting criminals; yet all this, it is proposed, shall be given up and the poisoner go free.

And finally the lower animals themselves are benefited by vivisection to a degree unappreciated, save by a few. A general must sometimes utterly sacrifice one corps of his army to win a battle. The few lives lost there save the whole army. Pasteur has slain not a few animals in his researches on splenic fever and chicken cholera. What now are the results? Last year it is stated that 80,000 sheep were "vaccinated" in one department (Eure et Loire), and only 0.65 per cent. died of splenic fever as against an average for the last ten years of 9.01 per cent. or nearly sixteen times as many; of 2308 vaccinated sheep 8 died, or one in 288, while of 1659 not vaccinated 83 died, or one in 20. If the anti-vivisectionists have their way, the dumb brutes may well pray to be delivered from their friends.

Moreover, another question arises. There are not in all the United States over a dozen of professed vivisectionists who for any large part of the year give up their time to this work. Nor are there in this State over a dozen who work at it even irregularly. Is it worth while to organize a great society, hold public meetings, flood every city with documents, and spend money largely to suppress these few? Suppose their work *is* of doubtful value, should man or the animals have the benefit of the doubt?

REVIEWS.

Index-Catalogue of the Library of the Surgeon-General's Office, United States Army. Authors and Subjects. Vol. IV. E–Fizes. 4to. pp. 12, 1033. Washington: Government Printing Office, 1883.

The fourth volume of the *Index-Catalogue* has just been published, and includes the letters E to Fizes, covering 1033 pages, and 4802 authorities, 12,361 book-titles, and 49,977 journal articles. A cursory inspection of the volume shows that the same painstaking care and intelligent supervision in its preparation have been exercised by Surgeon Billings as in that of its predecessors.

The extent of the references may be shown by a few examples selected at random. We find 36 double-column pages given to the bibliography of the ear, 109 to the eye, 28 to the femur, 11 to empyema, 328 to fevers, 38 to fistula, etc.

The publication of this work reflects the highest credit on the intelligent liberality of our Government, and we trust that nothing will occur to interrupt its speedy progress to completion.

Observations on Lithotomy, Lithotrity, and the Early Detection of Stone in the Bladder, with a Description of a New Method of Tapping the Bladder. By Reginald Harrison, F.R.C.S., etc. 8vo. pp. 71. Illustrated. London: J. & A. Churchill, 1883.

This rather long title precedes a short book containing an agreeable and instructive account of some of the author's experiences and conclusions in regard to the general subject of stone. Those who are familiar with Mr. Harrison's writings need not be told that he has a pleasant way of putting his opinions, nor that these opinions are well worthy of attention. The book now under consideration is not likely to prove especially valuable to the student; but the surgeon can gather from it just such ideas as he would look for from another surgeon with whom he might be conversing. Everywhere one finds in it hints which are not to be looked for in text-books, but which make pleasant and profitable reading to one who has no longer need to be instructed in the rudiments of lithotomy and lithotrity.

The part of this book which refers to tapping the bladder contains an account of a case where Mr. Harrison relieved the tension of a bladder obstructed by prostatic hypertrophy, by passing a trocar and canula into the former through the perineum and prostate, and leaving the canula in as a permanent drain. The effect was not simply immediate relief, but eventually closure of the wound, recovery of the power of retention and voluntary urination, together with an almost total disappearance of the functional and physical evidences of enlarged prostate. This procedure he now recommends for general adoption. In this he fortifies himself with the endorsement of Prof. S. D. Gross, to whom his book is dedicated. American surgeons have contributed very materially to Mr. Harrison's opinions, as is evident from the frequency with which he quotes them, and the manifest respect and regard he feels for them. It would appear that it was not without its effect that he has had the opportunity to meet so many representative American surgeons in their own country. Certain it is, that in some way Mr. Harrison has acquired a manner of writing which makes the critic feel most kindly toward him, and which adds a charm to the excellent matter of his literary work.

SOCIETY PROCEEDINGS.

THE TRI-STATE MEDICAL SOCIETY.

Ninth Annual Meeting, held at Indianapolis, September 18, 19, and 20, 1883.

(Specially reported for The Medical News.)

The Tri-State Medical Society held its ninth annual meeting in English's Hall, Indianapolis, Indiana, on September 18, 19, and 20, 1883.

Tuesday, September 18th, First Day.

The meeting was called to order by Dr. J. Livingston, of Indianapolis, at eleven o'clock A.M. After prayer, Dr. Thompson introduced **Dr. Wm. Porter**, of St. Louis, Mo., **The President** of the Society, who at once assumed the Chair.

Governor Porter, of Indiana, was then introduced, and delivered an

ADDRESS OF WELCOME,

as follows:

Gentlemen: It has been said by some wise man that one man with a will outnumbers fifty without, and in that respect, at least, *this* assembly is large and animating.

The salutations of our morning papers have so cordially welcomed you that further words are hardly needed to strengthen the assurance; nevertheless, as an official representative of the State, I desire to extend to you a most cordial greeting. You have your national, your State, your county, and your neighborhood associations, but this is not one of them. This may properly be called your kinship convention. The inhabitants of Illinois, Kentucky, and Indiana are allied by blood, similar habits, and largely by identical conditions affecting health and disease.

I do not think any of the professions are more progressive than yours. An opposite opinion prevails among some who misinterpret many of your rules, honestly designed, whatever their effect may be, to separate quackery and charlatanism from true medical progress. No profession is more hospitable to new suggestions and aids—none subjects them to fairer and juster tests to prove their value.

After referring to the enlargement of the domain of medical science, and the application of the principles of preventive medicine, he said:

Why should you not be welcomed here by a State?

The progress and glory of a State depend upon the mental and physical vigor of its citizens. Health invigorates, disease enfeebles. Whoever, in a large way, can prevent disease, or remove hereditary taints, or show how great cures can be wrought, performs a high service to the State, for which it may well feel grateful. The great physician, in his own calling, may perform the service of a patriot, not less than the warrior and the statesman.

Dr. J. L. Thompson then welcomed the Association with some pleasing remarks, and presented the report of the Committee on Programmes and Arrangements, which was accepted.

The Secretary, Dr. G. W. Burton, of Indiana, then read his report, including the minutes of the last meeting, and the work done during the year, mentioning the growth of the Society and its library; alluding to the death of Dr. J. W. T. Gerrish, of Indiana, one of the early members of the Society. Letters were read from Drs. S. D. Gross, Austin Flint, and others, regretting their inability to be present at the meeting. Dr. Gross called attention to the resolution he introduced at the Cleveland meeting of the American Medical Association in reference to the training of nurses in the smaller cities.

A paper, detailing a case of

TORTICOLLIS,

by Dr. D. S. Booth, of Sparta, Illinois, was read by Dr. Byrd. The case was congenital, in a boy aged twelve, and caused an extreme deformity, but was entirely relieved by the division of several muscles by the tenotome.

Dr. Ap Morgan Vance, of Louisville, then read a paper on

THE TREATMENT OF COMPOUND FRACTURES,

noting the opposite opinions upon the subject held by different authorities, one saying treat all cases as open wounds; another, close them all; a third says, supplement the first by drainage. It is the practice of Dr. Vance to dress compound fractures as simple, using the plaster-of-Paris dressing entirely, and trusting to the thermometer to tell if the case was going through as simple or compound. He used no antiseptic, but placed absorbent cotton around the wound. Some hemorrhage always occurs under traction, which purges the wound, and it heals under the scab cotton and blood. Fever of 101½° to 102½°, that cannot be otherwise accounted for, calls for investigation, but there ought to be no haste in opening the dressing, particularly if the elevation occurs within forty-eight hours. In such cases he gives a mercurial, followed by quinine; if it occur suddenly, from the third to the sixth day, he opens the wound and gives good drainage to the pus. In hot weather the use of ice bags increases the chance of success.

Afternoon Session.

A paper was read by Dr. H. J. B. Wright, of Olney, Ill., on

NERVE-STRETCHING,

which he has found to be of value in sciatica; five out of eight cases being cured, two dying of cancer. Dr. Wright operated upon a laborer, æt. 48, who had been treated intelligently in the usual manner for a long time; the nerve was stretched, inflammation occurred, pus formed, and the case was cured.

Dr. Byrd, of Quincy, reported a case resulting in a cure.

Dr. R. Haughton, of Ind., discussed the pathology of the operation, holding that the molecular condition of the nerve trunk was interfered with.

Dr. Wright stated that though the operation was empirical, so long as it was safe and successful the profession was justified in resorting to it. It had no effect upon a case of anæsthesia of fourteen years' standing, this being the only case of failure.

A paper on the *Pathology and Treatment of Pneumonia*, by Dr. J. C. Bundy, of Ill., was then presented, and in the absence of the author, was read by Dr. Byrd.

Dr. W. S. Haymond, of Indianapolis, then read a paper on

A CASE OF FRACTURE OF THE OS FRONTIS OF EIGHTEEN YEARS' STANDING.

The two tables were united. The bone was almost ulcerated through. The decayed parts were removed and the patient was entirely relieved.

Some discussion followed this paper, which gradually turned upon the question of trephining for epilepsy, in the most of which cases it was thought to be productive of good.

Dr. J. E. Link, of Terre Haute, read a paper upon the use of

THE ROLLER BANDAGE AS A DRESSING FOR STUMPS

after amputation, and as a means of preventing erysipelas and abscess. He used layers of sheeting, wrapped about the stump, leaving it open for drainage. Of his two hundred cases of amputations, he said, not a patient had died from the operation, nor suffered from after-pains. He used no antiseptics, and no formation of pus took place. This paper, and some cases introduced to show the bandaging, excited considerable interest.

Evening Session.

The President, Dr. Wm. Porter, of St. Louis, delivered his address. One of the chief results of a regular attendance upon the sessions of any medical association, he said, is an extension of personal acquaintance.

It has been said that its success is inimical to the interests of the different State societies and the American Medical Association. This is in no sense true. The aim is to refer all complaints back to such societies. There is probably no large society in the land the members of which more uniformly respect and indorse the principles of the national association. The President congratulated the members of the Society that there had been no "ethical" wrangle among them, and that the guiding lines laid down by Percival eighty years ago are honored by the Society to-day.

The President suggested that the interests of the organization are now so important that no one of them can be neglected. It is impossible, owing to the extent of territory and rapid increase in membership, to have full knowledge of the whole work. The success of the Society depends upon individual effort. Men should be chosen in each congressional district, or in each local Society, who would use their personal influence for the advancement of the Society. The question of extension of territory must soon be considered. Originally including the three States, in a few years Cincinnati and St. Louis were added, which, with Chicago, Louisville, and other cities; gave the Association a large following. Delegates from beyond these confines are now sent, and men from other States ask to join the Society. What better structure, the President suggestively asked, could be built upon the solid foundation of the Tri-State Medical Society than the stately walls of a Western Medical Association; added territory and coming years bringing the certainty of added work at the sessions? In another year it will be necessary to extend the time to four days, or to divide into sections during some of the sessions. The latter should only be considered when it becomes unavoidable.

Dr. A. W. Brayton, of Indianapolis, reported a case of

MYELITIS DUE TO ARSENICAL POISONING,

interesting from the person having taken an ounce of arsenic, yet recovering without antidotal treatment. Paralysis followed, and mental impairment. The question was debated whether lead and arsenic cause paralysis of the extremities by affecting the spinal cord or the peripheral nerves.

Dr. H. M. Post here read a paper on *Syphititic Interstitial Keratitis*, which was well received.

Dr. R. E. Haughton, of Indiana, read a paper on

THE RELATIVE MERITS OF RESECTION AND AMPUTATION,

in which he discussed the subject at length. He argued that amputation is much the safer and better. The mortality, he said, even under the best methods of disinfection, is not likely to be less than after amputation, and as the mortality is now shown to be seven times more in amputation, when considering all varieties of resections, it must be regarded as a question of grave consideration to the surgeon, and especially to his patient, when about to be submitted to an ordeal which is so much the more dangerous than amputation is now known to be. In giving his conclusions, Dr. Haughton said that (1) no excision should be made in aged persons; (2) no excision should be made in very young persons; (3) no excision should be made if there is even a suspicion, much less evidence of the existence of phthisis or other constitutional diseases; (4) no excision should be made in acute disease or injury; (5) excision may be made in cases where the hand or foot and limb are to be saved, and which are of more than common value to the patient; hence the elbow- and knee-joints may be excised under proper considerations; (6) the shoulder- and hip joints may be excised when amputation would cause greater mutilation and a greater loss than incision, and the patient has equally good chances for recovery after excision as after amputation, which is rarely possible; (7) excisions are not to be made in cases of malignant disease of the articular ends of bones or other parts of bones; (8) excisions should not be made for acute abscess in the knee-joint, and most likely not in any case of acute abscess; (9) excisions of joints generally are seven times more fatal than amputations under the same circumstances and in the same class of cases; (10) no surgeon is justified in subjecting his patient to excision, in view of all the facts made known, unless there are good and substantial reasons for assuming the greater risks by seven times over for his patient; and the extraneous circumstances which must overbalance in favor of an excision against it is a moral and surgical responsibility that is anything but conservative.

Dr. Byrd exhibited *Hutchinson's Modification of Swift's Inhaler*, which he uses in administering the following anæsthetic, which he prefers:

Ethyle bromide, ...	1 ounce.
Chloroform, ...	2 ounces.
Alcohol, ...	4 "

Wednesday, September 19th, Second Day.

Morning Session.

Dr. N. Field, of Indiana, read a paper on the *Physiology of the Brain in Relation to Insanity*, which, after some discussion, was followed by a paper on *Insanity*, by Dr. P. S. Hayes, of Chicago, and one by Dr. C. G. Comegys, of Cincinnati, upon *Some Mental Problems in Questions of Medical Jurisprudence*. These three papers were referred to the Committee on Publication, with the request that they be published.

Dr. N. P. Goddy, of Indiana, then followed with a paper on *Heredity*, which elicited some discussion.

Dr. Chenoweth then read a paper giving the particulars of a case of *Peritonitis*, supposed to have been due to an induced abortion, which resulted in death. The uterus and its appendages were exhibited to the Society, eliciting much interest, and Dr. W. H. Wathen, of Louisville, Ky., was appointed to examine the same and report.

Afternoon Session.

Dr. Wathen, from the pathological indications furnished by the uterus exhibited by Dr. Chenoweth, decided that:

1. No pregnancy existed.
2. That no abortion had been attempted.
3. That there was one opening penetrating the uterus, and a second one going through the parenchyma only.
4. That the so-called corpus luteum was a cyst.
5. That the size of the uterus is normal.
6. That dysmenorrhœa might have induced sufficient trouble to cause death.

The business for the hour being the report of the Committee appointed to

REPORT UPON THE SUGGESTIONS CONTAINED IN THE PRESIDENT'S ADDRESS,

Dr. Porter, in the absence of any of the Vice-Presidents, called Dr. T. B. Harvey, of Indiana, to the Chair.

Dr. Byrd, of Quincy, Ill., Chairman of the Committee, recommended that the Society be known as "The Medical Society of the Mississippi Valley," which was adopted. This scope includes the territory between the Rocky and Allegheny Mountains, and from Canada to the Gulf.

A recommendation to reduce the registration fee to $2 was lost.

Dr. Rauch moved that all offices be filled by a committee consisting of one member elected by each State represented; this was seconded and carried.

It was also ordered that all local Societies be considered affiliated bodies, and entitled to representation.

A paper was then read by Dr. E. Bock, of St. Louis, on *Sponge-grafting*, which elicited much interest.

Dr. Wathen, of Louisville, read a paper on *Vesico-vaginal Fistula*.

Dr. A. B. Thrasher, of Cincinnati, read a paper on *Naso-pharyngeal Catarrh*.

Dr. H. H. Mudd, of St. Louis, gave a paper on *Stone in the Bladder*.

Dr. Louis D. Brosse, of Evansville, read a paper on *Tuberculosis*, as produced by the inhalation of sprayed sputum—illustrated by fifteen cases.

Dr. L. E. Stocing, of Ill., reported a paper on the *Relation of the Condition of the Digestive Organs to Insanity*.

Dr. H. N. Clark, of Ill., presented a paper on *Amputation—Hot-water Applications*.

Dr. W. H. Wathen, of Louisville, Ky., exhibited a new *Sutural Needle for Use in Vesico-vaginal Fistulæ*, or similar operations, that presented some unusual points of interest.

Evening Session.

Dr. Charlton, of Seymour, Indiana, read a *Memorial of J. W. T. Gerrish*, of the same place, who was one of the first members of the Society, and who always took a prominent part in its proceedings.

The Committee on Nominations then reported the following persons as

OFFICERS FOR THE ENSUING YEAR:

President.—Dr. B. M. Griffith, of Springfield, Ill.

Vice-Presidents.—Dr. J. M. Matthew, of Louisville, Ky.; Dr. C. G. Comegys, of Cincinnati, Ohio; Dr. J. E. Link, of Terre Haute, Ind.

Secretary.—Dr. G. W. Burton, of Mitchell, Ind.

Treasurer.—Dr. F. M. Beard, of Vincennes, Ind.

Chairman of Committee of Arrangements.—Dr. F. L. Matthews, of Springfield, Ill.

Place of Next Meeting, Springfield, Ill.

Dr. G. C. Smythe, of Greencastle, Ind., then read a paper on the *Antipyretic Treatment of Typhoid Fever*, giving the details of a large number of cases so treated; the treatment resulting unusually successful. Several members discussed this mode of treatment, giving an almost unqualified voice in its favor.

Dr. D. S. Reynolds then read his paper, making some remarks on *Opacities of the Cornea*, noting that he had met with considerable success in relieving that condition, except when interstitial, by the operation of tattooing.

Dr. J. M. Matthew, of Louisville, presented a paper on the use of the *Ligature in Rectal Surgery*.

Dr. G. J. Cook, of Indianapolis, gave a paper on *Diseases of the Upper Part of the Rectum*.

Thursday, September 20th, Third Day.

Morning Session.

The session was opened by the reading of papers on *Tait's Operation*, by Dr. T. B. Harvey, of Indianapolis, and Dr. W. A. Byrd, of Quincy, Ill., after which a paper on a case of *Prolapsus of the Left Ovary; Battey's Operation; Death*, was read by Dr. J. Iutzie, of Richmond, Indiana.

Dr. J. F. Hibberd, of Richmond, Ind., then presented a paper on *What is the Proper Management of a Child during the First Seventy Hours of Post-uterine Existence*, taking the ground that the dosing of infants with various substances and the strapping with tight bandages were wrong, and favoring as little interference as possible with nature. The opinions of the Society were in accord with the views of Dr. Hibberd.

Afternoon Session.

The afternoon session was held in the amusement hall of the Insane Asylum, by invitation of Dr. Fletcher, some seventy members being present.

Dr. G. V. Woolen, of Indianapolis, read a paper on the *Use of Chloroform in Parturition*, advocating the view that in many cases it was desirable to carry the patient to full anæsthesia. Considerable discussion followed this paper, many members preferring the use of ether to chloroform.

Dr. H. C. Fairbrother, of East St. Louis, Ill., read a paper upon *Phlebitis*.

Dr. W. H. Myers, of Fort Wayne, read a paper on *Tracheotomy*, holding that in cases of obstruction of the trachea, it is the duty of the surgeon to at once open it, and remove the foreign body.

The Society then visited the wards of the Asylum, and found them clean, well ordered, and containing 621 male and 477 female patients.

Evening Session.

Dr. S. J. Jones, of Chicago, read a paper on the *Influence of Errors of Refraction and Defects of Accommodation of the Eye*, showing the danger of the indiscriminate selection of improper spectacles.

The President, Dr. W. Porter, of St. Louis, then introduced the President-elect, Dr. B. M. Griffith, of Springfield, Ill., who assured the Society of a hearty welcome and ample accommodations at Springfield, in September, 1884, at which time and place the next meeting of the Society is to be held.

The Society then adjourned.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting September 19, 1883.

The President, Wm. M. Welch, M.D., in the Chair.

Dr. Wm. R. D. Blackwood reported

AN INTERESTING CASE OF FEMORAL HERNIA IN AN AGED PATIENT; STRANGULATION; OPERATION, WITH CURE.

Mr. B., aged seventy-three, was taken ill with supposed cholera morbus on August 11, 1883, but from the suppression of alvine dejections shortly after the seizure, and the rapid change of the vomited matter to a stercoraceous fluid by the time his family physician—Dr. John Ivison—saw him, the diagnosis of the family was set aside for one of more grave nature. The gastric distress was very great, the desire to vomit urgent, and the act occurred at short intervals.

The case was believed to be one of obstruction, with possible invagination of the bowel, and efforts were made toward overcoming the difficulty and obtaining an operation in a normal direction, but without success. The question of strangulation by hernia was not at first accepted, because, although there existed an evident swelling at Poupart's ligament, the size of it was so small as to be taken for an enlarged gland, the patient having had glandular enlargement previously. There was no local *pain*, no *tenderness*, no *tension*, no *dragging* sensation at the site of the swelling, no tympanites—in short, the usual local signs of strangulated hernia were absent. The little tumor was also movable to such an extent as to easily deceive one, even when closely examined. Dr. Blackwood saw the case in consultation; as the patient was rapidly sinking from exhaustion, it was decided to make an exploratory incision and determine the nature of the enlargement. After cutting down to the sac the mass was found to be an entero-epiplocele. The sac contained very little serum, and considering the fact that strangulation had doubtless existed for at least thirty-six hours, the bowel, though highly congested, was in good condition. The gut was tightly nipped at the crural ring and was nearly empty, which accounted for the small size of the tumor. The hernia was internal to the femoral vessels, but closely adherent to them. It was reduced with some difficulty and pushed far up to clear the deep thrust of the needle in closing the wound. The stitches, four in number, were deeply taken and the ring obliterated as nearly as possible. He reacted well, and in an hour and a half passed an alvine dejection without pain or difficulty. In a week the old gentleman was able to walk his room with comfort.

The diagnosis of femoral hernia is, at times, not easy, being, as here, liable to be confounded with enlarged glands, or localized varix of the saphena. There was no impulse on coughing, no effort at reduction affected it, and, excepting only the very small tumor, all the local signs of strangulated gut were absent. The advanced age of the patient was against him, and his depressed vital power was a bad factor. The result shows the value of exploratory operation under the circumstances, and Dr. Blackwood believes that the attendant is unfaithful to his patient if he does not insist upon it in every suspicious case. The wound is of little account—it does not enhance the danger which is already imminent, and it may, as here, save a valuable life.

Dr. Benjamin Lee presented a specimen of

VERMIFORM MUCOUS DISCHARGE FROM THE RECTUM,

the interest of which lies in the close resemblance it bears to a tape-worm, and it was sent to him under the impression that it was a portion of a tape-worm partly dissolved by medicine.

Dr. Chas. M. Seltzer exhibited a

SPECIMEN OF ANEURISM OF THE ASCENDING POSTERIOR PART OF THE AORTA.

The patient from whom it was obtained was aged 35, and was admitted to the Eastern Penitentiary in September, 1882. Sixteen years of his life were spent in various prisons under different sentences.

His medical history dates back sixteen months ago, when he complained of pain between the shoulders, but he continued in comparatively good health until six months ago, when he began to complain of diffuse intercostal pains in both sides and pain in the epigastrium; also poor appetite, nausea, and indigestion; anæmia and general debility. Upon careful examination, no organic disease was discovered. The heart was rather weak, but otherwise normal. Thoracic percussion was normal, except slightly increased dulness under upper part of the sternum. Pulse feeble, but otherwise normal. There was no syphilitic history, no œdema, no palpitation of the heart or præcordial pains, and no interscapular pain during the past year. No bulging of the chest-walls, either anteriorly or posteriorly. No discoverable aneurismal bruit. In fact, there was nothing to indicate any organic disease. The scae was examined by six reputable physicians, and all of them arrived at the same negative conclusion. The patient's physical condition steadily grew worse, and he was given the liberty of a large yard, excused from work, and allowed a plentiful nutritious diet, general tonics, and anodynes for the neuralgia. Under this treatment he seemed to improve, but the neuralgia and insomnia continued.

On August 28, 1883, while sitting in the yard, he suddenly grew very pale, complained of faintness, and was caught while in the act of falling to the ground. He was carried to the hospital department and given stimulants. The physician arrived in a few minutes, and found him dying.

At a post-mortem examination, a large tumor, found just above the heart, proved to be an aneurism of the posterior ascending portion of the aorta. The sac contained one and a half pints of freshly clotted blood, unorganized, and its posterior wall was formed from three dorsal vertebræ, the bodies of which were very much eroded. There was also some erosion of the corresponding ribs, and a slight bulging of the sac between them. The heart was very small, but free from disease. No other organic trouble observed.

A careful review of the case suggests the following thoughts: 1. That the disease was one of long standing, and that on account of the enforced quiet life of the subject, no inconvenience was experienced until erosion of the vertebræ was so extensive as to cause neuralgia of the adjacent nerves, and slight interscapular pain of but short duration. 2. That the case was rendered still more obscure by the facts that the opening into the sac was large, and that considerable portion of the sac-wall was made up of bone—both of which tend to destroy the possibility of there being a diagnostic aneurismal bruit. 3. That if there had been much interscapular pain, due to the erosion of the vertebræ, and it had been treated by introducing a seton or issue in its vicinity, as has been lately recommended (Thomas Hayden, Quain's *Med. Dict.*), there would have been considerable danger of puncturing that portion of the sac protruding between the ribs. 4. That there can be a very large thoracic aortic aneurism without any bulging of the chest-walls, and that it may erode much of the bodies of the vertebræ without causing spinal curvature. 5. That as there was no hemorrhage into the thoracic cavity or canal of the spinal cord, death must have been due to pressure on some of the cardiac nerves or ganglia, and consequent collapse from heart-failure.

CORRESPONDENCE.

CELSUS ON THE TREATMENT OF HYDROPHOBIA.

"*Dos est magna Parentium virtus.*"

To the Editor of The Medical News.

Sir: The virtue of our ancestors is a grand inheritance, and we must treasure their reputation. The humanity and devotion of our predecessors in our noble profession are what we have a right to feel proud of, and anything that calls them in question, even if inadvertently, may well arouse a feeling almost of resentment.

In a recent article in the *Philadelphia Medical Times*, headed "Remarks on Hydrophobia," I find the following statement made in regard to the treatment recommended by Celsus for hydrophobia: "Celsus advised throwing the victim of hydrophobia unexpectedly into a pond, where, if he could not swim, he was allowed to sink, and, if he could, he was held under until he was full of water." It would appear from this that Celsus, who is one of the glories of our profession, whom very great men have styled *admirabilis in omnibus, medicorum deus*, the Cicero of medicine, was very deficient in ethics. I wish, therefore, to offer a translation in full of the treatment he gives for hydrophobia, in defence of one so distinguished:

"The bite of a mad dog, when no remedies have been used, causes ordinarily a fear of water, called by the Greeks hydrophobia. This is one of the most frightful accidents, wherein the patient is tormented by thirst and by fear of water. When the disease has gone this far, there is little hope left. The only remedy that we can try is to throw the patient unexpectedly into a pond, to let him sink to the bottom several times if he does not know how to swim, that he may drink, and then to bring him up: if he swims, he is to be pushed under at different times, and forced to drink, whether he wishes or not; in this way, we succeed in driving away thirst and the fear of water. This method is not without danger, for if the patient has a bad constitution, the cold water may give him convulsions that will kill him. To prevent this, it is right to put the patient in a bath of warm oil as soon as he is taken from the water."

In a report on the Duval prize, for the year 1854, Broca used the following language, which is so admirable as to require no additional comment:

"There is a false erudition that consists in citing at second-hand, on the faith of others, authors never read, and in copying bibliographical references that have been transmitted from one book to another, every time with some alteration, without any one ever taking the trouble to verify them.

"In this way, a writer succeeds in furnishing a text all sprinkled with citations, and gives himself at little cost a varnish of erudition and of polyglottism that fills the reader with admiration. Many reputations have been built upon such foundations. These reputations have been or will be merely momentary, because they are badly constructed. When any one acts in this way, he becomes, without wishing it, the falsifier of science."

Nescire quid anteaquam natus sis acciderit id est semper esse pucrum, Cicero tells us very truly. The very *father of medicine*, as we now call him, twenty-two centuries ago wrote on *Ancient Medicine:* he tells us that "numerous and excellent discoveries have been made in the long course of ages, and that he who rejects and disdains the past deceives himself and deceives others." It is most praiseworthy to search into the teachings of the great physicians of past ages, and to cite their doctrines and their methods, but let it be done with a strict regard to correctness, and, it may be added, with the respect and the reverence that are owing to our honored *confrères*, or rather forefathers.

LOUIS W. ATLEE, M.D.

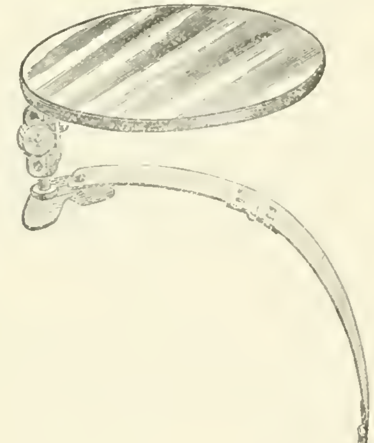
AN IMPROVED ATTACHMENT FOR THE HEAD-MIRROR.

To the Editor of THE MEDICAL NEWS.

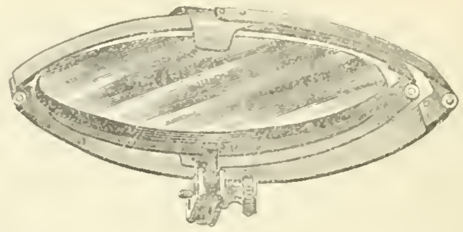
SIR: The issue of THE MEDICAL NEWS of a few weeks ago contained a description of an attachment for the head-mirror, consisting in a continuous steel band, which clasps the head, extending from forehead to occiput.

The advantages of any such contrivance over the miserable rubber bands in such general use are manifest; therefore I desire to call attention to an invention of Mr. Ivan Fox, optician, of this city, which I have been using for the past fifteen months, which far surpasses every other device for the purpose, and seems to leave nothing to be desired in the way of perfection.

Two bands of steel, three-quarters of an inch wide by three inches in length, rest horizontally, one on the forehead, and the other on the occiput, and these pieces are connected by a band of similar width passing over the vertex. To the piece on the forehead the head-mirror is attached by a double ball-and-socket joint, which is kept tight or looser by a binding-screw. This allows free play to the mirror. The vertical band is made of four separate pieces, joined by three delicate hinges on the under side. These hinges are placed at such intervals that when the mirror is not in use, the whole attachment wraps compactly around the glass affording complete protection in carrying.



By a slight turn the horizontal forehead piece is brought flat against the back of the mirror, when the first piece of the vertical band reaches to the rim of the glass, where a hinge allows the second longer piece to lap over the reflecting surface, on the opposite side of which the second hinge drops the third piece across the back, and this is hinged again to the last piece which falls on the face, and the glass is now completely protected by the horizontal occipital band lying at right angles to the others across the centre. The whole thus folded will slip into any pocket in which the mirror alone could be easily carried.



When opened for use, the ends are five inches apart; they are then *sprung* a little further out, and laid on the head. It then takes a firm grasp, and gives a solid support to the mirror.

Contrasted with a rubber-band and buckle encircling the head, the advantages may be claimed, that of *protection* of the mirror from injury when laid aside; that it is *quickly* and easily applied; that it is *neat*, never disordering the hair by any number of adjustments, and this is one of the most important points; and that having a firm basis of support, it gives perfect *precision* in reaching and keeping in view any objective point. Respectfully yours,

HOWARD A. KELLY, M.D.

323 SOUTH SEVENTEENTH STREET,
PHILADELPHIA.

NEWS ITEMS.

YELLOW FEVER IN HAVANA.—There were nine cases of death from yellow fever in Havana last week, and twelve the week before.

YELLOW FEVER AT VERA CRUZ.—There were thirteen deaths from yellow fever at Vera Cruz for the week ending September 13th.

AMERICAN ACADEMY OF MEDICINE.—The American Academy of Medicine will meet at the New York Academy of Medicine, on Tuesday, October 9 (three o'clock), and Wednesday, October 10. The Address by Dr. H. O. Marcy, of Boston, Mass., President, will be on "The Recent Advances of Sanitary Science; the Relations of Micro-organisms to Disease." The following papers have been promised for the general meetings: Dr. L. S. Pilcher, of Brooklyn, N. Y., on "The Relations of Medical Journalism to Higher Medical Education in America." Dr. Traill Green, of Easton, Pa., on "The Imperfection of Technical Studies as a Means of Mental Culture." Dr. Benjamin Lee, of Philadelphia, on "The Value of an Acquaintance with Botany as a Preliminary to the Study of Medicine." Dr. Charles McIntire, of Easton, Pa., "Is it Fair? The Study of the Comparative Political Position of the Medical Profession in the United States." Dr. A. D. Rockwell, of New York, on "The Exact Value of the Electrolytic Method." Dr. J.

Cheston Morris, of Philadelphia, "The Milk Supply in Large Cities." Dr. Charles E. Cadwalader, of Philadelphia, "Considerations upon the Public Provisions for the Care of the Indigent Insane." Dr. A. D. Rockwell, of New York, "The late Dr. George M. Beard—a Sketch." Report of the Committee on Laws of Medical Practice in the United States and Canada.

The Meeting of the American Public Health Association.—Among those who will present papers at the next meeting of this Association, to be held at Detroit, on November 13th, are Surgeon Sternberg, U. S. A., and Surgeon Woodhull, U. S. A., on *Malaria*. Surgeon Smith, U. S. A., and Dr. Solmon of the Agricultural Department, on *Texas Cattle Disease*. Rudolph Hering, C. E., and Commissioner Raymond, of Md., on *House Drainage and Sewerage*. Prof. Sargant and Prof. Watson, on *Physical Exercises for Schools*, and Prof. A. R. Leeds and Dr. Wm. R. Newton, on *Food Adulterations*.

New Medical Journal.—The first number of *The Texas Courier-Record of Medicine*, edited by Drs. F. E. Daniel and E. L. Stroud, Fort Worth, Texas, is lately received. It will be published monthly.

The Foot and Mouth Disease in Great Britain.—The latest reports state that this disease is spreading with remarkable rapidity throughout the counties of Derby, Lancashire, Suffolk, and Denbighshire.

In the twenty-five weeks ending September 8th, there were, according to the weekly returns in the *London Gazette*, 5600 fresh outbreaks reported, and 145,218 animals attacked.

The Koch Mission.—Dr. Koch arrived in Egypt on August 23d, and went immediately to the Greek Hospital to make post-mortem examinations of persons dead of cholera.

Biological Laboratories: their Organization and Value.—Prof. E. Ray Lankester, in his Address on Biology, delivered before the British Association for the Advancement of Science, on September 21st, advocated the endowment of research, especially in biology, urging that in the past it had produced discoveries of the greatest service to humanity, and that it was retarded in England by the want of means to prosecute it. In the following extract he compares England and Germany in the endowment of research, and gives an interesting sketch of the basis of organization of the German laboratories.

The knowledge of the growth of the chick from the egg and of other organisms from similarly constituted beginnings has been slowly and continuously gained by prodigious labor, extending over generation after generation of students who have occupied the laboratories and lived on the stipends provided by the governments of European States—not English, but chiefly German. It is this history of the development of the individual animal and plant from a simple homogeneous beginning to a complex heterogeneous adult which has furnished a starting-point for the wide-reaching doctrine of evolution. It is this knowledge, coupled with the knowledge of the myriad details of structure of all kinds of animals and plants which the faithful occupants of laboratories and the guardians of biological collections have in the past one hundred years laboriously searched out and recorded—it is this which enabled Darwin to propound, to test, and to firmly establish his theory of the origin of species by natural selection, and finally to bring the origin, development, and progress of man also into the area of physical science.

It may be laid down as a general proposition that scientific discovery has only been made by one of two classes of men, namely: 1. Those whose time could be devoted to it in virtue of their possessing inherited fortunes; (2) Those whose time could be devoted to it in virtue of their possessing a stipend or endowment especially assigned to them for that purpose. Those who wish to defend the present neglect of the Government, and of public institutions, to provide means for the carrying on of scientific research in this country, are accustomed to declare as a justification for this neglect that we do very well without such provision, inasmuch as the cultivation of science here flourishes in the hands of those who are in a position of pecuniary independence. The reply to this is obvious. If those few of our countrymen who, by accident, are placed in an independent position, show such ability in the prosecution of scientific research, how much more would be effected in the same direction were the machinery provided to enable those also who are not accidentally favored by fortune, to enter upon the same kind of work?

It is altogether a mistake to suppose that the existence among us of a few very eminent men is any evidence that we are contributing largely to the hard work of careful study and observation, which really forms the material upon which the conclusions of eminent discoverers are based. In every department of biological knowledge the hard work of investigation is being carried on by the well-trained army of German observers. Whether you ask the zoölogist, the botanist, the physiologist, or the anthropologist, you will get the same answer. It is to German sources that he looks for new information; it is in German workshops that discoveries, each small in itself, but gradually leading up to great conclusions, are daily being made. To a very large extent the business of those who are occupied with teaching or applying biological science, in this country, consists in making known what has been done in German laboratories. Our English students flock to Germany to learn the methods of scientific research; and to such a state of weakness is English science reduced for want of proper nurture and support, that even on some of the rare occasions when a capable investigator of biological problems has been required for the public service, it has been necessary to obtain the assistance of a foreigner, trained in the laboratories of Germany.

In the German Empire, with a population of 45,000,000, there are 21 universites. These universities are very different from anything which goes by the name in this country. Among its other arrangements devoted to the study and teaching of all branches of learning and science, each university has five institutes or establishments devoted to the prosecution of researches in biological science. These are respectively the physiological, the zoölogical, the anatomical, the pathological, and the botanical. In one of these universities of average size each of the institutes named consists of a spacious building containing many rooms fitted as workshops, provided with instruments, a museum, and, in the last instance, with an experimental garden. All this is provided and maintained by the State.

It is the business of the professor, in conjunction with his assistants and the advanced students, who are admitted to work in the laboratories free of charge, to carry on investigations, to create new knowledge in the several domains of physiology, zoölogy, anatomy, pathology, and botany. It is for this that the professor receives his stipend, and it is on his success in this field of labor that his promotion to a more important or better paid post in another university depends. In addition to, and irrespective of, this part of his duties, each professor is charged with the delivery of courses of lectures and of elementary instruction to the general students of the university, and for this he is allowed to charge a certain fee to each student, which he receives himself. The total of such fees may, in the case of a largely attended university and a popular subject, form a very important addition to the professorial income; but it is to be distinctly understood that such payment by fees is only an addition to the professor's income, quite independent of his stipend and of his regular occupation in the laboratory; it is paid from a separate source, and for a separate object.

There are thus in the German Empire more than one hundred such institutes devoted to the prosecution of biological discovery, carried on at an annual cost to the State of about £80,000, equal to about £160,000 in England, providing posts of graduated value for three hundred investigators, some of small value—sufficient to carry the young student through the earlier portion of his career, while he is being trained and acting as the assistant of more experienced men—others forming the sufficient but not too valuable prizes which are the reward of continuous and successful labor.

In addition to these university institutes, there are, in Germany, such special laboratories of research, with duly salaried staff of investigators, as the Imperial Sanitary Institute of Berlin, and the large museums of Berlin, Bremen, and other large towns, corresponding to our own British Museum of Natural History. There are, in addition to the universities in Germany, a number of other educational institutions, at least equal in number, which are known as polytechnic schools, technical colleges, and agricultural colleges. These furnish posts of emolument to a limited number of biological students, who give courses of instruction to their pupils, but they have not the same arrangements for research as the universities, and are closely similar to those colleges which have been founded of late years in the provincial towns of England, such as Bristol, Nottingham, and Leeds. The latter are sometimes quoted by sanguine persons, who are satisfied with the neglected condition of scientific training and research in this country, as really sufficient and adequate representatives of the German universities. As a matter of fact, the excellent English colleges in question do not present anything at all comparable to the arrangements of a German university, and are, in respect of the amount of money which is expended upon them, the number of their teaching staff and the efficiency of their laboratories, inferior not merely to the smallest German university, but inferior to many of the technical schools of that country.

A Polluted Mineral Spring.—*The British Medical Journal*, Aug. 18th, calls attention to a curious instance which has just been brought to light of the contamination with sewage-matter of a well that has long enjoyed a high reputation for its salutary virtues. When visiting in the south of Scotland lately, Dr. Crichton Browne, who, like all good Scotchmen, is a devoted admirer of Burns, made a pilgrimage to the Brow Well, a small village on the shores of the Solway Firth, where the great national poet, by the advice of his medical attendant, spent the last fortnight of his life in a despairing effort to repair his shattered health. Struck by the character of the water of the Brow Well, and by the accounts which he received of its beneficial effects in gastric, renal, and nervous affections, Dr. Crichton Browne determined to have it analyzed, and, for that purpose, sought the aid of Professor Dewar, at the Royal Institution. Professor Dewar's analysis shows the water to be of a unique description, and suggests that it may have valuable medicinal properties; but, at the same time, it reveals the fact that it is strongly tinctured with sewage. It seems probable that the drainage from the adjoining cottages and pigsties, and from the heavily manured lands in the neighborhood, finds its way into the well. Professor Dewar thinks that it ought to be closed, in the interests of the community, until means can be taken to insure its purification, as large numbers of invalids resort to it at this season of the year, and drink freely of the water, of which the regulation quantity is six pints *per diem*.

Health in Michigan.—Reports to the State Board of Health, for the week ending September 22, 1883, indicate that consumption, rheumatism, and inflammation of the brain have increased, that dysentery has considerably decreased, and that remittent fever, intermittent fever, erysipelas, cholera infantum, neuralgia, and pneumonia have decreased in area of prevalence.

Including reports by regular observers and others, during the week ending September 22, and since, diphtheria was reported present at twenty places, namely, Clam Lake, Coldwater, Detroit, East Saginaw, Forestville, Grand Rapids, Hastings, Ida, Lansing, Lowell, Manistee, Mt. Pleasant, Newberry, Pontiac, Reading, Sherman, Somerset, St. Joseph, South Arm, and Utica. Scarlet fever at seventeen places: Bingham, Cadillas, Charlotte, Detroit, East Saginaw, Edmore, Grand Rapids, Ithaca, Kalamazoo, Manistee, Mendon, Nashville, Northport, North Adams, Port Huron, Six Lakes, and Tyrone. Measles at four places: Charlevoix, Detroit, Ithaca, and Union City.

NOTES AND QUERIES.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM SEPTEMBER 24 TO OCTOBER 1, 1883.

Tilton, H. R., *Major and Surgeon.*—Assigned to duty as Post Surgeon at Fort Wayne, Michigan.—*Par. 4, S. O. 183, Department of the East*, September 28, 1883.

Brechemin, Louis, *Captain and Assistant Surgeon.*—Relieved from duty at Fort Columbus, N. Y, H., and assigned to duty at Fort Wadsworth, N. Y.—*Par. 5, S. O. 183, Department of the East*, September 28, 1883.

De Loffre, A. A., *Captain and Assistant Surgeon.*—Assigned to duty at Fort Niagara, N. Y.—*Par. 5, S. O. 182, Department of the East*, September 27, 1883.

Havard, Valery, *Captain and Assistant Surgeon.*—Assigned to temporary duty at post of San Antonio, Texas.—*Par. 10, S. O. 120, Department of Texas*, September 21, 1883.

Reed. Walter, *Captain and Assistant Surgeon.*—Relieved from duty at Fort Omaha, Neb., and assigned to duty as Post Surgeon, Fort Sidney, Neb.—*Par. 5, S. O. 103, Department of the Platte*, September 22, 1883.

Appel, A. H., *First Lieutenant and Assistant Surgeon.*—Assigned to temporary duty at Fort Warren, Mass.—*Par. 3, S. O. 181, Department of the East*, September 25, 1883.

Carter, W. F., *First Lieutenant and Assistant Surgeon.*—Assigned to temporary duty at Washington Barracks, D. C.—*Par. 5, S. O. 182, Department of the East*, September 27, 1883.

Richard, Charles, *First Lieutenant and Assistant Surgeon.*—Relieved from further duty at Creedmoor, New York, to return to his proper station, Fort Adams, R. I.—*Par. 1, S. O. 180, Department of the East*, September 24, 1883.

Richard, Charles, *First Lieutenant and Assistant Surgeon.*—Granted leave of absence for two months, with permission to apply for extension of two months.—*Par. 1, S. O. 49, Military Division of the Atlantic*, September 25, 1883.

Wakeman, William J., *First Lieutenant and Assistant Surgeon.*—Relieved from temporary duty at Fort Sidney, Neb., to rejoin his proper station at Fort D. A. Russell, Wyoming.—*Par. 5, S. O. 103, Department of the Platte*, September 22, 1883.

ORIGINAL LECTURES.

LOCOMOTOR ATAXIA.

A Course of Three Lectures delivered before the Cincinnati Medical Society.

By PHILIP ZENNER, A.M., M.D.,

OF CINCINNATI, OHIO.

LECTURE I.

SYMPTOMATOLOGY.

Gentlemen: The frequent occurrence of locomotor ataxia, the importance of its early recognition, and the many interesting physiological and pathological questions involved, will, I trust, be sufficient justification for speaking rather fully on the subject. Yet I do not propose to treat it exhaustively. For instance, some trophic changes, diseases of joints, affections of bones, finger-nails, etc., which have been largely dwelt upon of late years; certain symptoms on the part of the central nervous system, as hemiplegias, paraplegias of short duration, will be passed by without further notice. For, though of great interest in themselves, they do not help us to a clear idea of this disease; their pathology is obscure, and their relationship with locomotor ataxia not fully determined. But I wish rather to give a clear description of this disease, bringing into prominence practical things, especially such as are of great diagnostic value, and to dwell at some length on the physiological and pathological questions involved. It is true that in the latter we shall find far more questions entirely unanswered than facts definitely ascertained. But for purposes of scientific progress it is always important to know what are the present limits of our knowledge, what problems are yet unsolved or to be solved.

Locomotor ataxia may be briefly described as clinically represented by characteristic lightning-like pains, sense of numbness or formication in the legs, peculiar perversion of tactile sensation in the soles of the feet, so that the ground does not feel natural, anæsthesia, ocular paralysis, disturbances of the genital functions, of the bladder, rectum, and other viscera, but most prominently a loss of muscular coördination, an ataxic gait. As a pathological substratum for these symptoms, we find degenerative changes chiefly in the posterior portions of the cord.

We will begin with the symptomatology, as we shall later be able to take up with greater interest the physiological and pathological questions. In the beginning the most prominent symptoms are pains, I might say characteristic pains, most frequently in the back and legs. These pains are very sudden in their onset, so sudden that they are usually termed lightning pains, and are described as of a boring, pressing, tearing, or shooting character. They occur sometimes in limited portions of the skin, more frequently in the deeper parts, the calves of the legs, joints, bones, etc. They often persist in one part, and become very agonizing in intensity. These pains come in paroxysms, which may be of only a few seconds or minutes duration, or continue for hours or days, each paroxysm being composed of a large number of single pains of the kind already described. The free intervals are also of various duration, sometimes only a few hours or days, sometimes many months intervene before a recurrence of the paroxysms. These are also of various degrees of severity. In some they are so mild that it is difficult for the physician to elicit an account of them in taking the history, the patient looking upon them as mere rheumatic pains that require no mention. In others, the pains are so intense that they make existence a constant torture. Changes in weather, mental excitement, etc., often have a deleterious influence, bringing on or increasing the severity of the paroxysm. Though, as already mentioned, these pains most frequently occur in the back and legs, they sometimes occur, then usually at a later period, in the upper extremities, even in the face or occipital region. They are generally the first symptoms of the disease, and may occur many years before the development of ataxia. They usually persist during the whole duration of the disease, though not infrequently they become milder at a later period and even disappear altogether.

Though they are described differently by different individuals, there is that about them, their sudden onset, their paroxysmal occurrence, etc., which usually enables us to recognize them easily. Of the other anomalies of sensation, we may mention first what is termed girdle sensation, a sense of constriction or painful pressure about the waist. This is very frequently present. There is often a sense of numbness, of formication, or of coldness or heat about the legs moving from part to part. But the most noticeable of these parasthesias is a peculiar perversion of the tactile sensation of the soles, so that the ground or floor does not feel hard as usual, but one feels as though walking upon some yielding surface, velvet, or cork, or bladders of water.

One of the most common symptoms is anæsthesia, so that the touch, pinching, etc., are not so distinctly felt or are not properly localized. This, though perhaps the most common sensory manifestation does not usually appear as early as the symptoms previously mentioned. It is often only noticeable when the ataxic symptoms have also appeared. We never find complete anæsthesia, such as often is present in hysteria and in organic disease, destroying the sensory tracts. Sometimes it is so slight that the patient knows nothing of its presence, and it is only detected on the careful physical examination of the physician; again it is so marked that the patient himself calls attention to it. It is usually greater in some parts than in others, as over the soles, calves, in the trunk between the shoulders and in the sacral region, in the upper extremities on the ulnar side of the hands and arms. Some peculiarities of the anæsthesia are deserving of mention. There is often partial anæsthesia, some kinds of sensation being impaired, others not. For instance, the sense of pain is lost while the tactile sensation is unimpaired; this is called analgesia. The opposite is found, tactile sensation is impaired, and the sense of pain is retained. Usually the sense of pressure is earliest lost, while the appreciation of temperature, the ability to distinguish hot and cold, is longest retained. Then there are peculiar anomalies which have been termed retarded and double sensation. If the surface be touched, it is not felt immediately, but only after the lapse of several seconds is the contact observed. Or different kinds of sensation may be conveyed with varying rapidity; one is pricked with a pin, either immediately or after an interval of time the sense of contact is appreciated, then a few seconds intervene before there is also the sense of pain. There are some other peculiarities of this kind which cannot be dwelt upon here. But the anæsthesia does not alone involve the integument, the deeper parts, muscles, bones, joints, etc., are also thus affected. Probably due to this, we very frequently find that the patient loses knowledge of the position of his limbs. If, when he is in bed and with eyes closed, you place his limbs in strange positions, he can neither tell where they are nor in what posture, and has probably also not felt the passive movements.

We will next mention a symptom allied to the preceding and perhaps also to that which will follow it—ataxia. That is what has been termed Romberg's symptom. While the patient can still walk with no apparent difficulty, if told to stand with closed eyes, he is observed to waver, and, when the condition is well marked, may fall to the ground. This appears to be directly dependent on the anæsthesia. At least Erb mentions that even in cases of ataxia it is never present unless there is also anæsthesia. Indeed, it is sometimes the first indication of the latter, pointing to its presence even when the most careful objective examination leaves the physician in doubt. The symptom may be thus explained. The maintenance of the equilibrium of the erect position is due to our knowledge of our position in space, a knowledge due to the constant centripetal impressions to the sensorium from the periphery through the cutaneous, muscular sensation, vision, etc. When the cutaneous and muscular sensations are impaired, if the vision is also excluded, our knowledge of our position in space becomes obscured, we waver or fall to the ground.

We now approach the most prominent symptom of this disease—that which has given it its name: the loss of muscular coördination; the ataxic gait. We have here the singular anomaly that individual acts can no longer be performed with precision and accuracy, or not at all, while the muscular power upon which they depend is not at all impaired. Previous to the development of the ataxic gait, the patient observes a feeling of heaviness and stiffness in his limbs. He tires easily. He first notices some difficulty in ascending a flight of stairs, in arising from a chair, in suddenly turning around, walking on a smooth floor, etc., all of which difficulties are greater at night. Walking is difficult just after rising in the morning, also changing from a rapid to a slow, or a slow to a rapid gait; while at this time, in an ordinary even gait by daylight, nothing peculiar is observed. The ataxic gait is first noticeable through a certain irregularity or awkwardness in its performance. When it becomes well marked, its peculiarities are observed by every one. The feet are usually raised higher than necessary, are thrown outward and forward in a jerky manner, and the heels fall in a stamping manner to the ground. The knees are held stiff, and the eyes are constantly directed toward the feet.

The ataxia, though most marked and most frequent in the lower extremities, occurs sometimes, though generally at a later period, in the upper extremities, and even in muscles of the trunk and face. In the hands it is first observed in performing delicate actions, picking up a pin, writing, etc. The ataxic movements are always most marked in the dark or when the eyes are closed. The ataxic manifestations vary greatly as regards the rapidity of their development. Sometimes, very shortly after they are first observed, they already become excessive, but more frequently years pass before the ataxia becomes marked. At times it improves considerably, the improvement being of some duration; again it becomes suddenly worse through the effects of cold or the like. Ataxia is not the only muscular symptom; very frequently there is considerable muscular weakness in the earlier stages, and at a later period true paralysis is no uncommon sequel.

We will now speak of a number of visceral symptoms. The genital functions are often affected. In the beginning there is often an increase of sexual appetite, but when the disease is advanced, the sexual functions and appetite are usually lost. There is often a slight disturbance of the bladder, slight incontinence, or slight retention; the latter should never be overlooked, as it may cause serious cystitis. Rectal symptoms are less common, most frequently a slight anæsthesia, so that the feces escape without the knowledge of the patient. But paroxysms of pain of a spasmodic character, both in the rectum and in the bladder or urethra, are not uncommon symptoms, and are probably allied in character to the lightning pains of this disease. Pains, probably of the same nature, attack also other internal organs, so that we find paroxysms of gastralgia, nephritic colic, etc.; of these the most common and distressing are the paroxysms of gastralgia. These are sometimes very severe, and may be accompanied by vomiting, vertigo, and even temporary diminution of urine and albuminuria. I was called to such a case recently in the middle of the night, where no history excepting that of the present attack of gastralgia could be obtained. But when the patient called at my office some days later, a casual examination was sufficient to reveal the presence of the well-developed disease. He then informed me that he had been under medical treatment for some years for rheumatic pains.

We now approach a series of symptoms, which, to the untutored, appears less noticeable as symptoms of spinal disease, but which has the highest diagnostic value, and first the ocular symptoms. Paralysis of the external or internal muscles of the eye, causing ptosis, strabismus of various kinds, irregularity of the pupils, etc., belong to the most common symptoms of locomotor ataxia. They are present in more than two-thirds of all the cases of that disease, and, further, they belong usually to the initial symptoms. They are frequently of temporary duration. Strabismus or the like will occur at an early period, disappear after a few weeks or months, perhaps recurring at various periods to again disappear, though when the paralyses occur at later periods, they are likely to remain permanently. I do not wish to dwell longer upon these ocular paralyses further than to mention specially one form, that is what is termed spinal myosis or Argyle-Robertson phenomenon. Here the pupils are much contracted, they do not respond to light, neither become larger in a darkened chamber, nor contract when a bright light is brought before them, but do contract during the act of accommodation. I mention this symptom because it is almost pathognomonic of this disease. I do not know of its occurrence in any other disease.

The other ocular symptom I shall mention is one especially noticeable, as it is the greatest affliction with which the patient is visited—amblyopia or amaurosis. This is less frequently found than the other ocular symptoms, but it is frequently present. Cyon found it in sixty of two hundred and three cases; Erb in eight of seventy cases. It is also frequently an early symptom. I have seen one case in which it preceded the ataxia fully ten years. The vision generally begins to fail at the periphery, central vision being longest retained. It varies very greatly in the rapidity of its development, sometimes complete blindness occurring soon after the first impairment of vision, more frequently being slow in its development. Some believe that its progress is sometimes checked by hypodermic injections of strychnia. The amaurosis is due to degenerative changes in the optic nerve, apparently quite like those we will later have occasion to observe in the posterior columns of the spinal cord. The disease begins in the nerves, and extends backward into the optic tracts, sometimes reaching the corpora quadrigemina.

The symptom of which we will now speak is one of prime importance in the diagnosis: it is the condition of the tendon reflexes, the absence of the patellar tendon-reflex. That a blow upon the ligamentum patellæ would cause a sudden contraction of the quadriceps femoris has long been known, but it was only after Westphal pointed out that this phenomenon cannot be elicited in cases of locomotor ataxia that it began to assume a clinical importance. Since then, very much attention has been paid to the subject. Much has been experimented and written about the nature of this phenomenon. This question, not yet settled, will not detain us here; but its clinical value is a subject of so much importance that I may be pardoned for dwelling upon it at some length. This phenomenon can be almost always elicited in health. Berger examined over fourteen hundred persons, and failed to detect it in less than two per cent. of the cases. Eulenberg examined a large number of adults and children, and failed to find it in about five per cent. of all the cases. Westphal claimed, until very recently, that he never failed to find it in healthy persons. I have myself examined a large number of healthy persons, and have never failed to find it in adults. In one, a young man of about eighteen years of age, I succeeded in obtaining it at some times, and failed at others. Why this difference, I do not know. Usually it is very easy to elicit this phenomenon; but when it is difficult, it will not suffice to merely examine the patient in the ordinary manner, that is, when one knee is thrown over the other, to give a tap on the tendons; but one must rather lay the knees bare, have the patient sitting upon a table, so that the feet swing freely, and then tap upon every part of the ligamentum patellæ. Only after a fair trial of this kind can it be said that the patellar tendon-reflex is absent.

Westphal believes that this phenomenon is always absent in locomotor ataxia. Some physicians of prominence have believed that they found it still present in typical cases of this disease. I have seen one case of very excessive ataxia, where the patellar tendon-reflex was even exaggerated. But this case, in its entire history as well as in the special appearance of the ataxia, was quite different from ordinary cases of locomotor ataxia. But even though this phenomenon be sometimes present in the disease, and though it be occasionally absent in healthy persons, each of these are such rare occurrences as scarcely to detract from its diagnostic value. And its value is the greater because its absence is noticed in the early periods of the disease, and is often its first indication.

The latter symptoms mentioned, the ocular manifestations, the absence of the patellar tendon-reflex, should never be forgotten when trying to make a diagnosis in an obscure case. They will often enable us to make a diagnosis early in the disease, and, what is of equal if not of greater value, will often enable us to exclude the existence of this disease. Patients will often come to you with what is termed spinal irritation, neurasthenia, and the like, with flying pains in various parts of the body, feelings of numbness and formication, inability to stand with closed eyes, etc., believing that they are suffering with some organic disease. If you examine carefully into their history, observe that the patellar tendon-reflex is present, that there are no ocular symptoms, none on the part of the bladder or rectum, you can inform such patients with a great degree of assurance that they are not suffering with any organic disease. You thus relieve their minds of a great weight of anxiety, and by removal of causes and proper general treatment may soon restore them to complete health.

I will mention one other set of symptoms—perhaps I should rather say complications—of this disease, that is, the mental symptoms.

Moelli has found mental disease in seventeen of eighty-nine cases of locomotor ataxia. Of these, ten were general paralysis or other dementia, four had delusions of persecution, and three were hypochondriacs. General paralysis is the most frequent complication of this disease. Not infrequently the degenerative changes in the cord of locomotor ataxia develop during the history of general paralysis. But in that case the spinal are obscured by the mental symptoms. When general paralysis develops in a case of locomotor ataxia, it is often slower in its progress and milder in its character than is usual in the typical disease.

Herewith we have mentioned the most prominent symptoms, and though some have been omitted and some but slightly noticed, I believe enough has been said to give a distinct picture of the disease, and to enable one always to make a diagnosis where a diagnosis is possible. And now a few words on the progress and duration of the disease. Usually we have, then, in the earlier stages, lightning pains, girdle sensation, formication and numbness, perverted sensation of soles, ocular symptoms, disturbances of bladder, rectum, and genital functions, and absence of patellar tendon-reflex. This earlier stage, before the appearance of ataxic manifestations, may be of very short or very long duration. Sometimes only a few weeks elapse after the first symptoms are manifested before the ataxia appears. More frequently a year or more intervenes, and sometimes ten, fifteen years, or more. In the second stage, we find the anæsthesia and ataxia. This stage, too, may be of very short or very long—ten or twenty years—duration. The last stage is called the paralytic one, in which there is true paralysis, sometimes atrophy of muscles, sometimes cystitis, decubitus, marasmus, leading to a fatal termination. This stage, like the preceding, may be of indefinite duration. Leyden, in his most recent article on the subject, mentions a case then under observation, which had already been twenty years in what was termed the paralytic stage. In fact, the disease in itself rarely leads to a fatal termination, and yet patients suffering with it do not usually grow old, owing to their being more subject to accidents, and to their having less power to resist intercurrent diseases.

CRUSH OF BOTH LOWER EXTREMITIES, AND TWO COMPOUND DEPRESSED FRACTURES OF THE SKULL;

SIMULTANEOUS AMPUTATION OF LEFT LEG AND RIGHT THIGH; RECOVERY.

BY W. L. ESTES, M.D.,
MEDICAL SUPERINTENDENT OF ST. LUKE'S HOSPITAL,
SOUTH BETHLEHEM, PA.

GOTTLIEB F., æt. 29 years, German, married, admitted May 8, 1883. About three hours before admission, while walking on the railroad, the patient stepped from one track to another, in order to avoid a train moving towards him, only to be struck by a locomotive coming from behind. He was picked up immediately, and brought as soon as practicable to the hospital. A period of about three hours intervened, however, between the time of the accident and that of the examination at the hospital. The examination showed that the left foot was hanging in shreds, and that the skin was torn off up to the lower third of the external aspect of the leg; the right leg was crushed into a pulp from the foot up to the upper third, the skin being severely contused as far as the middle of this region. Compound depressed fracture at the inner angle of the left orbit through the ciliary ridge, a round, even, cup shaped depression, admitting the end of the index finger. Another fracture, also compound and depressed, at the right frontal prominence. Here the area of depression was larger than the end of one's thumb, and the edges of the contiguous bone were sharp and jagged. Occipital, and the right deltoid regions were severely contused. Slight punctured wound about one inch and a half above the olecranon process on the posterior aspect of the left arm. Patient was conscious; pupils reacted normally, were of normal size and equal on both sides. The patient had recovered sufficiently from the shock to answer intelligently and quickly. Hands warm, and surface of skin had recovered its normal healthy hue and temperature. Pulse of pretty good volume, but rapid and compressible. No attempt had been made, previous to his admission into the hospital to control the hemorrhage, so that the patient had lost a great deal of blood before his arrival, and was fast becoming exsanguinated. The first care after getting him on the table, therefore, was to apply an Esmarch bandage to both extremities. A full dose of morphine was then administered hypodermically, and he was etherized as quickly as possible. While my senior assistant, Dr. Cartmell, amputated the left leg through the lower third by the lateral flap method, I amputated the right extremity through the femoral condyles, as follows: Long oval anterior and short posterior skin flaps were formed, circular division of muscles and tendons, the condyles of femur were sawn slightly obliquely from above downward, then the tendon of the quadriceps femoris was divided from within outwards at its attachment to the patella, leaving only a few external fibres and the sheath. The articular surface of the patella was scraped thoroughly by longitudinal scratches with the knife. After the vessels had been tied and hemorrhage controlled, the patella was drawn down carefully, its articular surface placed in apposition with the sawn extremity of the condyles, and secured in position by two silver wire sutures passed deeply through the flaps and through the fibrous covering and attachments of the patella. A medium-size drainage-tube introduced from one angle to the other through the bottom of the wound; flaps carefully fitted together and held in apposition by catgut sutures. Lister dressing applied to each stump. During the operation the pulse sank once or twice, so that it was necessary to give two or three hypodermics of whiskey and ether. The patient reacted quickly and well, notwithstanding his frightful mutilation. He passed a quiet night, and next morning at 8 A.M. pulse was 90 and temp. normal. At 5 P.M. pulse 96, temp. 102° F. Complained bitterly of pain in the right stump, evidently from the traction of the silver sutures.

May 10.—8 A.M. Pulse 108, temp. 100.6° F. Patient suffering agonies from the silver sutures. Inasmuch as he was becoming very nervous, restless, and weak from the pain, I thought it best to remove the offending sutures. I did so, but just as they were withdrawn the patient gave a sudden start and, notwithstanding firm manual support from above downward, the patella was drawn forcibly upwards about one inch, with evident giving way of pretty firm adhesions. An attempt was made to return it to its former place, but was only successful to the extent of bringing it just below the upper rim of the condyles, where, on account of the terrible pain this manœuvre occasioned, I was fain to leave it after securing it by firm strapping with adhesive plaster strips. At succeeding dressings it was drawn a little further down by adhesive plaster, and finally remained firmly and securely.

12th.—8 A.M. Pulse 102, temp. 105°. This was the highest temperature during the whole after-treatment. It subsided readily after a dose of 1.5 gramme quinine and an enema.

From this time on the recovery was very rapid. The right stump healed without suppuration; the left was retarded, and suppurated from a slough of about three-quarters of an inch of injured skin which had been inadvertently included in the flaps. This healed by granulations (but slowly) afterward.

On the thirteenth day after the operation the patient was allowed to get out of bed for the first time. After this he was up daily in a wheel-chair. The wounds in the head seemed to heal very kindly at first, the smaller one, at the ciliary ridge, indeed had cicatrized in about a fortnight. The other and larger one also did well, and was nearly healed externally, when, on the 8th of June, the patient complained of severe headache and had a slight rigor. The next day an abscess had formed. This was freely incised, evacuating a small quantity of thick pus. An examination with a probe showed the bone still bare, and evidently necrotic at the bottom of this cavity. In the course of the following week flat pieces of dead bone were removed from time to time, until they amounted to a superficial area of perhaps the size of a silver quarter, when granulations soon filled the cavity, and in a short time thereafter it was entirely healed. The exfoliated bone was evidently the outer table of the skull. This abscess caused the only "head symptoms" the patient had during his treatment. He was discharged July 7th. The right stump was so firm and painless that he could easily bear his whole weight on it without inconvenience; the left stump had still a superficial ulcer, very small, at the upper angle of the flaps where the skin had sloughed, but was contracting rapidly. Wounds in head entirely healed.

Remarks.—Though double synchronous amputations are not very rare, the case just narrated being the third the reporter has had in the last eighteen months, the percentage of mortality is so overwhelming that a *successful* case of *uncomplicated* double simultaneous amputation, for a railroad crush, is even worthy of record. As far as I have been able to search, I have found not a single recovery recorded after a synchronous amputation of both lower extremities together with *two compound depressed fractures of the skull* in the same individual. I believe, therefore, that I have the honor of recording a unique case of physical stamina, and a successful issue of what was certainly one of the gravest of surgical conditions.

Gross[1] gives the credit of the first known case of double synchronous amputation to Dr. Morris, of Quebec, and states that the introduction of these double amputations is due to the surgeons of the hospital to which Dr. M. was attached—Hotel-Dieu. Since Morris' time almost every surgeon of any hospital practice has had occasion to do these multiple operations more than once. Our surgical literature is nevertheless very poor in statistics of these amputations, most authors being content to pass them by with a mere mention of their occasional necessity, and their almost invariable mortality. Dr. John Ashhurst[2] gives a table of eleven cases occurring in his own practice. Of these eleven cases, two successful ones were for frost-bite of the toes, in which only a portion of the feet was removed. The remaining nine cases were for accidents, and of these only two recovered. One of these was the remarkable case of hip-joint amputation and amputation of the other leg below the knee-joint (the case, a boy fifteen years old), for a railroad crush. The same author[3] has collected a list of eight cases of *successful quadruple* amputations, but none of them appears to have been synchronous. Nine cases of *successful triple* amputations are also mentioned by him.[4] The most remarkable of these was a boy thirteen years old, for whom Dr. Koehler, of Schuylkill Haven. Pa., amputated one arm and both legs below the knee.

Besides the unique complication and the happy result in my case, I desire to note the *osteoplastic* operation performed on the right extremity. Though there was not sufficient good skin remaining to permit of an amputation at the knee-joint, it was nevertheless obviously important, for the sake of the man's life, to operate as low down as possible. As the patient was a very poor man, it was more than probable that he would have to depend upon his knee on the left side, and, as much as could be left him, on the right, for locomotion. It was therefore important to equalize the length of the thighs as much as possible. The patella presented itself as a ready expedient to add the necessary increment to the right thigh. Besides, for the proper accomplishment of this "shuffling along," it was necessary to furnish a hard, firm, non-sensitive stump. Making the anterior flap long and the posterior one short would naturally bring the line of cicatrix out of danger from pressure; it remained, then, only to have a firm, painless, bony support at the end of the stump, and the interposition of the patella seemed to fulfil all these conditions. I mentioned that it was necessary to liberate the patella on the third day, and how difficult it was to bring it again into place. Were I to do the operation again, I should cut every fibre of the tendo-quadriceps, thus obviating the torturing pull of the thigh muscles, and assure the stability of the patella.

The method is no new one. Introduced by Gritti in 1857,[1] modified by Stokes some time after, it has been done, according to Dr. Weir,[2] seventy-six times, with a death-rate of about 28.5 per cent. Strictly speaking, the osteoplastic operation which Gritti introduced at this region, was sawing off a thin slice from the articular surface of the patella, and then opposing it to the sawn condyles; but so much difficulty was experienced in keeping the bones in apposition that Stokes[3] modified the operation by dividing the femur just above the condyles, thus leaving less strain for the tendo-quadriceps femoris. It remained. however, for Szymanowski[4] to suggest and to first practise divisions of the tendon after following the Gritti method in other particulars. The operation was further modified in the case just narrated by slightly varying the form of the flap—long oval, instead of the Gritti rectangular anterior flap—but especially by simply *scraping* the articular cartilage, so that sufficient inflammatory action might be excited for the desired union instead of removing it. In this particular case it was done in order to save time, and the idea occurred to me from seeing the late Dr. James R. Wood leave the articular cartilage in his Syme's foot amputations, and having on several occasions proved the efficacy of the scraping in the Syme amputation myself. The advantages of the modified Gritti amputation were, I think, clearly illustrated in this case. Rapidity of healing, beautifully rounded stump, absolutely firm and painless point of pressure for walking or false limb.

Notwithstanding the little confidence surgeons have hitherto shown in this operation, it appears to me that, with the help of antiseptic dressings, the evident theoretical advantages of this method should be more thoroughly tested. That two raw, bony surfaces, closely and smoothly apposed, will unite more quickly than is required for the extremity of the bone to round off and become firm and painless by the conventional "button-forming process," with subsequent calcification, no one will doubt. That a stump formed by the direct union of two such bones will be better rounded and stand more pressure, is also according to reason, notwithstanding Schede's strictures to the contrary. The comparative death-rate is also greatly in favor of the Gritti operation. Dr. Weir's figures, as before stated, show a rate of about 28.5 per cent. of mortality, while the mortality of the ordinary operation at this point is above 40 per cent. There certainly appears much reason for more extended trial of this operation, and in this age of plastic surgery and non-suppurative healing, it behooves an operator to attempt every possible reparation to the unfortunate who loses a limb under his knife.

Even Pirogoff's operation is still meeting with unqualified condemnation at many surgeons' hands. Still, the many triumphs that every well-qualified operator can show for this, and many similar, operations should stimulate us to attempt greater things in making bones repair one another.

TWO CASES OF EMPYEMA; ONE CURED SPONTANEOUSLY, THE OTHER BY INCISION.

By A. C. GIRARD, M.D.,
ASSISTANT SURGEON UNITED STATES ARMY.

Prof. McSherry's elaborate article in No. 20 of your journal induces me to add a sketch of two cases, lately under my treatment, to the literature of the subject.

M. B., a servant girl, was taken sick with symptoms of pleurisy, which shortly led to effusion into the left pleural cavity. A reasonable time having been given to the action of absorbents and blisters, aspiration was resorted to. Much to my astonishment, a pint of *pus* escaped in place of the serum I had expected. (There had been no hectic symptoms.) The pus accumulating again, the aspirator was resorted to the second time, with like result, but lesser quantity. I then determined, if the secretion continued, to operate by incision, but, fearful of possible fatal result, I again aspirated in five days, intending this to be the last effort of that character. Three days after that the patient expectorated a large quantity of pus—evidently the effusion had made its way into a bronchus. Nature did the remainder of the work. Expectorations of the same character continued in lessening quantities, and finally ceased. The patient is now well. A year has elapsed.

R. R., a teamster, was admitted to hospital with delirium tremens, from which he recovered very slowly, with a certain amount of cough. Examination of the chest revealed effusion in the left pleural cavity. Aspiration revealed it to be of a purulent character, but the pus being very thick, the tube choked up after evacuation of six ounces. Hectic fever appearing in a few days, incision of the cavity was determined on and performed under ether, a large quantity of pus welling out. A drainage-tube was introduced, and the cavity washed out with one per cent. carbolized water. This was done twice daily for four or five days. The discharge having become much lessened, and the injected water returning clear, the tube was removed, and the opening allowed to close. Every few days a slight discharge will escape from the wound, but it is lessening in quantity. The patient, whose temperature before the operation had reached 104°, is recovering rapidly, and has gained fifteen pounds, and has no more fever.

The lesson to be derived from these two cases confirms my belief in the advisability and safety of *aspiration* as soon as the active stage of pleurisy has ceased (which is my practice, and has always proved successful), and the safety of *incision* when the effusion is purulent, although in exceptional cases, as evidenced in Case I., the work will be done by nature.

Speaking of aspiration, I desire to report a unique case which came under my observation five years ago, and which I have long desired to place on record with the medical profession. It was at the time of occurrence reported in full to the Surgeon-General.

Trumpeter V. B. T., of the Second Cavalry, received a gunshot wound from a pistol in the right hypochondriac region. The shot was fired from below, and the bullet, after having passed through the liver, diaphragm, and right lung, was extracted by me through a counter-incision between the eighth and ninth rib, near the angle. He was suffering from shock and internal hemorrhage, accompanied by hiccough, and the next day complained much of distention of the abdomen, which, in place of tympanitic sound, revealed flatness in the lower half. Patient had rallied, and further internal hemorrhage apparently being arrested, the effusion remained to be dealt with. Temporizing, in my opinion, meant death to the patient from chronic peritonitis. I plunged an aspirator needle midway between umbilicus and symphysis into the cavity, and removed fifty-six ounces of fluid blood, much to the relief of the patient. To my regret, however, the swelling and hardness of the abdomen recurred in a few days, with increased area of flatness of sound, but without corresponding symptoms of continued internal hemorrhage. Effusion of bile through a lacerated bile-duct being suspected, the aspirator was again resorted to, and one hundred and twelve ounces (carefully measured) of *clear bile* removed, with great relief to the patient, and no untoward consequences. The same operation, under similar indications, and with less apprehension, was repeated three days afterwards, yielding seventy-two ounces; four days after that, ninety-four ounces, and in five days more sixty-eight ounces. After this the effusion did not reappear, presumably owing to cicatrization being completed, and patient recovered, deserted, was captured, served a term in prison, and a few days ago I saw him in robust health.

Fort Keogh, Montana Territory, July 6, 1883.

A PORRO-MÜLLER OPERATION.

By W. H. PARISH, M.D.,
OBSTETRIC PHYSICIAN TO THE PHILADELPHIA HOSPITAL, BLOCKLEY.

[*A paper read before the Obstetrical Society of Philadelphia, October 4, 1883.*]

Sallie Smith, a deformed dwarf, applied for admission to the Philadelphia Hospital in April, 1883. One of the Internes placed her among the pauper women of the out-wards of the almshouse. There, all the conditions surrounding the dwarf were such as to contribute to her physical deterioration. The women in that portion of the institution are unduly crowded—the ventilation is entirely inadequate, and the food of a character unfit for a pregnant woman. Her presence in those wards was unknown to any of the visiting obstetricians of the hospital until June 15, when Dr. Pauline Root, one of the Internes, ascertaining her pregnancy and her surroundings conveyed the information to me.

I at once had her transferred to the obstetric wards, where she was specially provided for and her condition carefully investigated. She was a native of Philadelphia. She was unable to give her age—although dwarfs usually appear to be older than they actually are, yet from what could be learned of her past life, from evident atheroma of her bloodvessels and from her appearance, I concluded that she must be over forty years of age. Her parents were poor, were born in Ireland, and died in this city during her early infancy. She had been told that her father died of heart disease, and her mother of insanity at the menopause. She did not know how or by whom she was cared for during her early childhood. She attributed her deformities to a fall supposed to have been received when she was a very small child. She was unable to walk until she was seven years of age. Her occupation, from the time she was first able to work, had been that of a house servant. Menstruation began at sixteen years, continued at the usual periods, but rather profusely until the beginning of pregnancy.

She could not recollect ever having been seriously ill. I learned from some of her acquaintances that for a number of years she had been of intemperate habits, repeatedly becoming intoxicated, and indulging in promiscuous sexual intercourse. Her bad habits led to exposure to inclement weather, and, with the influence of cold and damp, doubtless led to the disease of the kidneys, to which I shall again refer.

She was pregnant for the first time. The date of the last menstruation was given by her differently at different times. At one time she would give the 1st of October, at another time, the middle of October as the date when menstruation last ceased. She felt movement of the child about the middle of February, though she was also uncertain in reference to the date. The *fundus uteri* reached nearly to the ensiform cartilage, and I concluded that the full period of pregnancy would be attained about the 10th or 15th of July.

She was fifty-one inches high, the head small, mind sluggish, and memory defective; yet she was not an imbecile. The clavicles and bones of the upper extremities, though small, presented no special deformities; they did not show the usual rachitic incurvations. The right thorax was very prominent posteriorly and laterally; the left thorax markedly depressed posteriorly and laterally. Both lungs, but more especially the left one, were greatly encroached upon by the deformed thoracic walls. The heart was displaced upward and to the left, its apex being on a level with and external to the left nipple. Pulse 86, of good volume, but intermittent. Bowels moved daily; urination frequent. Urine contained one-quarter albumen, and also granular and hyaline tube-casts. The eyelids were slightly œdematous, but œdema was not recognizable in any other part of the body. The patient complained of frequently recurring frontal headache. At times things seemed darkened to her, and dark specks appeared before the eyes. She had never experienced convulsions, but occasionally had slight fainting attacks.

The vertebral column was markedly curved. The upper third of the dorsal region was slightly convex posteriorly, the lower two-thirds markedly convex posteriorly and also decidedly convex to the right. The lumbar portion was convex anteriorly and to the left. A left anterior lumbar convexity, compensating for a right posterior convexity of the dorsal region. In the erect position, the lower ribs and the crests of the ilia seemed in contact, and the left iliac crest about one inch higher than the right. Posteriorly there was a deep depression at the sacro-vertebral articulation, and the posterior-superior spines were unduly approximated. Externally examined, the sacrum, in its upper two-thirds, seemed directed nearly horizontally backwards.

External measurements with a pelvimeter showed about fifteen centimetres, or six inches, between the posterior surface of the top of the sacrum and the anterior surface of the top of the symphysis pubis. Normally this measurement is about eight inches. Deducting three inches from the external conjugate of six inches, would have made the internal or true conjugate three inches. The distance between the anterior-superior spines measured twenty-five centimetres, or about ten inches, the normal being ten and one-quarter inches. Between the normally widest portion of the crests of the ilia the distance was a little less than that between the anterior spines—that is, a little less than ten inches, the normal being eleven and one-half inches. The measurement between the crests being less than that between the spines, indicated the pelvis to be rachitic, though it will be seen that the pelvis was not the more usual, typical rachitic one. The external measurements did not indicate decided transverse narrowing of the true pelvis, though internal manual examination did show decided transverse narrowing.

Repeated internal examination showed the promontory to be jutting forward, and the anterior surface of the sacrum to be nearly straight, and directed almost horizontally backward. The symphysis pubis was correspondingly inclined downward and backward.

The oblique conjugate measured three and one-fourth inches, the depth of the symphysis pubis one and a half inches; hence, according to Lusk, deducting three-fourths of an inch from the oblique conjugate, I estimated the true conjugate to be two and a half inches. The transvere diameter of the superior strait was evidently considerably shortened, but I could not satisfactorily determine the degree of the shortening. The antero-posterior diameter of the excavation was taken to be less than the corresponding diameter of the superior strait, and all the measurements of the outlet less than the corresponding ones of the superior strait. The pelvis was diagnosed to be a generally contracted one, with proportionally greater diminution of the conjugates, and the general contraction increasing from above downward, so as to produce a somewhat funnel-shaped pelvis. The vaginal canal was narrow, the os uteri high up, and the uterine fundus markedly tilted forward. The abdomen was remarkably pendulous.

When the patient first came under our observation, pregnancy seemed to have reached about the end of the ninth lunar month, according to the most probable interpretation of the symptoms, and of the information she gave. The question arose, would it be best to produce a premature labor at the end of the ninth month, with a generally contracted pelvis, and a true conjugate of two and a half or two and three-quarter inches? I decided that should a premature labor be attempted under such circumstances, craniotomy, or some other similarly dangerous operation, would be eventually necessitated, and that the dangers of such operation would be increased by the addition of those incident to the production of premature labor. Delivery with forceps, or by podalic version, seemed out of the question. There was a choice between craniotomy, symphysiotomy, Cæsarean operation, gastroelytrotomy, and the Porro operation.

In such a pelvis, craniotomy would have been difficult and tardy, and has been shown, especially by Parry, to be attended with a mortality of mothers too large to compete with abdominal section.

I did not prefer the Cæsarean operation, because of its excessive mortality to mothers in European hospitals, and because of the six Cæsarean operations performed in hospitals in this country, all were fatal to the mothers. A condition almost essential to recovery after Cæsarean operation is rarely met with, even after normal deliveries, in hospitals. I refer to sufficient retraction of the uterus. A flabby uterus, after a Cæsarean operation, leads to blood-poisoning and to general peritonitis. The experience of many hospitals, as also *à priori* reasoning, would make the Cæsarean operation of very questionable justification in hospitals, especially in large maternities, and more decidedly still in general hospitals. The Philadelphia Hospital is not only a general hospital, but is also part of a large almshouse. Gastroelytrotomy and symphysiotomy have given good results in the hands of a few operators, the former especially in America, the latter in Europe; but both operations have been performed with comparative infrequency, and the question of their respective merits cannot be determined by the very limited number thus far performed.

I do not desire to discuss *in extenso* here the general question of the relative value of the different operations performed for the relief of advanced pregnancy in very small pelves. Among the considerations inducing me to adopt the Porro operation, with Müller's modification, were, the smaller mortality to mothers attending this operation in hospitals, and the opportunity it allows the operator of selecting daylight, and of securing the needed assistants.

The patient was placed under the influence of quinine, of Basham's mixture, and of occasional doses of the compound jalap powder. Woollen underwear and proper diet were secured for her. She was isolated from all lying-in women. Her condition did not improve, however, as the time for operation approached, but on the reverse, a persistent œdema of the face, more troublesome headache, and more marked disturbance of vision, with an increasing quantity of albumen in the urine, all pointed to steadily increasing uræmia. The time chosen for the operation was what was supposed to be the end of the thirty-eighth week of pregnancy. A large, well-lighted, well-ventilated room in the Children's Asylum, remote from the obstetric wards, and one that had for years been used as a private parlor, was selected in which to operate, and in which the patient was to remain after the operation. This room was divested of curtains, carpets, and furniture; its walls and floor were thoroughly scrubbed with carbolized water. The room was then refurnished with chair, table, and a new bed. In short, every means was resorted to to improve, as far as possible, the unfavorable conditions incident to so large an institution as the Philadelphia Almshouse.

The members of the obstetric staff had agreed with me in the diagnosis of the patient's deformities, and also as to the propriety of the performance of a Porro-Müller operation. The patient was also kindly examined prior to the operation by Drs. Albert H. Smith, Robert Harris, M. O'Hara, and Anna Broomall. After receiving a full explanation of the nature of the operation, the patient gave her entire consent. The operation was performed on June 30, 1883, with the assistance of Drs. Duer, Keating, Musser, Stryker, Montgomery, Clara Marshall, and Bernardy, all members of the obstetrical staff, and also with the assistance of Dr. McLoughlin, warden of the hospital. There were present Drs. S. D and S. W. Gross, Ellwood Wilson, J. L. Ludlow, Albert H. Smith, Anna Broomall, J. H. Brinton, Hannah Croasdale, and other physicians. On the morning of the operation the room was carbolized with the spray, but the latter was not used during the operation. All instruments were kept in a two per cent. carbolized solution, and Listerism, minus the spray over the patient, was in the different details observed. On the morning of the operation the patient received a general bath, and the bowels were moved by enema. A half hour before the operation she received two ounces of whiskey. Dr. Joseph Hearn, one of the surgeons of the hospital, and an experienced anæsthetizer, kindly administered ether during the operation. After etherization the bladder was emptied with the catheter. An incision was then made in the median line of the abdomen about seven inches in length, extending from two inches above the symphysis pubis to about one inch above the umbilicus, passing to the left of the umbilicus. The slight bleeding from the lips of the abdominal incision was controlled by artery compressors before opening into the peritoneal cavity. The absence of intestine from in front of the uterus was ascertained by percussion before making the incision. The uterus was easily raised from the abdominal cavity.

Owing to the anterior lumbar curvature, and to the length of the incision, it was impossible to completely prevent the escape of intestines. After the uterus had been turned out, a protector made of two layers of flannel, with an intervening layer of protective silk, was placed over the abdomen; the object being to avoid chilling, and to prevent the escape of blood and other fluids into the peritoneal cavity. This protector, when used, was wrung from a warm carbolized solution. The next step was to place around the cervix the wire of an écraseur, and to constrict the tissues in its grasp to such an extent as to stop all circulation of blood through the uterus without cutting through the peritoneum. This step required speed, care, and judgment. The liability of a loop of intestine or of omentum to be caught by the constricting wire had to be carefully guarded against. Immediately that sufficient constriction had been secured, a short incision was made with a pointed bistoury through the antero-uterine wall down to the placenta, for the placenta proved to be attached anteriorly. The incision was then rapidly extended, from near the neck to the fundus, with a probe-pointed bistoury, guided by two fingers of the left hand introduced into the incision. The blood pent up in the uterus by the constricting wire escaped freely, but did not enter the abdominal cavity. The incision passed to the external surface of, but not through, the placenta. The hand was immediately introduced into the uterus through the exposed membranes at the fundus, and the child quickly turned out, the placenta being in this manœuvre detached in main from the uterus. The cord was promptly tied and cut, and the child handed to Dr. Keating. It was asphyxiated when delivered, and presented a very unpromising appearance.

It, however, quickly breathed and cried under the efforts of Dr. Keating at resuscitation. The rapid resuscitation was effected by alternately dipping the child in basins of hot and of cold water. After removing the infant, the uterus, with both ovaries and both tubes, was amputated a half-inch above the constricting wire—this point was about at the internal os. It was then seen that the wire had completely controlled the circulation, and not a drop of blood escaped from the stump of the uterus.

The next step consisted in passing obliquely through the stump two steel pins five inches in length, one above, the other below, the wire. After this a strong carbolized silken cord was passed around the stump, in the line of the wire, and partly tightened. The wire was then cut and removed, and the silk cord then very firmly tightened and securely tied. Special care was given to the tightening of this cord and to the tying of a secure knot. The ends of the pins rested laterally on the abdominal walls, and under the ends, on each side, was placed a piece of sheet-lead. The stump was thus secured outside of the abdominal cavity, and rested at the lower angle of the wound. New carbolized sponges on handles were introduced into the peritoneal cavity, down into Douglas's pouch, but the entire cavity was free from blood or other fluid.

The abdominal wound was then closed by deep and superficial silver sutures. The deep ones were introduced so as to include the peritoneum. During the introduction of the deep sutures, flat carbolized sponges were introduced beneath the incision, so as to catch what oozing might occur from the needle punctures. The external portion of the uterine stump was brushed over with carbolic acid, and then invested with lint saturated with carbolized oil. A strip, two inches wide, of dry carbolized lint was placed on the incision; over this a few strips of rubber adhesive plaster were applied transversely, over these a thick layer of carbolized cotton, and over all a flannel binder. The patient was put to bed, and surrounded with pans of hot water. Dr. Montgomery took charge of the patient's general condition during the operation, and administered during its performance four hypodermic syringefuls of whiskey. He reports that the time taken up in the operation, from the beginning of the abdominal incision until its complete closure, occupied forty minutes. During the operation the pulse ranged from 100 to 128, the greater frequency being during the making of the incision in the abdominal wall, and was probably due to impeded respiration. The constriction of the cervix had no appreciable effect upon the pulse. Soon after being put to bed, the pulse was 132, but in two hours was 108 per minute, and of good volume. The respirations during the anæsthesia became disturbed and imperfect, producing considerable cyanosis, and probably causing increased frequency of the heart's action.

The patient rallied well, as was shown by return to consciousness, by bodily warmth, and a fair pulse. For about sixteen hours her condition seemed very favorable, excepting that the kidneys had ceased to act. At the end of twenty-three hours there was marked change for the worse; the mind wandering, pulse 140, temperature 100° F. An inspection of the dressing at that time, showed some oozing from the stump—perhaps six ounces—but it had then stopped. An additional ligature was placed around the stump, and one of the uterine arteries was separately ligated, the other could not be found; the stump was also brushed over with Monsel's solution. There was no subsequent oozing. That there should have been any loss of blood in this manner was a surprise to me, as the original ligature was so very firmly tightened and secured, and had for a number of hours after reaction so perfectly controlled all bleeding. There was marked atheroma of the vessels of the stump, as was revealed *post-mortem*. After the twenty-third hour the patient grew progressively worse, became uncontrollable and delirious, had convulsive manifestations, and died in coma. There was no vomiting until twenty-six hours after the operation, and it recurred only once. She experienced but slight pain, and sulphate of morphia was given in small quantity—¼ gr. hypodermically, soon after the operation; again ⅙ gr. at the end of eleven hours—and subsequently about the thirty-sixth hour, because of the great jactitation and the difficulty of keeping the patient in bed. The morphine was given hypodermically by Dr. McLoughlin in such small amount that the coma could not have been due to it. Eight hours after being put to bed the urine was drawn with the catheter. Subsequently the catheter was introduced at different intervals, but on each occasion the bladder was empty, and it was also found empty at the *post-mortem* examination. Only three ounces of urine were secreted after the operation. The patient survived forty-two hours.

Dr. John Gillespie made a careful analysis and microscopic examination of the urine secreted after the operation, with the following report:

The specimen of urine from the woman upon whom the modified Porro operation was performed was examined, with the following result:

The specific gravity was 1023; reaction decidedly acid. The urine was of a dirty, yellowish-brown color, and contained a large amount of albumen (rather more than one-third).

The amount of urea contained in the urine received by me was 10.5 gr. for the entire amount. Therefore, if only three ounces of urine were excreted in forty-two hours, the total amount of urea excreted would be about fifteen grains.

The sediment contained granular, hyaline, and epithelial casts, renal and bladder epithelium, and granular detritus and blood-corpuscles.

Dr. Wile, the acting pathologist of the hospital, conducted the *autopsy*, and I extract the following from the pathologist's records:

On opening abdominal cavity several slight adhesions were found between the visceral and parietal peritoneum in the region of the surgical incision. Bloodvessels around incision markedly congested. No exudation or other evidences of general peritonitis.

Stomach and intestines distended with gas; spleen small, atrophic.

Left kidney: Considerable displacement, found between sixth and seventh ribs. Somewhat lobular, on surface pea-sized cyst, which extends somewhat into the cortical substance of kidney. Cortex reduced, the seat of parenchymatous, solid, interstitial change.

Right kidney: Position normal; shape altered, considerable flattening on upper surface; hilus very marked; capsule adherent, seat of parenchymatous change. Both kidneys in state of contraction.

Pelvis: One ounce of bloody serum in Douglas's pouch. Peritoneal and subperitoneal tissue the seat of considerable œdema.

Veins around vagina enlarged.

Cervix uteri virginal; orifice round.

Liver enlarged; fatty,

Thorax: Left, upper, anterior, side pleura adherent.

Heart: Left side firmly contracted; right relaxed. Right auricle and ventricle seat of a firmly adherent chicken-fat clot. Left ventricle contained small amount of dark, slightly coagulated blood. Left ventricle markedly hypertrophied. Mitral valve, slight thickening. Papillary muscle considerably hypertrophied.

Lungs: Hypostatic congestion; œdematous.

. Cause of death: Heart-clot.

The bloodvessels are for the most part congested, filled with corpuscles, and surrounded by a growth of connective tissue. The uriniferous tubules are found filled with cellular and granular debris. Some contain pigment, the result of slight hemorrhages. The epithelial lining of the tubules is granular, and in some places in a state of proliferation, indicating a catarrhal process. The growth of connective tissue between the tubules and about the Malpighian bodies is more marked in some places than in others, and the interstitial process may be regarded as fairly established. A careful measurement was made by Dr. S. D. Lazarus and myself after the pelvic viscera had been removed, with the following result:

	Conjugate.
Superior strait,	3 inches.
Transverse,	4 "
Right oblique,	3¾ "
Left oblique,	4 "
Oblique conjugate,	3¼ "
Depth of symphysis,	1½ "
Obstetrical conjugate,	2¾ "
Excavation:	
Conjugate,	2¾ "
Transverse,	4 "

Upper four sacral vertebræ directed nearly horizontally backward; lower portion of sacrum and coccyx curved sharply forward.

Inferior strait:	
Conjugate,	2½ inches.
Oblique,	2¾ "
Transverse,	3½ "

Perpendicular to plane of superior strait, nearly horizontal, striking abdominal wall about midway between umbilicus and top of symphysis.

Perpendicular to plane of inferior strait would strike the upper part of the third sacral vertebra.

The death of the dwarf must be attributed chiefly to the existence of interstitial and parenchymatous nephritis. She had rallied from the shock of the operation. There was no peritonitis, excepting in the immediate vicinity of the incision.

It was too early for septic poisoning to produce death, and there were no indications that such had occurred. The loss of blood had been trifling, and death occurred too soon to be attributable to exhaustion from this cause.

The acute and almost complete suppression of urine, the symptoms after the operation, the symptoms prior to the operation, and the results of examination of the urine and of the kidneys after death, all pointed to the diseased kidneys as the cause of the fatal result to the mother.

It is well to note that union had occurred throughout the entire extent of the abdominal wound. There were adhesions between the small intestines and the parietal peritoneum along the line of incision. The latter fact is of interest, viewed in the light of death in a few instances after laparotomy being attributed to strangulation of the bowel, due to constricting inflammatory bands.

The child was of small size, and died at the end of three weeks, of inanition.

CHINESE OPIUM-SMOKING: THE DRUG USED IN THE FORM OF AN AQUEOUS EXTRACT.

MANNER IN WHICH THIS IS PREPARED AT HONG KONG UNDER THE SUPERVISION OF THE GOVERNMENT.

BY J. G. KERR, M.D.,
OF CANTON, CHINA.

[THE Chinese are said to *smoke* opium, and inhale the smoke. This will be shown to be an error, in the sense that the drug is burned, as it is used in a moist state, and the flame drawn over it, so as to produce a steam or vapor, which is drawn into the lungs, with the air inhaled through the flame. Dr. Kerr, in this paper kindly sent me, explains the whole subject of the preparation and use of the poison. We were aware that the drug was used in the smoking-dens of the consistence of molasses, and given by the dealer to the smoker on a wire, after having been heated over a lamp; but the paper here presented opens up a new subject, and shows that the Colonial Service has a monopoly in preparing the extract, and derives a large revenue therefrom.—R. P. Harris, M.D.]

The opium brought from India into China in such large quantities[1] is known by three names—Patna opium, Benares opium, and Malwa opium. The Patna comes in round balls, weighing on an average four pounds each, and one chest contains forty balls. The opium is in the form of a soft, black mass, and is enclosed in a shell made of the leaves of the poppy, of which several layers make a thickness of about one inch. The shell weighs one pound, and the opium three pounds.

The other two kinds are in lumps of irregular size and shape, weighing from four to six or eight ounces, and being more dry and solid than the other, have no external shell, but are packed in large chests with dry and broken leaves.

The opium as thus imported is not in a state suitable for smoking. It is taken through a process by which a very fine inspissated, watery extract is produced, and it is this only which is fit for smoking. A description of the process of preparing the smoking extract may be of some interest to physicians and pharmaceutists, and to others who study the opium question.

Through the kindness of J. H. Stuart Lockhart, Esq., and of Mr. Seth, of the Colonial Service, Hong Kong, I was favored with every facility for observing the "boiling" of opium as it is conducted under the supervision of the government. All the opium prepared in Hong Kong, whether for local use or for export, must be brought to this establishment—221 Praya West—weighed, and boiled under the supervision of an officer appointed for the purpose. From eighty to one hundred balls are boiled every day, and a tax of $2.25 is levied on each ball.

There are two stages in the process of preparing the extract, and two days are required.

First Stage.—The shops licensed to deal in opium send as many balls as they wish worked up with a man skilled in the business. A register is kept of the shop name, the number of balls sent, the weight, and the amount of dross or seconds to be mixed in. The balls are then cut in halves, the opium carefully taken out and deposited in copper pans. The inner layers of the shell, which are saturated with opium, are taken out, boiled separately, pressed, and the water strained. This water is poured on the opium, and more added if necessary. The pans are now placed on furnaces, over a hot charcoal fire, and boiled for three, four, or five hours. During the latter part of the time, the fire is slowed down, and constant stirring with a wooden paddle is required. When most of the water has been evaporated, and it has attained the consistency of a pill-mass, it is made into thin sheets in the following manner: The mass, being first thoroughly worked up, and made into a ball, is spread out over the bottom of the pan by pressing it with a large, round ladle. The pan is then placed, with the opium downwards, over the furnace. In two or three minutes a layer of the opium is dried, and this is peeled off with the fingers. The pan is again placed over the fire, another layer dried and separated, and this is continued until the whole of the opium is made into sheets, forty or fifty in number. Each sheet is about one-eighth of an inch in thickness, is porous and friable, crumbling to pieces between the fingers. These sheets are then placed in a copper pan, covered with water, and the first stage is completed.

Second Stage.—On the day following, the second stage begins by carefully filtering the water in which the thin sheets of opium have been steeped over night. A filter is made by arranging six or eight layers of filtering paper in a light basket. This is set over a stoneware vessel, and the water containing the opium poured into it. After a part of the water has passed through, other layers of paper are placed over the opium, and the liquor is passed several times, and finally clear water, until all the soluble parts are exhausted. What is now left on the filter is a black mass, called "nai cha," or dregs, which, when dry, is pulverulent, and is practically worthless, being sold for two or three cents a pound.

The filtrate in the jars is next transferred to copper pans, and boiled rapidly over a strong charcoal fire until a large part of the water is evaporated. The fire is then lowered, and the boiling continued with constant and careful stirring, until it has attained the appearance and consistence of treacle. It is then ready for use, and is put in earthen jars, which are enclosed in closely fitting tin boxes.

The second stage requires from four to six or seven hours, according to the skill of the operator. One ball containing three pounds of crude opium yields by the above process about two pounds of the smoking extract, and, when made without any admixture of seconds, is of deep brown color. If seconds has been added, the color is more or less black.

If the extract were prepared from the opium as it comes from the balls, it would have a uniform composition and strength, but in practice, the dregs or seconds from the pipe are mixed with the opium in greater or less proportion, according to the fancy of the dealer; and besides, numerous modes of adulteration are practised, so that it would be difficult to find in the shops two specimens agreeing in composition.

The dross or seconds is almost as valuable as the crude opium, one tael weight being worth, at the present rate, thirty cents, while crude opium is worth thirty-six cents. It is carefully collected from the pipe, and is sold in the form of a coarse powder of a dark-brown or blackish and somewhat charred appearance. It is perfectly dry, and is added during the first stage when the boiled opium is beginning to get thick. The variable proportions in which it is mixed will appear from the record of several lots brought in the morning I was there:

---

[1] About 100,000 chests, containing 4,000,000 balls, are annually imported.

To 1 lot of 2 balls, weight 93.2 taels,[1] 6 taels of seconds were added.

To 1 lot of 3 balls, weight 147.6 taels, 8 taels of seconds were added.

To 1 lot of 4 balls, weight 199.4 taels, 20 taels of seconds were added.

To 1 lot of 1 ball, weight 48.4 taels, 20 taels of seconds were added.

To 1 lot of 2 balls, weight 99.7 taels, 10 taels of seconds were added.

To 1 lot of 1 ball, weight 48.9 taels, 20 taels of seconds were added.

The highest here given is twenty taels of seconds to one ball or thirty-six taels of crude opium, and the lowest two and two-thirds taels of seconds to one ball or thirty-six taels of crude opium.

It is evident from the almost universal practice of mixing seconds with the crude opium, as well as from its market value, that dealers consider that it contains a considerable quantity of the virtue of the opium. We may therefore reasonably infer that, in smoking, the alkaloids in which the virtue resides *are not destroyed by being charred.*

We will now follow the opium extract, thus prepared, as it passes through the pipe, and note the obvious changes which occur during the process of smoking. The smoker, lying on his couch or divan, with the pipe, lamp, and other implements on a tray, takes a portion of the opium-extract on the point of a wire, and warms it carefully over the flame of the lamp. He dips it again in the little jar of opium until the requisite quantity adheres, alternately warming it over the flame of the lamp, and pressing it on the flat bowl of the pipe, turning it over and over, and working it carefully on the end of the wire, until it is reduced to the state of a soft solid by the evaporation of a portion of the water contained in the semi-fluid extract. During this process, it swells up into a light porous mass from the formation of steam, and it must, therefore, be heated up to the boiling-point of water, and the presence of water prevents combustion.

When the little bolus is brought to the exact state fitted for smoking (being still a soft solid), it is worked into a ring around the wire, the point of the wire inserted into the round hole of the pipe, and by twirling the wire around while withdrawing it, the opium is deposited on the pipe and adheres to it, the hole in the ring of opium corresponding to the hole in the bowl[2] of the pipe. The stem being now applied to the lips, and the bowl held over the lamp, the flame is drawn in over the opium, converting into vapor all the volatizable material it contains. To understand what takes place, it is important to note that, preparatory to smoking, the opium has been slowly and carefully heated until steam has been formed in its substance. While in this heated state, and with water enough to prevent charring and to form more steam, the flame of the lamp is drawn over it by successive inhalations, producing the so-called smoke, and leaving a solid residue—the "in-she" or "seconds." The smoke is inhaled into the lungs, and comes in contact with the immense surface of the respiratory mucous membrane, and through it acts upon the system.

It has been denied by gentlemen who have paid some attention to the matter, that morphia and its compounds are volatilizable, and therefore that any of the alkaloids can be carried by the smoke into the system. However this may be, it is demonstrated a thousand times every day, by every whiff a Chinaman takes of his pipe, that certain constituents of the *watery extract of opium* are convertible into vapor; and the sallow complexion, stupefied visage, and wasted frames of old opium-smokers afford strong reason to infer, if they do not absolutely prove, that every whiff of the smoke or vapor conveys more or less of the alkaloids into the victim's blood.

The whole of the watery extract is, of course, soluble in water, and it is probable that the water—being rapidly converted into vapor by the flame of the lamp in the act of smoking—carries the alkaloids with it in the smoke. There is no proper combustion, and the so-called smoke is not smoke, but the watery extract converted into vapor. When all the water is exhausted from the bit of opium on the pipe, combustion might begin, but the smoker is skilled, from long practice, in withdrawing the heat at the proper time, so as to retain the value of the dregs, and thus diminish somewhat the outlay of an expensive habit.

The confused ideas which prevail as to what takes place in the act of smoking opium, and confounding it with the combustion of tobacco-smoking, have led to much misconception. Chemists need not have been puzzled about the volatilization of morphia and its compounds, had they first studied the conversion of the watery extract of opium into vapor by the process invented and practised so extensively by the Chinese, to the ruin of so many thousands of their race.

[If the reader desires to know more of the opium-habit of the Chinese, the amount of the drug smoked, its cost on the average *per capita*, the extremes of its consumption, and the curse it is to the nation, we may refer him to a review in The American Journal of the Medical Sciences for April, 1883, page 545, and particularly to a calculation made on page 550. It is impossible to estimate the amount of opium used in China, as the poppy plant is being more and more extensively grown in the empire every year, to the exclusion of cereals and other vegetable productions, and to the greater injury of the natives.]

---

[1] 12 taels = 1 pound.

[2] There is not, properly, a bowl, but a flat surface with a hole in it.

A CASE OF FOREIGN BODY IN THE AIR-PASSAGES FOR TWO YEARS; SPONTANEOUS EXPULSION.

By G. GRANVILLE FAUGHT, M.D.,
OF PHILADELPHIA.

The accidental inhalation of foreign bodies into the air-passages is so frequent that the following case is added to statistical surgery only on account of its remarkable nature. I am indebted to Drs. Casselberry and Radcliffe for notes on the case.

W. C., aged 46, had been an inmate of the Germantown Hospital for a year previous to the accident. He had been admitted for necrosis of the femur, and had been operated upon shortly after his admission. In November, 1880, he was allowed to visit his own home for the afternoon, and while there, and doing, as he expressed it, "a little fixing around," according to his own account, placed *three* tacks in his mouth. He was standing upon a chair, when it slipped; he fell, and the force of the fall ejected two of the tacks from his mouth, the remaining one disappearing down his throat. His impression was that it went down his "windpipe." He continued his work, however, and did not return to the hospital until about seven P. M., when he reported the occurrence to the nurse, and handed him the two tacks he had spit out. These the nurse immediately gave to Dr. William E. Casselberry, the resident physician. They were large tacks, about five-eighths of an inch in length. The patient persisted that the remaining tack, which was like the others, had gone down his "windpipe." He complained of some pain at a point beneath the upper portion of the sternum and to the right side. There was a slight, nervous cough, which he had not previously had. Physical examination of the chest disclosed nothing unusual. Nothing could be seen in the pharynx; the patient could swallow readily and without pain. No laryngoscopic examination was made, as there were absolutely no symptoms referable to the larynx.

A consultation of the staff was called that evening, and they summoned the consulting surgeons. Dr. William Hunt responded. At both consultations it was decided to do nothing, as there was no evidence as to the position of the tack. The nurse was directed to search carefully for the tack in each of the patient's stools, and after the first day, the patient was allowed to go about as usual. At the end of forty-eight hours, the tack was found in one of his stools; it resembled the other two, and was slightly corroded. The patient also saw the tack removed from the stool, and was greatly rejoiced to be rid of it. Dr. Casselberry informs me that the nurse was a reliable man, who had occupied his position about two years, and was not likely to have practised any deception, even if such were possible. The patient complained of no further symptoms referable to the tack during the time—about one year—that he remained under Dr. C.'s observation.

During my own service of one year at the hospital, the patient was troubled at times with a slight hacking cough, principally at night, and without expectoration. Several times during the year he had a sudden and severe chill which could not be accounted for by any condition of his leg, the bone of which was still in a necrotic condition.

In October, 1882, Dr. McCluney Radcliffe succeeded me at the hospital. One evening, late in November of the same year, Dr. Radcliffe was summoned to the patient, and found that he had just had a severe chill. The following morning there was another chill, but feeling comparatively well towards evening, the man concluded to get up and sit by the open fire in the ward. While seated on the side of his bed, leaning forward, and engaged in tying his shoe, he coughed suddenly and violently, and ejected from his mouth a tack, exactly similar to the one swallowed two years previously. The tack was corroded and covered with mucus. The patient was as much astonished as the nurse and fellow-patients, and remarked that he would have been very miserable had he known that it was "there." The expulsion of the tack is beyond all question of deception. Since the occurrence, the patient has been free from all cough, and has had no repetition of the chills. Physical examination of the chest gives negative results.

142 North Fifteenth St.

HOSPITAL NOTES.

VIENNA GENERAL HOSPITAL.

Service of Prof. Neumann.

(Specially reported for The Medical News.)

MERCURIFORM AMIDE.

Mercuriform amide is the name of the remedy which Prof. Neumann is now trying upon a large scale as an anti-syphilitic. The agent was produced early in the present year in Liebreich's laboratory, but the process of its manufacture is a secret. As received in Vienna from Berlin, it is a one per cent. solution, and is without color or odor.

The remedy is exhibited hypodermically in quantities of 1 c.c. While the drug is efficacious in causing the rapid disappearance of syphilitic efflorescences, its absorbent effect upon scleroses is not comparable with that of mercurial inunctions.

Two very unpleasant effects have been noticed. *Pain* following the hypodermic injection is severe, of a peculiar character, and frequently lasts the entire day. In a number of cases abscesses and diffuse cellulitis of an alarming severity have been provoked. *Salivation* occurs more rapidly after mercuriform amide than after any other known form of mercury. Twelve hypodermic injections have been sufficient in a number of cases to seriously affect the gums. At time of writing, most cases of recent syphilis in Prof. Neumann's wards are being treated either with an ethereal solution of iodoform (one to seven), or with mercuriform amide.

MEDICAL PROGRESS.

The Action of Antiseptics Used as Dressings.—M. Gosselin has recently made some interesting experiments on this subject, which consisted in spreading on a plate of cork pierced by an opening, the transparent membranes of certain animals, on which one may see, under the microscope, the capillary circulation. He employed, generally, the transparent membranes between the toes of frogs; in three other cases the mesentery of rabbits, frogs' mesentery, and the bladder of a mouse. When the membranes were well spread out under the microscope (about two hundred powers), the movement of the blood in the capillaries was well seen, and the antiseptic substance was placed on the membrane. The experiments were made with carbolic acid solution, pure alcohol, alcohol diluted with water, and camphorated brandy. The results were as follows:

1. *With carbolic acid solutions 1-20 and 1-40*, the circulation was suddenly arrested in a few seconds after the first application, slowly began again, and then ceased suddenly after a second or third application. With a 1-40 solution it was necessary to make three applications in four or five minutes, to completely arrest the movement of the blood. On the next day the circulation had not recommenced, though the blood-vessels were clearly seen. The absence of any current was attributed to coagulation of the blood in the capillaries; at the end of the third or fourth day, the membranes were brownish, shrivelled, and in process of exfoliation, that is to say, gangrenous, and the animal died, probably from carbolic acid poisoning in the case of the frogs, and from the traumatism in the case of the case of the other animals.

2. *Carbolic acid solution of 1-60.*—The results were practically the same as with the 1-40 solution, except that the processes took place more slowly.

3. *Carbolic acid solutions of 1-80 and 1-100.*—The arrest of the circulation took place still more slowly, and was only complete at the end of about fifteen minutes. In one case, after having been arrested, the circulation was found reëstablished on the second and third days, and was again set up after having been arrested a second time.

4. *Alcohol at 86°.*—The immediate results were analogous to those with 1-20 solutions of carbolic acid, except that the arrest of circulation was not so sudden.

5. *Alcohol and water in equal parts.*—At first there was a general slowing of the current, and then, in about ten minutes, and after four applications, complete arrest in several vessels, but no arrest in others. This incomplete arrest of the circulation persisted for several days, but there was no gangrene.

6. *Camphorated brandy.*—The same results were obtained as with carbolic acid solutions of 1-60 and 1-80, and with dilute alcohol, immediate slowing of the blood-current, and complete cessation in twelve or fourteen minutes after four applications. On the second and third days the circulation was not reëstablished, but there was no gangrene. With camphorated brandy and water, in equal parts, the circulation was not arrested.

From these experiments it appears that on the application of an antiseptic, the circulation is arrested in the capillaries by the more or less rapid coagulation of the blood. It is more quickly arrested when the antiseptic is strong. In one case the circulation was restored on the day after its arrest. M. Gosselin attributes this arrest to the coagulation of the blood, caused by contact with the antiseptic substance which had penetrated the thin membranes and capillary walls.—*Gaz. Hebdom.*, No. 36, 1883.

THE PRODUCTION OF ANÆSTHESIA IN ORGANIC AFFECTIONS OF THE ENCEPHALON.—In a series of communications to the Academie de Médecine, M. BROWN-SÉQUARD attempts to show that anæsthesia, paralysis, and amaurosis produced by an organic affection of one of the various parts of the encephalon, depend generally, if not always, upon other causes than have been assigned to them, that is to say, a loss of function of the part destroyed. Numerous experiments on dogs, rabbits, and Guinea-pigs show that anæsthesia due to an organic lesion of the brain may disappear suddenly, or very rapidly. He then gives a series of arguments, the outcome of several thousand clinical observations made during the past thirty years.

1. All parts of the encephalon may produce anæsthesia. This explains how localists, committing the fault of thinking that a function which disappears necessarily appertains to the organ found injured, have advanced the opinion that the centre of perception of sensitive impressions, locate anæsthesia in the cerebellum, the optic tract, the posterior lobe, in certain convolutions, etc. Facts authorize us in placing that centre in the so-called motor region of the base of the brain, or of the internal capsule, in one or the other of the corpora striata, in all parts of the anterior lobes, middle or sphenoidal, etc., since lesions localized in one of these regions have sometimes produced anæsthesia.

2. Each portion of one-half of the encephalon may be destroyed without causing anæsthesia. The lesion itself may be quite considerable without causing symptomatic evidence of it. Richet has published a case of destruction of the middle lobe and a large portion of the posterior, without the production of anæsthesia. Abercrombie, Rostan, Porta, and other observers have found that a hemisphere may be almost entirely destroyed without causing anæsthesia.

3. Of the similar parts of the two sides of the encephalon, there are comprised those which are supposed to serve for the perception of sensitive impressions, and which may be destroyed without giving rise to evident anæsthesia.

4. Instead of producing anæsthesia, destructive lesions of parts, which are believed to be centres and conductors of sensation, sometimes give rise to hyperæsthesia.

5. In more than one hundred cases, lesions of the most different parts of the encephalon have given rise to anæsthesia on the injured side, the side upon which it should not have appeared.

6. A considerable destructive lesion of the parts considered as centres or conductors of sensitive impressions, instead of producing anæsthesia of the two limbs of the opposite side, has sometimes only produced it in the arm or the leg.

7. In certain cases of encephalic lesion, anæsthesia, instead of being total, is only present as regards certain characters of sensitive impressions (tactile, painful, thermal).

8. Anæsthesia may be produced only on one side of the body when the lesion reaches the same depth of the two similar parts at the base of the brain on the two sides.

9. Experiments on animals (and in harmony with very many clinical facts) show that transverse section of a lateral half of the base of the brain, from the bulb to the internal capsule, inclusive, give very varied results as to the production of anæsthesia. While, in every case, the experimenter may cut the entire mass of fibres believed to be conductors of sensitive impressions coming from opposite sides of the body, he finds, on the one hand, that each of the portions may be cut without causing evident or persistent anæsthesia; and on the other, that certain portions, especially the internal capsule, determine anæsthesia much more oftener than others.

If, in the face of these facts, one persists in considering anæsthesia of organic encephalic cause as demonstrating that the injured part is the conductor of or the centre for the perception of sensitive impressions coming from one-half of the body, he is necessarily reduced to upholding one of two absurdities—first, that each part of the encephalon is the only path for the transmission or centre for the perception of sensitive impressions; or, second, that no part of the encephalon is a conductor or perceptive centre of sensitive impressions.—*Gazette Méd. de Paris*, No. 27, 1883.

Aphthous Vulvitis of Children.—**Sarazin**, *Thèse de Paris*, July, 1883, gives the following conclusions regarding this affection. 1. Aphthous vulvitis is a well-characterized disease. It is peculiar to little girls from two to five years of age. Rare in private practice; it is observed especially in hospitals.

2. Measles is the principal cause of this affection. It furnishes two-thirds of the cases.

3. Gangrene of the vulva has most frequently for its point of departure aphthous vulvitis.

4. The prognosis, which was unfavorable before the employment of the iodoform treatment, has become quite favorable since the introduction of this agent as a topical application.

5. The treatment consists in sprinkling the affected parts with iodoform powder, and keeping them separated with pledgets of lint. The internal administration of tonics is a useful adjuvant of local treatment.—*Journal of Cutaneous and Venereal Diseases*, October, 1883.

Extravasations of Blood into the Labyrinth Produced by Quinine and Salicylic Acid.—Experiments made by **Kirchner**, of Würzburg, on animals have demonstrated to him that the auditory troubles supervening on the ingestion of large doses of quinine and salicylic acid are produced by extravasations of blood into the various parts of the ear.

The functional disturbances are especially grave when the exudation is into the labyrinth; in the middle ear less marked and later symptoms are produced, and the prognosis is always more favorable.

Beside the anatomical lesions of the mucous membrane of the tympanum—red color and slight reddish-yellow exudation with considerable engorgement of the vessels—Kirchner has observed hyperæmia and hemorrhage into the labyrinth in the animals upon which he experimented. In the brain and on the internal face of the skull there was considerable engorgement, notably at the level of the temporal bone; the vessels of the dura and pia mater were markedly engorged. The nervous substance presented no important modifications.

With the microscope, one can see, in the case of animals subjected to these experiments, a marked vascular injection with hemorrhagic extravasations, both into the cochlea and the semicircular canals. The small nerve-filaments subjacent to the fibres of the canal, appear, under these circumstances, to undergo equally profound alterations in their structure and function.

Kirchner gives the history of a case of deafness and cephalalgia, caused by salicylic acid, with vertigo and difficulty of walking straight. Paracentesis and frequent injections of air caused these symptoms to disappear rapidly, with the exception of a slight deafness on one side.—*Annales des Mal. de l'Oreille, du Larynx, etc.*, No. 4, 1883.

Hypogastric Cystotomy as a Substitute for the Perineal Operations.—**Prof. L. Villeneuve**, in an article on this subject, draws the following conclusions:

1. The hypogastric operation, which hitherto has been used only exceptionally, appears to be coming into more general, though not exclusive, use for the performance of cystotomy.

2. It should be performed with the newly perfected instruments made for it; ballonnement (ballooning the rectum by means of an air-ball), vesical injection, pushing back the peritoneal cul-de-sac, connected siphon-tubes, and antiseptic precautions and dressings.

3. Suture of the bladder should be discarded, but immediate union should always be attempted, which, if realized, shows the great superiority of the hypogastric operation.

4. The hypogastric operation is one of necessity in cases of large and encysted stones, intolerant bladder, and impermeable or strictured urethra or vagina.

5. Especially is the operation to be recommended in old persons and adult men, and in those in which lithotrity is not applicable, and which up to the present time have only been treated by the different perineal operations.

6. In male infants, it may be presumed that it is at least equally as good as the perineal operations. But the happy results obtained by these operations for a long time, render the indications of the high operation in these cases less pressing.

7. In female children, and females at the age of puberty, the hypogastric operation is the method of choice.

8. In married women the question of choice between the hypogastric and vaginal operations is undecided.

9. An inflammatory affection of the uterus, marked deformity of the bladder on account of deformity of the uterus, and notably cystocele, should lead one to adopt the high operation. In adult females the hypogastric operation should be preceded by dilatation of the urethra.

10. Constitutional and diathetic affections have no special indications in selecting the method of operation. The same holds good for lesions of various branches of the sympathetic plexus.—*Revue de Chirurgie*, No. 9, 1883.

Carbolized Sawdust in Antiseptic Surgery.—**Mr. H. P. Symonds**, Surgeon to the Radcliffe Infirmary, advocates the use of this material as a dressing for wounds. He says: One of the drawbacks of the usual antiseptic dressing is the rapidity with which the discharges come through on the first day or two after operation, often necessitating the redressing of the case within a few hours. To prevent this, and yet not to interfere with the aseptic condition of the wound, is a distinct advantage both to the patient and the surgeon. The material I have used recently in a considerable number of cases is coarse sawdust, soaked in (1 in 10) solution of absolute phenol and spirit of wine, then allowed to dry slightly so that the spirit may evaporate, leaving the sawdust charged with carbolic acid. When used it is enclosed in a bag made of several layers of gauze, and applied outside the deep dressing, the usual external dressing being put over it. The sawdust thus takes the place of the padding of loose gauze which is generally used. Its absorbent power is very great, and it has the additional advantage of keeping up an equable pressure on the divided tissues. I find that fourteen ounces of sawdust will readily absorb about one pint of fluid.

He reports five cases, two of amputation, two of operation for tumor of the mammary glands, and one of compound dislocation of the elbow, in which it was used. In all these cases primary union took place without any formation of pus. In only one did the temperature reach 100°, and that on the day after operation, after which it became normal. I have not quoted these cases as being at all remarkable, but merely as common instances in antiseptic surgical practice in which the sawdust dressing was used. Surgeon-Major Porter, in *The Surgeon's Pocket-book*, states that he has used sawdust as a dressing in suppurating offensive wounds; but I am not aware that it has been tried, when prepared in the way I have described, in antiseptic dressing. The three points in its favor are its powerful antiseptic qualities when saturated with carbolic acid, its great absorbent power, and its adaptability to any surface. I may add that the sawdust should be coarse, as I find that if it is very fine it passes through the gauze and irritates the skin.—*Lancet*, September 22, 1883.

EFFECT OF METALLIC POISONS ON THE SPINAL CORD.—The affections of the nervous system produced by contamination with certain metals, as lead and mercury, have been studied more extensively clinically than pathologically, and even yet it may be held to be undetermined whether the action of the poison is upon the peripheral or the central apparatus. Dr. Popow has recently put on record the results of an anatomical investigation upon animals (chiefly dogs) poisoned by arsenic, lead, and mercury respectively (Virchow's *Archiv*, 93, Heft 2), and in most cases he was careful to administer the poisons in varying quantities, so as to contrast the effects of acute and chronic poisoning. The general result of his inquiry goes to show that marked changes of a inflammatory character occur in the spinal cord, both in the gray and white matter, under all these conditions. In acute arsenical poisoning the spinal cord was softened, the gray matter especially being reddened and swollen; there was proliferation of the nuclei of the bloodvessels, and an exudation of a peculiar hyaloid substance. The nerve-cells were swollen, their processes dwindled, and their protoplasm granular or vacuolated, whilst in the white columns the axis-cylinders showed irregular thickenings. In chronic poisoning it was difficult to discriminate between the two portions of the cord, the divided surface having a yellowish-red color throughout; the walls of the vessels were thickened, and hyaline masses abounded; the nerve-cells vacuolated, or shrunken and pigmented; whilst free pigment masses, representing traces of hemorrhage, occurred throughout the sections. In other words, there is, in poisoning by arsenic, a central myelitis at first, and later a diffuse myelitis. Very similar changes were found in the spinal cord after poisoning by lead—namely, exudation from bloodvessels; a general affection of the nerve-cells, beginning as cloudy swelling, and passing into atrophy and pigmentation; and inflammatory swelling of the axis-cylinders. In mercurial poisoning, the early changes consist of hyperæmia of membranes and of the cord, followed by hemorrhages, inflammatory exudation, and changes in the nerve-substance hardly differing from those seen in the other two cases. In each instance the peripheral nerves and the nerve-roots showed no alteration, so that the conclusion is that the paralysis, spasms, etc., characteristic of the toxic effects of these metals, depend upon a central rather than a peripheral disturbance, all the degenerative changes described as occurring in nerves and muscles being strictly deuteropathic.—*Lancet*, September 22, 1883.

INDICATIONS FOR TRACHEOTOMY IN LARYNGEAL TUBERCULOSIS.—Although not often indicated in laryngeal tuberculosis, there are cases in which tracheotomy is necessary. This occurs when attacks of suffocation come on with violent orthopnœa. The situation of the patient is desperate, and the operation must be performed without hesitation. These cases are especially seen in acute phthisis, with caries of the arytenoid cartilages. Besides these cases, the operation may also be performed in chronic phthisis, when the laryngoscope, enabling us to judge of the progress of the lesion, will show the precise time for operating.

It is also observed that in certain circumstances there is alteration of the cricoid and thyroid cartilages; but it is only in cases in which there is caries *en masse* of these cartilages that attacks of suffocation come on. The above-mentioned lesions may be diagnosticated by increase in the size of the larynx, by fistulæ, and by direct examination, which warn the physician to be prepared for any emergency. The operation may prolong life for some time, for observation shows that these grave disorders may be only accompanied by slight pulmonary lesions. In other cases, phthisis produces lesions of the mucous membrane which are indications for tracheotomy. M. GOUGENHEIM has seen cases of true tumors, analogous to cancer, which, limited at first, invade the whole larynx with a fatal result. He reminds us that infiltration of the aryteno-epiglottic folds, called œdema glottidis, is often seen in cachectic and non-dyspnœic diseases, and does not require the operation.

Finally, lesions of the vocal chords are often indications for the operation; sometimes they are tumefied, but mobile, and the danger arises from progressive sclerosis of the glottis; at other times, they are less tumefied, but immovable and near together, the immobilization being due to nervous action (paralysis or contracture). The patients are then in a state which Sestier and Trousseau attribute to œdema of the glottis. Gougenheim has observed compression of the recurrent nerves in a case of this kind. Tracheotomy is obligatory, but here pulmonary lesions are certain, and the patients live but a short time.—*Gaz. Méd. de Paris*, No. 35, 1883.

THE CENTRE OF LANGUAGE.—PROFESSOR RÜDINGER, in a recent contribution to the anatomy of the centre of language, is of the opinion that if the centre of language is in the third frontal convolution, one should find anatomical differences according to the degree of the intelligence of the different living beings. Rüdinger has worked up the matter quite thoroughly in cases of diversely intelligent men, microcephalics, deaf-mutes, and apes of various kinds. In the orang-outang and chimpanzee this convolution is at the surface of the brain, but in the gorilla at the bottom of the fissure of Sylvius. In cases of microcephalic infants who could not talk, this convolution was rudimentary. In a Hottentot it was very small and very short, and was but little developed in a negro's brain.

A comparison of this convolution in the brains of men and women showed great individual differences. The volume of the convolution, and the number of folds and sulci are certainly augmented in proportion to the degree of intellectual activity. In the case of an advocate, distinguished as an orator, Rüdinger found that the third frontal convolution of the left side measured twenty-three centimetres, while that of the right measured only sixteen. There was an equally remarkable difference in the case of the German philosopher Huber. In the case of Buhl, celebrated for his works in pathological anatomy, the third *right* frontal convolution was much larger; a fine performer on the violincello, he naturally used his left hand a great deal in touching the strings.

In all the men of inferior culture, the symmetry is reëstablished between the two convolutions. In deaf-mutes, the third left frontal convolution was *always* small, while on the right side it was as large or a little larger. The fact established by these researches, says Rüdinger, is that apes and microcephalics have only a rudiment of the third left frontal convolution; that in deaf-mutes this convolution, though not rudimentary, is very simple; and that in orators it presents an extraordinary development. The hypothesis, then, that the faculty of language is situated in the lateral part of the frontal lobe is more than probable.—*L'Encéphale*, No. 3, 1883.

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

Communications are invited from all parts of the world. Original articles contributed exclusively to The Medical News will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

Subscription Price, including Postage,

Per Annum, in Advance, ...	$5.00.
Single Copies, ...	10 cents.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in registered letters.

Address, HENRY C. LEA'S SON & CO.,
Nos. 706 & 708 Sansom Street,
Philadelphia, Pa.

SATURDAY, OCTOBER 13, 1883.

IS EXTIRPATION OF THE CARCINOMATOUS RECTUM A JUSTIFIABLE OPERATION?

In the third part of vol. xxix., 1883, of the *Archiv für klinische Chirurgie*, will be found a report from the pen of his assistant, Dr. Heuck, of the experience of Professor Czerny, of Heidelberg, in regard to the operative treatment of carcinoma of the rectum, from which we glean many interesting facts that will be utilized, in common with the statistics furnished by other operators, in our effort to solve the query which constitutes the title of this article. In the issue of The Medical News of September 22, we briefly indicated that extirpation of the thyroid gland for malignant growths was attended with a mortality of 57 per cent., and in the subsequent number we expressed the opinion that the vaginal extirpation of the uterus for carcinoma was an operation full of promise. As the entire subject of the removal of the various organs for carcinoma is one of very great practical interest, our readers may look for an additional article in the near future on resection of the cancerous pylorus.

The experience of Czerny relates to 25 extirpations of the rectum, of which 1 died of septic peritonitis. In 15, or 60 per cent., there was recurrence, which took place, on an average, in a little more than eleven months. Of the 9 patients who remained free from a return of the disease, 2 were living more than four years after the operation, 1 was living at the end of three years and eight months, 1 was alive at the expiration of two years and a half, 2 were well at the end of two years, 1 was alive at the conclusion of one year, and 2 were alive at the end of six months. In 1 of the cases the disease had existed before removal for four years; in 3 for three years; in 3 for two years; and in 2 for less than a twelvemonth. These facts are remarkable, since they show that a carcinomatous rectum of long standing may be extirpated with a very fair prospect for final relief.

The death-rate of the operation appears to be improving with increased experience. Thus, Billroth, up to 1876, had lost 19, or 42.2 per cent., of his 45 cases; and Rose, up to 1877, had lost 8, or 50 per cent., of his 16 cases. Kocher, on the other hand, up to 1879, had lost only 2, or 20 per cent., of his 10 cases; while, as we have just pointed out, Czerny, up to 1882, had lost only 1, or 4 per cent., of his 25 cases. The success of the Heidelberg surgeon will be seen to be the more astonishing when we inform our readers that, in consequence of the high position of the neoplasm, he opened the peritoneum in 11, or 44 per cent., of his cases. In 6 the wound was closed with sutures, and it was left open in 5, the fatal case coming under the latter category.

The average duration of life in carcinoma of the rectum has been ascertained to be two years. Hence, with the results of Czerny to guide us, we are justified in concluding that the six cases which were living free from recurrence for periods varying from two to four years probably represent permanent recoveries. Lest this number may be deemed too limited to represent the actual state of facts, we have to add to the cases of Czerny 198 additional ones of which we have a record. Of the entire number, or 223, 180 recovered, and 43, or 19.3 per cent., died. Of 142 in which the final result is known, 64 remained well for periods varying from two months to ten years, and 78, or 54.9 per cent., recurred. Omitting the cases in which the recovery at the date of the last report had lasted only from two to sixteen months, we have 35 cases in which there was no reproduction of the disease for two years and upwards, 13, indeed, having remained well for between five and ten years, so that 15.7 per cent. of the entire 223 were in all probability permanent cures. If three years and upwards be regarded as still better representing a probable immunity from recurrence, the 28 cases which come under this category show 12.5 per cent. of cures; while the 21 cases which represent four years and upwards make the number of cures 9.4 per cent. With these results before us, and they are far better than have as yet been secured for carcinoma of other organs, we have no hesitation in answering our self-imposed question in the affirmative.

In conclusion, we may add a word in regard to the operation, as the surgeon may be tempted to save a strip of apparently sound mucous membrane or a piece of the sphincter, but the experience of Czerny is condemnatory of this practice. Thus, in 8 cases in which all the tissues were removed, recurrence was witnessed in only 3; while in 8 others in which portions of the mucous membrane or the margin of the anus were left, recurrence occurred in 6. In addition to these pregnant facts, Czerny teaches, and Billroth agrees with him, that, by trying to save too much, the discharge of the secretions is interfered with, and the dangers of septic infection are greatly increased.

CALCULOUS DISEASE OF THE PANCREATIC DUCT.

The subject of calculous disease of the pancreatic duct has always been shrouded in a good deal of darkness, partly because the isolated instances of it have occurred at such long intervals, and the published accounts of them have been so scattered throughout medical literature that it has been impossible for any one to compare them. In The American Journal of the Medical Sciences, however, for October, will be found a most valuable paper on this subject by Dr. George Woodruff Johnston, in which have been collected, probably without exception, all the published cases of this disease. The paper is part of an inaugural thesis, written by Dr. Johnston for the doctorate in the University of Pennsylvania. It bears the stamp of painstaking and laborious research, and is worthy of careful perusal.

There are three modes in which calcareous concretions are found in the ducts of the pancreas. 1. As free concretions. 2. As calculous incrustations of the duct-walls. 3. As "acne pancreatica." Of these the first include by far the greatest number. By "acne pancreatica" is meant a condition so named by Klebs, in which the normal pancreatic secretion is converted into a thick chalky pap. Of this the instances are few. The free concretions are found anywhere in the pancreatic duct or its branches, or in both.

The chief cause of pancreatic calculi is some obstruction to the free outflow of the pancreatic secretion which favors the accumulation of the pancreatic juice and subsequent precipitation of its inorganic constituents. But cases have been reported of calculous disease of the pancreas where no obstruction of the ducts was present, showing that some other influence than obstruction must be at work to produce such a change in the composition of the pancreatic fluid as to cause a precipitation of inorganic matters and the formation of calculi.

That a change in the normal composition of the fluid must take place, is evident from a comparison of the composition of the calculi with that of the fluid. The former contain large proportions of lime salts—phosphates and carbonates usually—where analyses have been made, about ninety per cent., whereas the pancreatic fluid contains but traces of lime. The same difference, although in less degree, exists between the composition of salivary calculi and the salivary secretion. The causes of these changes in composition of the pancreatic and salivary fluids which result in such precipitation, says Dr. Johnston, "must still remain a matter of doubt." He says it is possible that physiological variations which are occasionally present, may become sufficiently permanent to permit the precipitation to occur; or that local changes in the secreting tissue of the pancreas or its ducts, may produce such an influence upon the secretion as would lead to the crystallizing out of its less soluble salts. But he has shown us that the composition of the resulting calculi is different from that of the fluid, that the salts indeed which make them up are scarcely represented in the normal composition of the fluid. So that there must result, first, a fluid which differs in composition from true pancreatic fluid. We think it much more likely that his second alternative, that local changes in the secreting tissue of the pancreas are at the bottom of these changes in the composition of the fluid, is the correct one. And we think it likely that these changes are the result of inflammation. Everywhere do we see that inflammatory new formations present a tendency to calcareous infiltration; and we know well that obstructed secretion everywhere gives rise to a certain degree of inflammation. Hence it is not unlikely that in the cases in which the calculous formation is an incrustation of the duct walls, it results directly from the calcareous infiltration of the inflammatory product itself, or of the tissue permeated by it, just as do the calcareous plates in a chronic endarteritis. Such inflammations, also, may be expected to change entirely the composition of an otherwise normal secretion. In this way, too, may be best accounted for those calculous formations which occur without obstruction in the pancreatic ducts. They are the result of inflammatory processes excited by other causes than obstruction.

Of some practical importance in connection with this subject is the question whether pancreatic calculi are ever discharged into the duodenum with the symptoms which attend the passage of biliary calculi—pain, colic, and jaundice. This cannot be denied, as it is evident that the same symptoms must accompany such discharge. On the other hand, since the symptoms would be identical, it would be impossible to decide between the two, except on the ground of the much greater frequency of hepatic colic. Should, however, such symptoms be associated with an evident tumor to the left of the umbilicus, suspicion of pancreatic calculus would be justified. But we do not know that the treatment would be different if the diagnosis could be made. In one case perforation of a pancreatic calculus caused fatal peritonitis.

The presence of pancreatic calculi must, of course, give rise to secondary results, among which dilatation and the formation of cysts and inflammation are the most likely. The degree of the former may be anything between that of a goose-quill and that of a child's head, and the latter may result in enlargement, atrophy, or suppuration. All of these alterations may give rise to physical conditions which may demand rare skill in their diagnosis from other abdominal affections.

The interesting question as to the relation of pancreatic disease to mellituria is referred to by Dr. Johnston without, however, adding to our knowledge of the subject. In four of the cases of pancreatic calculous disease, diabetes was supposed to be the cause of death, Dr. Johnston is inclined to ascribe the phenomenon of glycosuria to secondary changes in the cœliac ganglion produced by the presence of a pancreas made large and hard by the presence of calculi; while atrophy of the pancreas will follow changes in the cœliac plexus, as atrophy of the submaxillary gland will follow section of the vaso-motor nerves supplying it. But that there is something more than the effect of pressure of an enlarged pancreas which produces the glycosuria in cases of diseased pancreas, we think is evident from a case of our own—a case of most obstinate diabetes, attended with fatty diarrhœa, and terminating fatally—in which the autopsy revealed calculous plates in the duct walls, but no marked enlargement—at any rate, none sufficient to produce pressure upon the cœliac plexus. In such a case as this, however, there might still be a reflex influence from the pancreas to the cœliac ganglion which would cause the glycosuria.

Notwithstanding the supposed frequent association of pancreatic disease with fatty stools, but three of the cases collected by Dr. Johnston exhibited this symptom. Of these, in two there was also fat in the urine, the quantity in one instance being so great that it made its appearance one month before it was detected in the stools, and in such quantity as to float, when cool, in greasy flakes upon the surface. We can scarce conceive such a condition as this without supposing some communication between the intestinal canal and the urinary passages.

The profession is much indebted to Dr. Johnston for his paper. We hope it will so direct attention to the subject that further accurate knowledge will grow out of it, and that not only more accurate diagnoses will become possible, but some therapeutic measures may also be evolved.

PORRO-CÆSAREAN SECTION.

In another column we present the record of the fifth Porro operation performed in this country. The prognosis in this case was necessarily unfavorable. The age of the woman, her life of poverty and intemperance, the condition of her arteries, and, above all, the presumed change in her kidneys, made the risk in operating upon her unusually great.

Of 116 Porro and Porro-Müller cases, tabulated by Dr. R. P. Harris, in The American Journal of the Medical Sciences for October, 1883, where the pedicle was dressed externally; operated upon in Italy, Austria, Germany, France, Belgium, Switzerland, Great Britain, Russia, Holland, Spain, and the United States, this one stands alone in regard to the kidney complication, and its effect as a factor in leading to a fatal issue. But for this, the case would have compared favorably with many which have recovered in European hospitals. The fact that the patient died comatose; that her kidneys secreted but +℥iij of urine in forty-two hours, and that these organs presented evidences of disease to the eye and under the microscope after her death, shows the extra risk in the operation performed upon her. The subsequent death of the fœtus was no doubt due to its imperfect nutrition in utero, to its being somewhat premature, and to the unhealthy state of the mother. Where the mother has been healthy, and her own and her child's life saved under abdominal delivery in this country, the life of the latter has usually been prolonged, and even in cases where the mother was lost, the child has been saved to grow to maturity. Several of the subjects of Cæsarean delivery have reached advanced life in the United States, the oldest known being sixty-eight and seventy-four years respectively. Several of the children have been heads of families, and one in this city is now forty-eight years old, and has given birth to eight children.

The Porro operation thus far in the United States presents from its results no special advantage over the Cæsarean section (old style); but the results in European hospital practice show very decided advantages in a largely lessened mortality. In the United States, no hospital Cæsarean case has resulted in saving the mother. the record standing six operations and six deaths. The Porro-Müller operation of Dr. Parish is the first of its kind in an American hospital, and not by any means a test case. In all obstetrical cases in our maternities requiring abdominal delivery, we believe the result obtained with the Porro operation in the old Santa Caterina Hospital, of Milan, of saving 75 per cent. should be taken as an example against our universal death-rate in such institutions with the old method; and the operation of Porro should be put to the test where the disadvantages incident to delivery in hospital as compared with the advantages in private practice are to be overcome.

THE BRAIN TRANSFIXED BY A RAMROD, WITH RECOVERY.

It has long been known that the integrity of the cerebral hemispheres is not essential to the continuance of life, and that they may undergo considerable morbid change or mechanical injury, accompanied by extensive loss of substance, without fatal result, or even serious impairment of the vital functions.

Bearing upon this point, Fischer reports, in the *Deutsche Zeitschrift für Chirurgie* (Bd. xviii.), an interesting case of an accident which occurred during the unloading of a carbine, by which the brain was transfixed by a ramrod, without fatal result. The ramrod, which was of iron, entered the thorax to the right of the fourth dorsal vertebra, passed upwards in the deeper tissues of the right side of the neck through the base of the skull and brain, and projected to the extent of thirty centimetres out of the left side of the head. After an opening had been made into the neck, the rod was driven backward through the skull, by the strokes of a hammer, and taken out at the neck. The patient recovered, except that he remained blind in the right eye.

An effort to imitate the injury on the dead body showed that in the neck no important vessel or nerve was injured, that the instrument entered the cavity of the skull through the right optic foramen, tore the optic nerve, and then entered the space between the two frontal lobes, and penetrated the brain only to the slight extent of three centimetres, and wounded only the anterior edge of the left superior frontal convolution.

This case is similar to that reported by Bigelow in The American Journal of the Medical Sciences for July, 1850, in which a pointed iron crowbar was driven through a man's head by the premature explosion of a blast. The bar entered the left side of the face, near the angle of the jaw, and passed obliquely upward inside the zygomatic arch and through the anterior part of the cranial cavity, emerging through the frontal bone in the median line, in front of the union of the coronal and sagittal sutures. This patient became delirious and comatose, but subsequently also recovered, although with loss of vision in the eye of the injured side, and lived for twelve years.

THE RÔLE OF HYDROCHLORIC ACID IN GASTRIC DIGESTION.

The office of free hydrochloric acid in stomach digestion has been the subject of investigation lately by an ingenious method. By means of Kussmaul's pump, the contents of the stomach are withdrawn at any stage of digestion for the purpose of study. A new reaction for the acid now enables the operator to distinguish with some precision hydrochloric from any organic acid. By the application of this method, it has been ascertained that hydrochloric acid disappears from the stomach-juice in typhus and typhoid fevers, to reappear again when convalescence is established. In carcinoma, the absence of free hydrochloric acid has been demonstrated. This fact is not explained by the condition of feebleness, but is clearly due to the cachexia. Hence, if in a case of extreme weakness due to stomach-disease, free acid is present in the stomach juice, the case is not one of cancer. The disappearance of the acid cannot be referred to the chemical action of the cancer-juice, since the acid is wanting when there is no ulceration. In this way Van Velden diagnosticated cancer, and the autopsy confirmed his opinion. In another case, the symptoms of a neoplasm being present, cancer was excluded because of the presence of free acid in the stomach-contents.

In another series of researches, Van Velden has shown that saliva mixed with the aliment entering the stomach, does not act on starch when there is no free hydrochloric acid. There are, hence, two phases or periods of the stomach digestion: the first, when the action of the saliva still continues to be manifest; the other coincides with the presence of free hydrochloric acid. It is in the course of the latter that peptones are produced in quantity.

These observations have not gone unquestioned. Ewald maintains that the reactions relied on by Van Velden are vitiated by the presence of albuminates, blood, etc.; that in many cases of carcinoma the reaction of hydrochloric acid still occurs; and that the two periods of stomach digestion do not really exist. Van Velden in reply, however, reaffirms his original positions. The questions thus raised must therefore be regarded as still *sub judice*, but they offer an interesting subject for further inquiry.

CONTINUED FEVER AT ASBURY PARK AND OCEAN GROVE.

A few cases of continued fever and two recent deaths seem to show that Asbury Park and Ocean Grove have but just escaped a typhoid epidemic. The facts, however, are creditable to the health authorities. The trouble arose with those householders who would not connect with sewers, or who had, before the sickness, been notified as maintaining nuisances. In one case, a well was only eighteen inches from a boarding-house water-closet. The examination of the water showed the false security of a driven well when located near surface nuisance. Two cases have occurred in which driven wells have become saltish. In both cases the next neighbor kept an ice-cream saloon, and threw the freezing mixture on the ground. The other case of death occurred where the rear wall of the hotel formed the wall of the privy, the contents of which had leaked into the cellar so as to become ponded.

Engineer Owen, of New York City, has just made an elaborate report of a plan for the sewerage of Orange City. It contemplates the filtering, precipitating, and utilization of the sewage.

REVIEWS.

De L'Excision du Goître Parenchymateux. Par Le docteur Paul Liebrecht, Assistant d l'Universite de Liége. (Ext. du Bul. de l'Acad. r. de Médecine de Belgique, 3e Sér., t. xvii. No. 3.) 8vo. pp. 270. Bruxelles: H. Manceaux, 1883.

Excision of Parenchymatous Goitre. By Dr. Paul Liebrecht, etc.

This work contains, besides a review of the history of the subject and a careful description of the method of operating, a detailed account of 322 operations for the excision of goitre, with a careful analysis of them, and the conclusions to which this analysis has led the author. These conclusions are altogether favorable to the more frequent adoption of the operation than has heretofore been generally deemed advisable. They also indicate the author's preference for total as compared with partial excision, and for the method called antiseptic, *without* the spray. The facts cited by Dr. Liebrecht seem to confirm his opinion that the dangers of thyroïdectomy have heretofore been much overrated. For, when we come to look over his analysis we find that primary hemorrhage was the cause of death in only 7 out of 356 operations, and secondary hemorrhage in only 4—which scarcely warrants the common dread of these accidents. So when we examine to discover the effects of accidental injury to the inferior laryngeal nerve—another of the terrors of the operation—we find that these effects have been surprisingly harmless and transitory. So that it would appear that the author is right in claiming for excision of the diseased thyroid gland, a position in surgical practice equal to that of the removal of other tumors of the neck. It is interesting to observe that his statistics show a progressive diminution in the death-rate from year to year, an indication that the objections to this operation, however well founded, are only such as may be overcome by skill and care. This being the case, it is not unlikely that even the moderate death ratio of the present day—the author would make it only about 8¾ per cent. from inevitable causes—may be reduced yet more, and the operation meet with the general adoption which he urges. But, however this may be, he deserves great praise for the diligence and care with which he has gathered together and recorded the evidence upon which his own opinions rest, and upon which any one else may build, if he will, an opinion of his own.

SOCIETY PROCEEDINGS.

OBSTETRICAL SOCIETY OF PHILADELPHIA.

Stated Meeting, Thursday, October 4, 1883.

The President, R. A. Cleemann, M.D., in the Chair.

Dr. W. H. Parish reported a

PORRO-MULLER OPERATION,

and exhibited the uterus, the abdominal incision (which had united), and surrounding wall, the stump of the cervix in position at the lower angle of the wound, the entire external genitals and mons, including the vagina and bladder. The ureters were found entirely free. (For a full report of this case, see page 398.)

Dr. R. P. Harris remarked that this was the only Porro operation that had been complicated by diseased kidneys. The case was an unfavorable one in consequence of this complication. The albuminous character of the urine was supposed to be due to mechanical interference by the enlarged womb, but unfortunately this was not so. The bad habits of the patient had led to a general disease of the arteries as well as of the kidneys. The former were atheromatous. The Porro-Müller operation has been performed thirty-four times, the modified Porro eighty-two times, total, one hundred and sixteen cases, of which forty-eight per cent. have been successful in saving the lives of the mothers. When the pedicle or stump is dropped, it ceases to be a Porro operation. Of thirteen cases in which the stump has been dropped, eleven have been fatal. Dr. Godson is writing a full history of this operation, including the many experiments which have been made in animals to determine the best method for each step of the operation, and the cause of death. Dr. Porro has saved four out of five cases in his own hospitals. In the Milan Hospital, nine were saved out of twelve. In Germany the success has been poor, but in Austria better.

Dr. O'Hara asked why the Porro operation should be modified when it had been so successful in the hands of the originator.

Dr. Harris.—Dr. Müller was called upon to operate in a case in which the fœtus had been dead for some time and was putrid, the uterus being distended with gas. To prevent any septic matter finding its way into the abdominal cavity, he enlarged the abdominal incision, lifted the uterus out of the abdomen, and used cloths around it and over the wound before incising the uterus. This patient recovered. The mortality this year has been very slight.

Dr. E. E. Montgomery had been associated with Dr. Parish in this case, as one of the hospital staff, and at first thought the case should be allowed to go on to full term before operating, and that Cæsarean section or laparo-elytrotomy, as practised by Dr. T. G. Thomas, should be the selected form of operation; but Cæsarean section has been very fatal in large hospitals, doubtless because it is generally a last resort after the patient has been long hours in labor, and for that reason is dangerous. But if a large drainage-tube was passed through, entering at the abdominal incision and out of the vagina, and a constant flow of antiseptics kept up, a good condition might be secured.

During the operation, a few modifications suggested themselves; one of these was to divide the cervix uteri by a V-shaped incision, the peritoneal surfaces being united over the wound, a flat Peaslee drainage-tube being introduced, and the stump dropped. Dr. Harris tells me that this has been tried, but resulted unsuccessfully.

He thought the wire of the écraseur passed around the cervix before removing the child a source of danger to the latter, as well as being likely to embrace a loop of intestine.

DR. HARRIS, in criticising the plan of dropping the stump, called attention to the fact that the portion of uterus embraced in the ligature is not a pedicle, it is a stump, and will continue to contract, and oozing of blood, or even profuse hemorrhage, is liable to occur. It has been found impossible to prevent this by any form of ligature that has been tried. If the stump is dropped, this hemorrhage or oozing will take place into the abdomen, and will be a certain cause of death. Dr. Isaac E. Taylor came near success, but his patient died from thrombosis on the twenty-sixth day, during an attack of phlegmasia alba dolens. It would be very desirable to avoid the dragging on the abdominal wound.

DR. MONTGOMERY gave a short *résumé* of the cases treated by dropped stump and the causes of death in them.

DR. PARISH remarked that the disease of the kidneys was undoubtedly the cause of death, the implanting of the acute condition caused by pregnancy upon the previous chronic disease. He also spoke of the possibly deleterious effect of the ether upon the system laboring under such a condition of the kidneys. It made the administration of ether in such cases a very serious matter.

DR. PARISH also exhibited specimens from a case of

EXTRA-UTERINE PREGNANCY,

and made some remarks upon the history of the case. He had attended the patient in her first labor seven years ago. She was a brunette of very restless and active habits and disposition, and was quite uncontrollable; she was up and about her house a few days after her labor, and the result was sub-involution, which persisted until her death. During the interval she had passed out of his care and had been subjected to local treatment, including the use of sponge tents, these had developed pelvic inflammation, and later she was troubled with frequent micturition and dysmenorrhœa. She afterwards came under his care again for treatment of these troubles, and on one occasion he had applied leeches to the cervix and gave her positive orders not to leave her bed, but festivities were going on and she went down and assisted in making ice-cream and cake and later in eating them; this indiscretion was followed by a second metritis. He afterwards treated her for the dysmenorrhœa by numerous minute punctures of the cervix and the application of tincture of iodine, and the introduction of a sponge tent.

The next period was not so painful, and the second was missed. He told her she was probably pregnant; but two weeks later a slight show occurred, and, fearing an abortion, he advised rest in bed. She refused an examination, and would not be quiet. The flow continued, but did not increase; and there was pain in the pelvis in addition. Eleven days after the flow commenced, a sudden attack of intense pain occurred; the patient was completely prostrated, and was carried up-stairs. As he was not at home, Dr. O'Hara was called in, and used morphia hypodermatically. He found, on examination, a mass in the posterior part of the pelvis; the uterus was pushed forward against the pubes. He diagnosticated rupture of a Fallopian-pregnancy cyst, and internal hemorrhage, and gave opiates to relieve the intense pain. The pallor and exhaustion became more pronounced, and death occurred thirty hours after the first symptoms. Other physicians who saw the patient did not agree with Dr. Parish in his diagnosis. The autopsy revealed no recent peritonitis; there was blood in the pelvic and abdominal cavities; this had escaped from a ruptured cyst of the Fallopian tube. The fœtus exhibited was found free in the pelvic cavity. The position of the cyst was such that it would have been an easy operation to open the abdomen, and ligate and remove the cyst and ovary, and cleanse the pelvic cavity. The Fallopian tube involved is dilated, except at the uterine extremity. The other tube is occluded at the fimbriated extremity; inflammatory bands derange the relations of the different pelvic organs. We have here the history of inflammatory processes changing the epithelial linings and relations of the Fallopian tubes to the uterus and ovaries as predisposing causes of extra-uterine pregnancy.

DR. HARRIS remarked that the hemorrhage after conception, the peculiar location of the pain, and the pallor make the diagnosis an easy one. He had one patient that recovered spontaneously. The operation suggested by Dr. Parish has been performed once successfully. Dr. T. G. Thomas made the diagnosis in another case and wished to operate, but the husband, a physician, differed in opinion and would not consent; that patient lived sixty hours after the accident. Dr. Playfair in his book advises the operation.

DR. O'HARA saw the case early and could not make such a diagnosis; he saw no sign of internal hemorrhage then; he thought of peritonitis or cellulitis; there had been no history of a decidual cast of the uterus. He did not see how a positive diagnosis of extra-uterine pregnancy could have been made at that time. The patient was certainly going to die, and he would approve of an exploratory operation.

DR. PARISH remarked that Dr. O'Hara was perhaps right; he (Dr. P.) was the only physician present who looked at the case in that light, all the others disagreed and had their reasons. If this diagnosis of a probable extra-uterine fœtation had been made early, before the accident, then when the acute symptoms supervened a quick diagnosis could have been made as to the cause of the pain. He described a fold of peritoneum found behind the uterus, and as the clot had the appearance of different ages, portions being yellow, he suggested that an extra-peritoneal hemorrhage had first occurred under this fold, perhaps ten days before the intra-peritoneal hemorrhage which was the cause of death.

ACUTE GANGRENE OF THE ILEUM.

DR. BEATES reported the case of an infant which appeared well and hearty at birth, but died in collapse on the third day. An autopsy revealed acute gangrene of the mucous surface of eight feet of the ileum; hemorrhage had occurred into the intestine and was the immediate cause of death.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, October 4, 1883.

THE PRESIDENT, FORDYCE BARKER, M.D., LL.D., IN THE CHAIR.

THE first meeting of the Academy after the summer recess was held on Thursday evening, October 4th.

Previous to the meeting, the President, Dr. Fordyce Barker, issued the following circular:

"I assume that every Fellow of the New York Academy of Medicine must regard it as a most unfortunate event that anything should occur to interrupt its fraternal harmony, its useful work, and its progressive growth. While we cannot shut our eyes to the fact that this is the present condition of the Academy, it would be both useless and unwise to discuss the causes which have brought about this state of things, because, from their nature, they involve questions on which the most able, the most loyal, and the most conscientious men in the profession honestly differ. Let us accept this fact as inevitable, and that the Academy can do nothing which will effectively advance the interests of the profession by way of discussions, which irritate, but do not change convictions, or by arbitrary regulations, secured by shrewd tactics, but which carry no moral force.

"The Academy of Medicine is not fulfilling its mission when it is engaged in warm discussions of questions of casuistry, in polemical controversies, or in medical politics.

"The *Ephemeris* of Dr. Squibb quotes with approval an editorial from the *Boston Medical and Surgical Journal*, which contains the following sentence: 'The lesson also is so obvious that he who runs may read, that the more our Societies confine themselves to their proper field—the joint cultivation of medical science and good-fellowship—and the less they meddle with medical politics, the better will it be for their own future and the common good of the profession.'

"It seems to me that the truth of the above sentiment has been unfortunately, but clearly demonstrated by our Academy of Medicine.

"The question which we have now to meet is: What measures can be taken to secure for the Academy a return of its prosperity? by which I mean a restoration of its fraternal harmony and good memory of the past. The anodyne draught of oblivion is the first specific remedy for healing such ills as those under which the Academy is now suffering.

"The next point to be secured is such a change in our organic laws as will make it impossible that trouble and danger can ever occur again in the Academy.

"At our first meeting in October, certain amendments to the Constitution and By-laws will be proposed for discussion, and at the following meeting they will be submitted to the vote of the Academy.

"Every change proposed has been the result of a most careful study of the subject, and has a distinct purpose which will be obvious to all.

"I think that it will be apparent that the whole intent of the proposed amendments is to make the Academy of Medicine a purely scientific society, independent of all other organizations, to place its standard of ethics on a higher plane than before, and to prevent the possibility of any future troubles by the introduction of matters foreign to its avowed objects."

Accompanying this circular was a copy of the proposed amendments.

In consequence of this circular, the Council of the Organization for upholding the National Code of Medical Ethics in the State of New York, which consists of Drs. Abram DuBois, Austin Flint, Austin Flint, Jr., J. W. S. Gouley, John H. Hinton, Samuel T. Hubbard, William T. Lusk, Samuel S. Purple, and T. Gaillard Thomas, sent out the following communication to the Fellows of the Academy:

"The Council of the Organization for upholding the National Code of Medical Ethics in the State of New York beg to call your attention to a circular recently issued in which are proposed certain amendments to the Constitution and By-Laws of the New York Academy of Medicine.

"The Council cannot but regret the issuing of this circular as a covert movement, under a plea for harmony, in behalf of the organized effort in opposition to the National Code of Ethics. The proposed amendments, were they adopted, would eliminate from the Constitution and By-Laws everything relating to ethics, and surrender the Academy to those who advocate the abolition of all ethical codes. The Academy would thereby be deprived of the right of representation in the American Medical Association, and of affiliation with other medical organizations out of the State of New York.

"It may be assumed that there is no disposition on the part of those who are for upholding the National Code of Ethics to raise any discussion respecting the Code in the Academy. The Code has never been made a subject of discussion in the Academy by any one in favor of upholding it, and there is no ground for the supposition that it ever will be, unless it becomes necessary in the way of defence. The resolutions presented and adopted at the last meeting of the Academy had for their object the prevention of any future discussion relating to the Code.

"Every true friend of the Academy is earnestly requested to attend its meetings in order to resist the introduction of discussions and controversies in relation to ethics, by simply maintaining, in their integrity, the time-honored Constitution and By-Laws of this Institution, to which it owes its origin and prosperity."

At the meeting, after the reading the minutes, **Dr. Austin Flint, Sr.**, rose to a question of privilege, and he then made a personal explanation. Since the last meeting of the Academy, he said, he had been repeatedly accused of inconsistency because he had voted for the resolutions then adopted, after having. a year previously, offered a motion that all discussion of the question of medical ethics be indefinitely postponed in the Academy. He wished it to be distinctly understood, however, that he had acquiesced in the action then taken for the express purpose of permanently banishing all such discussion. He certainly did not want the question to come up again in the Academy, and would do what he could to prevent such an unfortunate occurrence.

The Secretary then read the following

COMMUNICATION FROM THE COUNCIL:

Hall of the New York Academy of Medicine,
October 4, 1883.

At a special meeting of the Council of the New York Academy of Medicine, held Monday evening, October 1, 1883, it was

Resolved, That the Council advise in the interests of the Academy and of peace and harmony that the proposed amendments to the Constitution and By-Laws be withdrawn.

Resolved, That the Council, after careful and mature consideration, do not approve of the proposed amendments to the Constitution and By-Laws.

The Statistical Secretary, D. F. V. White, read obituary notices of Drs. James L. Banks, Bronley Livingstone, Charles Wright, and Joseph Mosier, Fellows of the Academy, who had died since the last meeting; after which Dr. E. D. Hudson, Jr., Chairman of the Library Committee reported a large number of donations to the library.

Dr. Edward L. Keyes then moved the adoption, as a whole, of the following amendments to the Constitution and By-laws, recommended by the President; and in doing so remarked that he had undertaken to do this purely out of his personal regard for Dr. Barker, and his firm conviction that the amendments were for the best interests of the Academy. Their adoption, he thought, would offer an easy path to the solution of the difficulties which it was now encountering, since a neutral ground would thus be constituted on which all could stand alike. He was the agent of no party or faction, and had no connection with any, but stood for himself alone. He was not a New-Code man, but simply a supplicant for peace.

Dr. Alfred L. Loomis seconded the motion for the adoption of the proposed amendments, and remarked that he was fully convinced that grave dangers now threatened the prosperity and almost the existence of the Academy; but by adopting the amendments we place ourselves in a position in which such a state of affairs could never recur in the future. The discussion of medical ethics and politics would be banished for all future time. There were other Societies where all such questions legitimately belonged; but the Academy ought to be devoted solely to scientific work, and the promotion of good-fellowship in the profession. He would, therefore, urge their adoption, *first*, on the ground of the expediency; *secondly*, because medical ethics had no place in such a Society; *thirdly*, because if such questions are admitted, they would lead only to bitterness and dissension. Finally, he hoped that all present would endeavor to support the President in his efforts to save the Academy from degeneracy and perhaps destruction.

PROPOSED AMENDMENTS

CONSTITUTION.

Article VI. Section 1.—Strike out—2, A Committee on Medical Ethics; 3, A Committee on Medical Education.

Read: 1, A Committee on Admissions; 2, A Committee on Library.

Article VIII.—Strike out the whole as it now stands.

Read: The Academy reserves the right of discipline by admonition, suspension, or expulsion, by which all rights and privileges as a Fellow are forfeited, for violation of its By-Laws or Regulations, for unprofessional, ungentlemanly, or dishonorable conduct, and for public immorality and great crimes.

BY-LAWS.

By-Law X.

Strike out third paragraph in third sentence. Also strike out last sentence, for which read: Five members of the Council shall constitute a quorum for its ordinary meetings, but a majority of the Council shall be necessary for a quorum at its annual meeting in December, and at special meetings called by the President.

Add to *By-Law X.* as follows:

Section 2.—The Council, specially convened by the President for the purpose, shall have the power to inquire into any alleged infringement of the By-Laws or misconduct by any Fellow of the Academy, on a written charge, signed by three Resident Fellows; and the Fellow whose conduct is in question shall be invited to attend. If, after investigation, the charges are sustained by a majority vote of those present, the Council may determine by a majority vote whether the punishment shall be a private admonition or a public reprimand by the President at a meeting of the Academy (whether the offender be present or absent), or suspension for a definite period.

But in case the charge is of so grave a character that the Council, by a vote of two-thirds of those present, considers that the offender should be expelled, the report of the Council and its recommendations shall be referred to the Academy, of which due notice shall be given to every Resident Fellow four weeks previous to its final action. The vote shall be taken by ballot, and two-thirds of those cast shall be necessary to sustain the vote of expulsion.

By-Law XIII.

Strike out Section 3 as it now stands, and read as follows:

Section 3.—The Committee on Admissions, upon receiving from the Recording Secretary the names of the candidates proposed for Fellowship, with their professional credentials, shall make due inquiry concerning them as regards their personal character, their standing in the profession, and their eligibility as persons of honor, who do not assume peculiar designations, implying special modes of treatment.

Add to *By-Law XIII.* Sections 4 and 5, as follows:

Section 4.—The Committee shall report within three months such as may be deemed worthy of admission, and if for Resident Fellowship, the report shall specify the source whence the nominees derived their diplomas or license to practice, with the dates thereof.

Section 5.—If this Committee fail to report within the time specified upon any nomination submitted to them, any Fellow of the Academy may renew such a nomination; and, if this be seconded, a vote shall be taken, it being distinctly stated that the nomination has not been approved by the Committee on Admissions.

Strike out By-Laws XIV. and XV.; the subsequent By-Laws to be numbered XIV. consecutively to XXIV.

XXV. (new number as amended XXIV.):

Add: And all resolutions, except such as relate to its formal routine business, must be offered in writing at the meeting two weeks previous to the final action, and printed on the notice of such final action.

DR. AUSTIN FLINT, JR., moved that the amendments take the usual course and lie over for two weeks. DR. C. C. LEE moved, as an amendment, that the Academy go into committee of the whole for their discussion. DR. FLINT claimed that such an amendment was not in order, but the Chair having decided that it was admissible, it was amended and carried.

The President appointed Dr. Elsworth Eliot Chairman of the Committee of the Whole, and Dr. W. W. Carpenter was then appointed Secretary of the same.

DR. ELSBERG moved that, when the Committee rose, it should report to the Academy in favor of the amendments, but, before the motion was put to vote, DR. ROOSA called on Dr. Barker for a statement of his views in regard to the proposed changes in the Constitution and By-Laws.

DR. BARKER, after some preliminary remarks in which he said that he wished, as far as possible, to avoid everything that was connected with codes of ethics, he went on to say that after the action of the State Medical Society, in 1882, it was feared that the discussion of the questions raised by it would do great injury to the Academy, and interfere with its scientific work. In the April following, however, one who was esteemed and respected everywhere that medical literature was found (Dr. Flint), introduced a resolution to the effect that all matters pertaining to the Code should be indefinitely postponed. This was adopted unanimously, and the work of the Academy went on in the greatest prosperity until the proposal of the resolutions adopted at the last meeting, which had completely changed the aspect of affairs. Without wishing to cause the slightest ill-feeling, he could not but express the opinion that this action was most injurious to the Academy; imperilling its harmony and interrupting its progress. It divided the members into two parties, and on account of this it was impossible to elect any new Fellows. Without consulting with anyone, he set to work to discover some means by which this difficulty could be overcome, the prosperity of the Academy restored, and all possibility of the recurrence of similar troubles obviated. His aim was to place the Society on the highest plane of ethics, and at the same time rescue it from its present unfortunate condition; and as a preliminary step in his effort, he made a careful study of the constitution and by-laws of the great English Societies and of the Academy of Medicine in France. The amendments now offered were the result of much thought on his part, and he had drawn them up with no motive in view except the best interest of the Academy. It had seemed to him that those who had voted for the resolutions adopted at the last meeting (among whom were many of the hardest workers and most munificent benefactors of the Academy), would concur in the opinion that a solution of the difficulty could thus be reached; but to his astonishment and sorrow he had found that his judgment was wrong.

Dr. Barker then took up the proposed amendments *seriatim*, and briefly pointed out his reasons for the changes which he desired to have made. The abolition of the Committees on Ethics and Medical Education, he stated, would relegate the subject of ethics to the Council and the whole Academy. As to the Committee on Medical Education, such a committee at the present day was entirely useless. In enacting the proposed substitute for Article VIII., the Academy would protect itself from improper members, and at the same time it would be a purely scientific body. To the last By-Law, providing for the alteration of By-Laws, was added a clause, the object of which, he explained, was to prevent, in all future time, the adoption of resolutions introduced by parties or cliques without due notice.

Dr. Austin Flint, Jr., then rose and said, that before the meeting every member knew just what these proposed amendments meant. One of them simply left the Academy of Medicine without a code of ethics, and this amendment necessitated certain changes in the rest of the Constitution and By-Laws to accommodate them to this new order of things. Everybody knew that it did not make the slightest possible difference what the Committee of the Whole said or did about the matter. It had no power whatever, and the amendments would, of course, have to take the regular course and lie over until the next stated meeting. When they come up at that time, those who were in favor of the National Code would vote against them, and those who were in favor of the New Code would vote for them, and that was all that there was about the question of the adoption of the amendments. It required a three-fourths vote to secure their passage, and this, he believed, was absolutely hopeless. Consequently, he considered their introduction as nothing more nor less than a firebrand which would only increase the difficulties under which the Academy now labored. He did not see the slightest necessity for talking any more about these amendments. It took two sides to make a discussion, and he sincerely trusted that no friend of the National Code would say one word about them. The only way was for each Fellow who believed in that code, to come to the next meeting and vote against their passage. In conclusion, Dr. Flint explained that he would not have spoken at all if the Chair had not overruled his motion, and decided that the amendment to go into the Committee of the Whole was in order.

Dr. Barker now proposed as an amendment to the resolution of Dr. Elsberg, who accepted it, the following:

"*Resolved*, That, in the opinion of the Committee of the Whole, it is advisable to adopt the amendments to the Constitution and By-laws which have been prepared, and that the Chairman be instructed to report at the next stated meeting of the Academy on the morning of October 18th."

After some discussion on parliamentary points, this resolution was adopted. A motion was then passed that the Committee of the Whole rise, report progress, and ask leave to sit again at the meeting of October 18th.

The Committee accordingly rose, and Chairman Eliot made his report, after which Dr. Flint renewed his original motion, that the amendments take the regular course, and lie over until the next meeting. This was unanimously carried, and the Academy then adjourned.

CORRESPONDENCE.

ON THE MAPPING OUT OF VISCERAL DISEASES, IN AN ANILINE COLOR, ON THE SURFACE OF THE BODY.

To the Editor of The Medical News.

Sir: I have now used for more than sixteen months, throughout my residency in the Episcopal Hospital, a method of mapping out on the superficies of the body, in an indelible aniline color, the results of a physical exploration of the condition beneath. The markings remain fresh and clear in many cases, and visible in almost all, from one to several weeks or longer, affording a most valuable means of making daily or weekly comparisons in diseases running their course or changing within that time. The Eagle copying leads, found in every stationery store, afford the most convenient means of using the color. The leads are sold in sticks three and a half inches long, and the points simply need to be dipped in water to be ready for use.

By thus mapping them out, pneumonias, pleurisies, peri- and endo-carditis, and many other thoracic and many abdominal diseases can be made instantly to speak for themselves in staring lines and letters, not only faithfully and continuously representing the exact condition of a case when first examined, but making a mental picture long retained.

The following will serve as an illustration: I visited A. M. at his house, and, finding that he had right apex pneumonia, admitted him to the ward. After a careful exploration of the chest, the point of the pencil was quickly dipped in water, and the whole upper part of the right chest cut off from that below by a broad purple line running from sternum to spine, following the lowest level at which bronchial breathing was heard.

Then above the line over the third rib in front were printed in large letters, **Fl. Bron. br. Broncoph**, designating the whole area as *flat*, and that bronchial breathing and bronchophony were heard everywhere within its limits.

An inch and a half below this an interrupted line separated an area corresponding to the middle lobe, which was markedly congested, and the letters **D. Br. ves.** indicated dulness on percussion and bronchovesicular breathing. The month and day were recorded along with these signs, and then from day to day changes were studied by this map as the standard of comparison, or further changes were noted and distinguished from the paler ink of the older markings. Complete failure resulted in a few cases of typhoid fever where there was profuse sweating.

It afforded great satisfaction in a case of acute articular rheumatism to hear the clipping pericardial friction-sound over the base of the heart, and, after recording by a dot of the pencil with the date alongside, to be able to trace the slightest change in position or number of points throughout the whole history of the case.

A hard, nodular, cancerous mass at the pylorus was felt well up under the diaphragm, and its most prominent point marked by a small cross, the next day another cross marked a fall, and so its movements were traced over a large part of the epigastrium by measurements made when the stomach was in all states of distention, the record graphically showing on the harsh, dry skin through weeks of illness, and remaining to speak for itself on the post-mortem table. The device is so simple and almost self-suggestive that I am not surprised to learn that others have used it in a more or less limited way; but, if I have not already been forestalled in attracting general attention by publication, I feel sure that so valuable an expedient will be generally adopted when known, especially by all who are engaged in class-demonstration, or in studying a large number of cases at one time.

A chest or abdomen so mapped is legible over the largest of our clinical amphitheatres, and when the patient is reintroduced, no student needs a more impressive picture to recall all the conditions of the case at the last séance.

Personally, it has saved me hours of laborious investigation in my ward-work, and I carry in mind a picture of cases of small pleuritic effusion along the spine in typhoid, represented in aniline by an undulating outline enclosing the letters Æg. (ægophony), which must long since have slipped my memory as particular cases, had I depended on the usual routine of examination and note-taking.

A few seconds daily serve for verification, and in this way a large number of cases can be intelligently and satisfactorily kept within the mental horizon at one time. Yours respectfully,

Howard A. Kelly, M.D.

323 South Seventeenth Street,
Philadelphia.

CELSUS ON THE TREATMENT OF HYDROPHOBIA.

To the Editor of The Medical News.

Sir: In your issue for Oct. 6, there is a letter from Louis W. Atlee, M.D., taking me to task for a supposed slight to Celsus, in my recently published "Remarks on Hydrophobia." As the correction is founded on an assumption of your correspondent that I had not consulted the original writings of Celsus, I content myself, in regard to it, with pointing out that his assumption is erroneous.

But the fifth and sixth paragraphs of the letter referred to, charge me, by inuendo, with literary dishonesty. Of this I wish to say, that it is to be regretted that Dr. Atlee, who is an entire stranger to me, should have made an accusation which the smallest inquiry would have taught him was unfounded, and that, in his zeal for the "ethics" of Celsus, he should have forgotten what is demanded by the ethics of the present day. Yours truly,

Charles W. Dulles.

[We greatly regret that any paragraph should have appeared in our columns which, even by imputation, could be supposed to cast an imputation upon the literary methods of Dr. Dulles, whom we know to be a most painstaking and conscientious student. In this particular instance, too, it has happened to come within our knowledge that he took special pains to consult a large number of original authorities, and Celsus, we are informed, was among the number, in his research. —Ed.]

THE SO-CALLED CONSTANTINOPLE PORRO OPERATION. A CORRECTION.

To the Editor of The Medical News.

Sir: In several papers on the Porro operation, one case has been erroneously credited to Dr. Dallas, of Constantinople. A letter received from that city recently shows the operation to have been a utero-ovarian amputation in a case of intra-mural fibroid, with excessive floodings. There was no fœtus as reported (saved), but the woman, as stated, recovered. For such a condition we now perform the less dangerous operation of Battey, which we have seen produce a perfect cure, in the production of the menopause, and atrophy of the tumor.

Very respectfully,
Robert P. Harris, M.D.

CINCINNATI.

(*From our Special Correspondent.*)

The Cincinnati Health Board.—A great deal has been said of late by our local journals and newspapers about the inefficiency of our Health Board, and it certainly has the mark of inefficiency upon it. It has been the rule for a number of years that the City Council should elect a Board of Health, who in turn appointed a health officer. Dissatisfaction with this mode of caring for the sanitary interests of the city soon arose, and grew so strong that an attempt was made last spring to modify it. The Legislature enacted a law abolishing the Health Board, and providing for the appointment, by the Judges of the Superior Court, of a Health Commissioner, with a salary of $3000 annually, with full control of the sanitary department, and with power to appoint a large number of subordinates, including a Registrar of Vital Statistics, milk, meat, and market inspectors, district physicians, etc. But all this was offset by the refusal of the three Judges to perform the duty imposed upon them. The city was then left for several months without so much as a nominal Board of Health. During this time, however, Dr. D. D. Bramble, the health officer for the previous year, continued his services with the same energy and efficiency as before, and succeeded in freeing the city from smallpox—an end which it had been his aim to accomplish throughout his service. Then the Council decided that it was its duty to appoint a new Board of Health. Five saloon-keepers and a physician were their choice. The health officer appointed by this Board is not a physician, as has been customary, but a business man, with nothing to recommend him to the place but his promise to do his duty. The whole measure was confessedly a political one, and applicants for subordinate positions, even the district physicians, were made to profess allegiance to the ruling party before their applications were considered. Merit was a secondary qualification. That the present Board is illegal is, however, unquestionable, for the law abolishing such a body still exists, and it is probable that an attempt will be made during the coming winter to remodel the Act of the Legislature so as to have the appointing power placed in the hands of officers who will use it. This brief account, though of not much importance in itself, serves to show the need in our State of a more efficient means of providing for the health of its people, and at the same time the difficulty that stands in the way of all attempts in that direction.

Fortunately, we have not suffered from any lack of protection, for the city has been remarkably healthy during the past summer, and could have gotten along very well with no Health Board at all. The mortality report for the week ending October 6, shows 88 deaths, or 16.39 per 1000, per annum. This is a lower rate than at this season for several years. Of these 88 deaths, 25 were infants under one year of age, and 9 were 60 or upwards. Three were from diphtheria, the only contagious disease reported.

A Children's Hospital was opened on Monday of this week, with a capacity of thirty beds. It is the charity of a number of wealthy and benevolent gentlemen. The institution is in charge of Dr. F. Forchheimer, Professor of Physiology and Children's Diseases in the Medical College of Ohio, and it is to his energy that its origin is largely due. He will be assisted by Drs. W. S. Christopher and Robert Stewart. Dr. Ed. W. Walker is the Surgeon, and Dr. W. W. Seely the Ophthalmologist. The building occupied was formerly a residence, but has been thoroughly remodelled. A wing to be used as a mortuary is now building. This is the first hospital for children exclusively, that we have had. It is located in the most populous part of the city, where it is likely to do the most good. None but children under twelve years and infants will be admitted, and no contagious diseases will be treated.

The Cæsarean Section was performed recently at the Good Samaritan Hospital by one of the resident physicians, Dr. Edwin W. Ludlow. The patient was a woman, dying of phthisis pulmonalis, in the last month of pregnancy. A living child was extracted, but owing to its emaciated condition it lived but an hour.

CANADA.

(*From our Special Correspondent.*)

Quebec Medical Board.—The semi-annual meeting of the College of Physicians and Surgeons of the Province was held in Quebec on the 26th ult., Dr. Ternieux, President, in the chair.

Sixteen candidates for the license presented University degrees, and obtained the license without examination. Four candidates were examined, of whom three were rejected. The matriculation examiners reported that forty-nine candidates had presented themselves, of whom only nineteen passed, and were thereby qualified to enter upon the study of medicine.

A discussion took place on the causes of the high percentage of rejection at the preliminary examination, and a committee was appointed to confer with the masters of the high schools and seminaries, in order that a more suitable system of training should be given to pupils preparing for the examination.

Opening of the Schools.—The introductory lecture of McGill Medical Faculty was given by Dr. Workman, of Toronto, the oldest, save one, living graduate of the school, and a hale, active octogenarian. After the lecture, a conversazione was held in the Redpath Museum. The recently appointed Professors, Drs. Shepherd, Gardner, Browne, and Stewart, gave special introductory lectures to their classes on the 2d. Prof. Penhallow, late of Tokio University and of the Haughton Experimental Farm, is conducting the botany class in the Medical School during the absence in Europe of Principal Dawson.

The Montreal School of Medicine (French) reassembled on the 2d, when Dr. D'Orsonneus, the President, delivered the inaugural address, in which he reviewed the troubles of the school, and congratulated the members that they had been successful in their struggle with Laval.

The Kingston School of Medicine for Women opened on the 2d, when Dr. Lavell addressed the students. Three scholarships have been founded, and the prospects of the school as a separate institution are good. A guarantee fund of $7000 has been raised.

The Ravages of Yellow Fever in Mexico and Panama. — Surgeon Main, of the Marine-Hospital Service at Brownsville, Texas, reports to the Surgeon-General the following items brought by the latest Pacific mail: At Mazatlan, Mexico, yellow fever is still the reigning terror. Every house is a hospital. It is impossible to keep track of the deaths, which run into the hundreds daily. The inhabitants are fleeing in every direction.

Later reports from Brownsville state that yellow fever is still raging in Mexico, and that it is said to be travelling northward up the California Gulf; and that President Gonzales, in a recent message to Congress, referring to the unhealthy condition of the Capitol, said that a loan of $2,000,000, with which to improve the sanitary condition of Mexico, had been recommended.

The latest advices received from Mazatlan were dated September 16. At that time there were two thousand people sick, some of whom were dying of yellow fever, and others for want of attention or on account of a prevailing famine. The advices referred to stated that there were only two inexperienced doctors in the city, and they were worn out from overwork. At Manzille, the report says, "cartloads of dead bodies have been buried in one common receptacle."

Yellow fever has existed in Panama since April, but almost exclusively among the natives. It has recently become more pernicious, and is now spreading widely. It has made its appearance in the below-named Pacific coast cities: San José, Costa Rica, Nicaragua, Acapulco, Zucatula, Manzanillo, Corrientes, and San Blas; and is spreading northward.

At Guayamas so many are down with the fever that many die from want of attendance. The dead are buried by the cartload by Indians. At Hermosillo the fever death-rate is about twenty daily.

Surgeon-General Hamilton, of the Marine-Hospital Service, has telegraphed the collector at Yuma, Ariz., to appoint sanitary inspectors at that place and at Benson to inspect trains arriving from the south. This action has been taken because of information received from the Governor of Arizona that a soldier at Huachaca, in that Territory, had died of yellow fever recently.

A recent report from Guayamas, dated September 22, states that yellow fever, or malignant coast fever, still continues there, and has been particularly fatal to Americans in the employ of the railway company. A report to the State Department from the United States Consul at Mazatlan, September 12, says that the port is infected with yellow fever, and that all vessels leaving it for the United States refuse to receive passengers, and have no communication with the port.

A telegram from Guayamas, under date of October 3, states that there have been only three deaths in the last two days. Twenty-six deaths are reported from Hermosillo, and all along the road are victims who have been overtaken with the fever and who are unable to proceed further. News received from the Yaqui River reports that the fever is spreading among the Indians. A letter received here announces the death of two of the party which left here in August to survey the Tocolovampo Railroad. No names were given.

Despatches from Las Vegas, N.M., of Oct. 9, state that more yellow fever refugees have arrived there. They say the half has not been told about the horrors of the scourge at Guayamas and Hermosillo.

Yellow Fever in Alabama.—Reports from Brewton, Ala., give two deaths since the 3d inst, and thirteen cases under treatment. The physicians there are of the opinion that it is hemorrhagic malarial fever, but pressure is so strong that the neighboring towns are quarantined, and trains are ordered to go through Brewton without stopping.

Yellow Fever at Pensacola.—A telegram from Commandant Welch, at the Pensacola Navy Yard, dated 6th inst., states that three new cases of yellow fever have appeared, and one death has taken place. It has been intensely hot for a week past. There was also one new case and one death in Warrington from the fever.

Yellow Fever at Ship Island Quarantine Station.—The surgeon in charge of the quarantine station at Ship Island reports that during the week ending September 29th, there were eleven cases of yellow fever and three deaths at that station.

Quarantine in San Francisco.—The passengers on board the yellow fever steamer "Newbern," in the harbor of San Francisco, have been permitted to come ashore, with the exception of two patients and a nurse. All danger to the city from yellow fever may now be said to have passed.

Quarantine at New Orleans.—In accordance with a recommendation of the Board of Health of New Orleans, the Governor has issued a proclamation withdrawing the quarantine proclamation heretofore issued, to take effect November 1st. After October 15th, vessels from infected ports will be detained not less than three days for disinfection.

Smallpox in New Orleans —For the week ending September 22, there were ten deaths from smallpox in New Orleans.

Quarantine at Mobile.—Recent despatches state that quarantine was established at Mobile, on Oct. 9th.

Pleuro-pneumonia in Pennsylvania.—Information has been received by the Secretary of the State Board of Agriculture, that pleuro-pneumonia has broken out among the cattle of Lehigh County.

The American Climatological Association.—Forty names were enrolled in membership in the new medical society formed in the rooms of the New Academy of Medicine, New York, Sept. 25th.

The name chosen was "The American Climatological Association," and its objects were stated to be the study of diseases of the respiratory organs, together with the influence of climate thereon.

A committee consisting of Drs. Tyndale, New York; Bruen, of Philadelphia; and Garland, of Boston, was authorized to act temporarily as a Board of Censors, and to draft a constitution and by-laws, and submit the same to the next meeting.

The following officers were elected:

President.—A. L. Loomis, New York.
First Vice-President.—F. J. Knight, Boston.
Second Vice-President.—W. H. Geddings, Arkansas.
Secretary and Treasurer.—J. B. Walker, Philadelphia.

It was decided to hold the annual meeting in 1884 at Washington either immediately before or after the meeting of the American Medical Association, and the following were appointed a Committee of Arrangements: Dr. Garnett. Washington, Chm.; Drs. Donaldson, Baltimore; Bosworth, New York; Shurley, Detroit; J. C. Wilson, Philadelphia.

With bright auspices for a live, active, and most useful organization, the new Association starts on its career.

Harvard Medical School.—On Wednesday next, Harvard Medical School will celebrate its Centennial Anniversary and will dedicate its new building. The celebration will consist in an address by the President of the University, an oration by Emeritus Professor Oliver Wendell Holmes, and the presentation of a portrait of Prof. Holmes and a bust of Prof. Henry J. Bigelow. Subsequently the new building will be dedicated.

Health of Connecticut.—The report of the Secretary of the State Board of Health, for August, states that the prevalence of typhoid fever is the most important element in the sanitary history of the month, when the relative prevalence of this type of disease and malarial diseases are considered. A few years ago scarcely a case was reported from the malarial region; now the cases begin to exceed the malarial, and in places like Manchester, where the two types exist together, the influence is seen in the prevalence of typho-malarial fever. Two fatal cases of this form are reported from South Manchester, and several cases of typhoid fever. The use of a small stream for the disposal of sewage, which is obstructed by numerous dams, thus causing beds of deposits, which from the natural effects of the dry season must have been more or less uncovered and exposed to the sun, furnishes favorable conditions for the causation of typho-malarial fever. This has been repeatedly illustrated in different places. These same agencies would favor the spread of typhoid fever were the malarial influence wanting. The general decrease in the prevalence of malaria and the malarial influence upon other diseases is very marked in a large part of the territory where they have been for quite a long period the governing type. With a few exceptions, which tend to strengthen the idea that there must be some local causes to induce the unusual prevalence, he did not learn of any general activity in the progress or spread of malaria. While there is a much greater prevalence and a more marked influence over other diseases in the northeasterly frontiers of the region that has already been invaded by malaria, there is no such decided prevalence as exists in the region about Manchester. As has been stated, acute-intermittent is very common, and both typho-malarial and malarial fevers exist. In the present uncertainty as to the ultimate nature of malaria, all such manifestations are of peculiar interest.

The cases reported from Hampton this month and previously, were imported by a gang of Italian laborers. A few cases of typho-malarial are reported in August, also typhoid fever, the latter indigenous.

The prevalence of typhoid fever is noticeable in Waterbury; from New Hartford, Thomaston, and several places in Litchfield County; from a part of Killingly and from several towns in Windham County. More or less cases of typhoid fever are reported also from different parts of every county.

Health in Michigan.—Reports to the State Board of Health, for the week ending September 29, 1883, indicate that neuralgia, pneumonia, and remittent fever have increased, and that diarrhœa, consumption, influenza, and inflammation of the brain have decreased in area of prevalence.

Including reports by regular observers and others, diphtheria was reported present during the week ending September 29, and since, at twenty places, namely, Clarence, Coldwater, Coopersville, Detroit, Ensley, Grand Rapids, Hillsdale, Ida, Lansing, Lowell, Mt. Pleasant, Monroe, Nashville, Newberry, Niles, Polkton, Quincy, Houghton County, Reading, Somerset, and Utica. Scarlet fever at twenty-one places: Bingham, Belvidere, Coopersville, Detroit, East Jordan, Fenton, Grand Haven, Grand Rapids, Ithaca, Kalamazoo, Lansing, Lowell, Ludington, Manistee, Middleville, Monroe, Morenci, Nashville, Polkton, Tyrone, and Whitehall. Measles at four places: Charlevoix, Detroit, Monroe, and Somerset.

Obituary Record.—Surgeon-General Charles H. Crane, U. S. Army, died in Washington, D. C., on Wednesday, October 10th, of hemorrhage of the throat, after a brief illness. He was born in Rhode Island, in 1826, and was appointed to the Medical Department of the Army from Massachusetts in February, 1848. He was promoted to the rank of Surgeon in May, 1861, and to the position of Assistant Surgeon-General on July 28, 1866. His appointment to the position of Surgeon-General was confirmed by the Senate in August, 1882.

ORIGINAL LECTURES.

THE NEW CENTURY AND THE NEW BUILDING OF THE MEDICAL SCHOOL OF HARVARD UNIVERSITY.

An Oration delivered at the One Hundredth Anniversary of the Foundation of the Medical School of Harvard University, October 17, 1883.

BY OLIVER WENDELL HOLMES, M.D., LL.D.

THE Medical School of Harvard University enters, with the commencement of the present season, upon the second century of its existence. By a fortunate coincidence it takes possession at this same time of the noble edifice which a generous public has reared for the use of the teachers and students of this institution.

Yesterday; to-day; to-morrow. Let us look backward at the period when this school began its teachings, and mark some of the longer strides which bring the professional condition of the earlier epoch to that of our own. Let us see where we stand to-day, and we shall know better what to hope for the future of the teaching, the science, and the art of healing.

We are in the habit of counting a generation as completed in thirty years, but two lives cover a whole century by an easy act of memory. I, who am now addressing you, distinctly remember the Boston practitioner who walked among the dead after the battle of Bunker's Hill, and pointed out the body of Joseph Warren among the heaps of slain. Look forward a little while from that time to the period at which this Medical School was founded. Eight years had passed since John Jeffries was treading the bloody turf on yonder hill-side. The independence of the United States had just been recognized by Great Britain. The lessons of the war were fresh in the minds of those who had served as military surgeons. They knew what anatomical knowledge means to the man called upon to deal with every form of injury to every organ of the body. They knew what fever and dysentery are in the camp, and what skill is needed by those who have to treat the diseases often more fatal than the conflicts of the battlefield. They knew also, and too well, how imperfectly taught were most of those to whom the health of the whole community was intrusted.

Dr. John Warren, a younger brother of Dr. Joseph Warren who fell at Bunker's Hill, was the first mover in the project of founding a medical school in connection with Harvard College, and was the first Professor of Anatomy and Surgery. Those who remembered his teaching have spoken to me with admiration of the eloquence and enthusiasm with which he lectured. Dr. John Warren was a man of great energy, spirit, and ability. The Lectures of the newly founded school were delivered in Cambridge until the erection of the building known as the Massachusetts Medical College, in Mason Street, in the year 1815. It was no easy matter for a busy Boston practitioner to deliver a course of lectures in the University town. But Dr. Warren did not ask whether it was easy or not. "In the fulness of professional business he daily passed over Charlestown ferry to Cambridge, there not being a bridge at that time; and sometimes, when impeded by ice, was compelled to take the route through Roxbury and Brookline to Cambridge, and to return on the same morning, after himself performing the dissections and giving a lecture sometimes three hours long." So tells us worthy Dr. Thatcher, in the Appendix to his American Medical Biography.

Benjamin Waterhouse, honorably known for having been the introducer of vaccination into America, was the first Professor of the Theory and Practice of Medicine. I remember him well, and carry the scar of the vaccination he performed on me. His powdered hair and queue, his gold-headed cane, his magisterial air and diction, were familiar to me from my boyhood. Dr. Waterhouse had his degree from Leyden, where he wrote and defended a Thesis, *De Sympathia Partium Corporis Humani, ejusque in explicandis et curandis morbis necessaria consideratione.* He had some learning, which he was disposed to make the most of, as perhaps we all are if we have it, and laid himself open to the playful sallies of the students of his time, one of whom announced a course of Lectures on Oudenology, which was supposed to be a travesty of some of his prelections.

The first Professor of Chemistry was Aaron Dexter. It was the forming period of that science. Black, Cavendish, Priestley, Lavoisier were building it up with their discoveries. A course of Chemical Lectures delivered in Boston or Cambridge at that day was probably, as it certainly was at a later day, very entertaining and not wholly uninstructive. Phlogiston had not yet definitely taken itself to the limbo of negative entities. But however crude the theories, we may be pretty sure that there was left in the student's mind a memory of startling precipitations, of pleasing changes of color, of brilliant coruscations, of alarming explosions, and above all of odors innumerable and indescribable.

It is sad to think that professors honored in their day and generation should often be preserved only by such poor accidents as a sophomore's jest or a graduate's anecdote. The apparatus of illustration was doubtless very imperfect in Dr. Dexter's time, compared to what is seen in all the laboratories of to-day. We may admire his philosophy and equanimity, therefore, in recalling the story I used to hear about him.

"This experiment, gentlemen," he is represented as saying, "is one of remarkable brilliancy. As I touch the powder you see before me with a drop of this fluid, it bursts into a sudden and brilliant flame," which it most emphatically does *not* do as he makes the contact. "Gentlemen," he says, with a serene smile, "the experiment has failed; but the principle, gentlemen, —the principle remains firm as the everlasting hills."

Three teachers only, where we have forty, or nearly that number! But when the great University of Göttingen was established, the illustrious Haller filled the one Chair of Botany, Anatomy, Surgery, and Medicine. I called it a Chair—it was rather a Settee of Professorships.

It is to be regretted that we have not a list of the text-books in use during that first period of the school. Dr. Waterhouse would naturally refer his students to the learned Gaubius, the voluminous Van Swieten, the illustrious Boerhaave. The excellent Dr. Fothergill was his uncle; the immortal Jenner was his second Creator, and their names, with that of Dr. Lettsom, were often on his lips. Sydenham, Pringle, and Cullen, he speaks of as being in the hands of all his students, and his references show a considerable extent of reading.

The text-books in Anatomy were probably Cheselden and Monro, perhaps Winslow, and, for those who could read French, Sabatier. The Professor himself had the magnificent illustrated works of Albinus and of Haller, the plates of Cowper (stolen from Bidloo) and others. The student may have seen from time to time, if he did not own, the figures of Eustachius and of Haller. Haller's First Lines of Physiology were doubtless in the hands of most students. The works of Pott, of Sharp, and most of all of John Hunter, were taking the place of Heister and the other earlier authorities.

Smellie was probably enough the favorite in his department. What chemical text-books Dr. Dexter put into the hands of his students in 1783 I will not venture to conjecture.

And now I will ask you to take a stride of half a century, from the year 1783 to the year 1833. Of this last date I can speak from my own recollection. In April, 1833, I had been more than two years a medical student attending the winter lectures of this school, and have therefore a vivid recollection of the professors of that day. I will only briefly characterize them by their various merits; not so much troubling myself about what may have been their shortcomings. The shadowy procession moves almost visibly by me as I speak: John Collins Warren, a cool and skilful operator, a man of unshaken nerves, of determined purpose, of stern ambition, equipped with a fine library, but remarkable quite as much for knowledge of the world as for erudition, and keeping a steady eye on professional and social distinction, which he attained and transmitted: James Jackson, a man of serene and clear intelligence, well instructed, not over book-fed, truthful to the centre, a candid listener to all opinions; a man who forgot himself in his care for others and his love for his profession; by common consent recognized as a model of the wise and good physician: Jacob Bigelow, more learned, far more various in gifts and acquirements than any of his colleagues; shrewd, inventive, constructive, questioning, patient in forming opinions, steadfast in maintaining them; a man of infinite good nature, of ready wit, of a keen sense of humor, and a fine literary taste; one of the most accomplished of American physicians; I do not recall the name of one who could be considered his equal in all respects: Walter Channing, meant by nature for a man of letters, like his brothers William Ellery and Edward; vivacious, full of anecdote, ready to make trial of new remedies, with the open and receptive intelligence belonging to his name as a birthright; esteemed in his specialty by those who called on him in emergencies. The Professor of Chemistry of that day was pleasant in the lecture-room, rather nervous and excitable, I should say, and judiciously self-conservative when an explosion was a part of the programme.

Those who are curious to know what hand-books we students used in 1833 will find they were nearly as follows: In Anatomy, the works of John and Charles Bell, that of Wistar, and the Dublin Dissector. In Physiology, Haller's First Lines and Richerand. In Chemistry, Webster's edition of Brande. In Surgery, Samuel Cooper's work, with his Surgical Dictionary as a book of reference. In Theory and Practice, Dr. Good's Study of Medicine was adopted by Dr. James Jackson and generally followed. Gregory's Practice was often seen in the student's hands, and Laennec's Treatise on Diseases of the Chest and their Physical Signs was just coming to their notice in the form of Dr. Forbes' Translation. Denman and Dewees were the favorites in their special branches. Bigelow's Sequel to the Pharmacopœia was much sought after by the students of this school. Like the excellent and serviceable work recently published by his successor in the Chair of Materia Medica, it was unpretentious enough for the most scrupulous teachers of the high and dry Northern latitudes.

Other works read by students were, Hunter on the Blood, Fordyce on Fever, Heberden, and, of course, Cullen and the earlier standards which happened to be in their instructors' libraries. Louis was just beginning to be known among us. The Lectures of Sir Astley Cooper and of Mr. Abernethy were eagerly read. One fellow-student of mine read through the three solid quartos of Morgagni. These are the principal authorities I recall as lying about our study and lecture-rooms. But my memory is, no doubt, sometimes at fault.

Great stories had been reaching us for some time of the schools and hospitals of Paris. Dr. John Jackson, nephew of our old Professor, came home with news of the fine opportunities there offered. Young James Jackson, the Professor's son, was there still, writing home letters which remain on published record, to show how much of talent, and zeal, and high promise was lost to the medical profession by his early death. Especially did he speak of Louis, whom he had chosen as his principal teacher, and of whom he became the favorite pupil and the very dear friend. These circumstances decided me to seek the same centre of instruction, and so, in April, 1833, I left Boston to pursue my studies in Paris. Dr. John Jackson bade me farewell with a look as if I were indeed on my way to the good Bostonian's heaven, and handed me a small square of India-rubber, his own newly suggested pleximeter, or instrument to be used for mediate percussion, which he wished me to show to Louis and the other great Paris doctors.

I have said something of my Boston teachers, and I will devote a few words to those whose instructions I followed in Paris, and to their most renowned professional contemporaries in other European countries, at the risk of some repetition of what I have said elsewhere.

Old Boyer, Baron Boyer, who, in spite of his title, kept his own books for sale at his own house, was still creeping around the wards of La Charité. At Hôtel Dieu was the great surgeon Dupuytren. On the other side of the river was his large and loud rival, Lisfranc. Roux, best known by his report of his medical visits to England, was operating and lecturing—lecturing, parenthesis within parenthesis—ovum, germinal vesicle, germinal spot, until his embryo meaning vanished in the invisible; Velpeau, a reclaimed rustic, who, by sturdy industry, grew out of his wooden shoes into an erudite author and teacher and a celebrated practitioner; Civiale, the inventor of lithotrity; Ricord, whose mercurial temperament, to say nothing of his practice, displayed itself in his lively clinical promenades; these were some of the more famous surgical celebrities of fifty years since. Louis, Andral, Chomel, Rostan, Trousseau, Bouillaud were the best known teachers of clinical medicine. Cruveilhier was Professor of Anatomy in the École de Medecine, and Orfila, the handsome Dean of the Faculty, lectured upon some branches of medical jurisprudence.

Two or three water-logged old professors were moored to their chairs; one of them not so very old, but with a good many ancient barnacles about him, one formidable three-decker, Broussais, with his upper tier of guns still above the water-line, and banging away at the assailants of his famous "physiological doctrine." Some of the specialists I recall were Sichel, in ophthalmology, Biett, in dermatology, Dubois, the younger, and a younger Baudelocque, inventor of a certain lemon-squeezer-like machine about as threatening to the future of the race as the invention of that other medical practitioner, Dr. Guillotin.

The works in the hands of French students were those of the great teachers and practitioners just mentioned. Jules Cloquet's Anatomy was a favorite manual. Sabatier's and Maygrier's were sometimes met with. The much more extensive and thorough work of Cruveilhier was a little later to come into common use. The great work of the same author on Pathological Anatomy was of a still later date. Bourgery's magnificent, somewhat dandified Anatomy, if I may borrow this term, was in course of publication. Its showy figures were got up like opera dancers, primarily for anatomical study and secondarily for æsthetic gratification. Magendie's Physiology had replaced that of Richerand. Boyer was still a leading authority in Surgery. The name of Jean Louis Petit was frequently cited in the lectures of Marjolin, himself scarcely remembered at the present day. Bayle and Corvisart were giving place to Louis and Bouillaud. Laennec held his position as few inventors and discoverers can hope to do in the face of the after-comers who improve on their improvements.

What had been the most signal advances in the science and art of medicine between 1783 and 1833, the first half of the century we are considering?

In medical science the method of studying the human body by its constituent elements—the *General Anatomy* of Bichat—which is to common descriptive anatomy what geology is to geography, would still hold the first place if it could claim all that the microscope has done for it. It was at any rate a great onward movement, with far-reaching results for physiology and pathology.

Next to this would come the discoveries of Sir Charles Bell and Magendie of the distinct motor and sensitive functions of certain nerves and nerve-roots.

The most important practical achievement was the introduction of vaccination. I know that this practice has been and is even at the present day the subject of violent attacks and bitter prejudices. It is only very recently that our distinguished visitor — our fellow-citizen—by the female side—the Right Honorable Sir Lyon Playfair, at home alike in the laboratory of science and when presiding over the deliberations of the British House of Commons, has had to defend it—nobly and successfully he did it—in that august assembly. There is always an unconvinced and irreclaimable minority. Those who believed not Moses and the Prophets would not believe though one rose from the dead to convince them. Most of us, I feel sure, are ready to say of Jenner's discovery, borrowing some of Luther's words about justification by faith, that vaccination is a test *stantis vel cadentis medicinæ.*

Laennec's invention of auscultation holds the next place to vaccination in the records of practical improvement during our first half century. The recognition of the affection of the kidneys known as "Bright's disease," and the separation of the too familiar and fatal malady, diphtheria, from those with which it was long confounded, are other notable advances made during the period in question.

If we compare the two half centuries, we may balance the following improvements against each other:

Against the discovery of the double nerve function the extended knowledge of the reflex function.

Against "General Anatomy," the Cell-doctrine, due to the discoveries made by the use of the achromatic microscope, to which we also owe the discovery of the minute organisms, so important in the history of disease.

Against vaccination we may offset surgical anæsthesia.

Against the stethoscope the medical thermometer.

We must divide the honors of lithotrity and those of ovariotomy between the two periods.

The beneficent changes in the treatment of insanity, effected by the earlier labors of Pinel and Esquirol have been admirably carried on in the more recent period.

Many other and not inconsiderable improvements in medical science and art had taken place in our first half century, as may be seen in Cuvier's Report on the Progress of the Natural Sciences. But the last fifty years have been not less richly productive. I can only indicate in the briefest manner, some few among their acquisitions.

Modern scientific chemistry is a mystery to us who were brought up in the old school of pyrotechnic experimenters. It seems to us to make over its theories and its nomenclature about once in ten or twenty years. But that may be our ignorance. We know as much as this, that our Professors teach real and most valuable practical knowledge by making the student work, and work thoroughly, in the laboratory.

Physiology is a new science, we might almost say, since the perfecting of organic analysis, the invention of the achromatic microscope, and of the numerous instruments of precision which record the vital actions and conditions.

Anatomy has added the more exact study of regions and of sections to its earlier methods of investigation.

Operative surgery has of late years achieved its greatest triumph in the establishment of abdominal section as a legitimate and safe operation. First employed by an American surgeon, Dr. McDowell, of Kentucky, in 1809, in the hands of Spencer Wells and his contemporaries it has rescued and is rescuing hundreds of lives. Tenotomy by subcutaneous section is another new and valuable operation. Plastic surgery has learned to patch deformities as a skilful housewife patches a garment. Limbs which would have been sacrificed are saved by improved methods of dressing, especially by the use of antiseptics. Resection of joints or of portions of the shaft of a bone has in many cases taken the place of amputation. Let me not forget the operation of paracentesis with aspiration of the thorax in acute pleurisy, as first practised by Dr. Henry Ingersoll Bowditch and Dr. Morrill Wyman. But enough has been said to show that the last half of our century has justified itself for existing. I shall return to some of these matters when speaking of the new edifice where they are to be the subjects of instruction.

In the prevention of disease the gain has been extraordinary. The germ-theory, alluded to as one of the results of the perfecting of the microscope, has done much to account for the phenomena of many diseases and to indicate the means of arresting their development. The recognition of domestic malaria as the frequent source of disease is of vast importance. The phrase "drain fever" has saved hundred of lives.

It is harder to speak of medical practice—the treatment of internal diseases, fevers, visceral inflammations and the like. The practice of drugging for its own sake, the fatal bequest of the English apothecary, or "general practitioner," whose profit was made on his medicines, had infected the medical profession of this conntry, as I believed, when some twenty and more years ago in guarded terms, often misquoted, I denounced it somewhat too epigrammatically for some of my friends of the Massachusetts Medical Society. Professor Gairdner of the University of Glasgow has recently used language much plainer than my innocent allusion to the probable effect of sinking a cargo of miscellaneous drugs among the fishes. It has been objected, he says, "that the Scottish graduate in medicine was not sufficiently conversant with the details of compounding and dispensing powders, and pills, and mixtures, and above all draughts (at 2s. 6d. a piece) to be taken two, three, four, or five times a day; in other words, that he had not sufficiently mastered the technical details by which his neighbor, the English apothecary, was able to accomplish the great ideal of the 'surgery-boy' type—the dispensing of immense quantities of 'physic' in the most complicated prescriptions, to pass unquestioned down the willing throats of Her Majesty's lieges."

There can be little doubt that the practice thus originating influenced the whole professional public of England to a very considerable extent, and through that public introduced the over-drugging system into her colonial dependencies and the States which some of these became. However this may be, great changes have taken place within the later decades of my remembrance in the practice of medicine. Bleeding is an almost unknown operation. Of the four great remedies of Dr. Holyoke's and Dr. James Jackson's time, antimony has fallen from grace, and calomel, instead of being next the apothecary's right hand, as the letter e is to the printer's, has gone to an upper shelf, where it may be supposed to repent of its misdeeds like Simeon Stylites. Cotton Mather had said a century and a half ago, "I am not sorry that antimonial emetics begin to be disused." He had said too, more rhetorically, "Mercury, we know thee: but we are afraid thou wilt kill us too, if we employ thee to kill them that kill us." This was a lively way of putting a thought long afterward made into a famous saying.

While old drugs and old methods have become obsolete, new drugs and new methods have come in to take their place. The first aphorism of Hippocrates, "Life is short, art is long," and so on, is a glittering generality. The second aphorism is one of daily practical application, never to be forgotten. "Not only must the physician attend properly to his own duties, but he must see that the patient, the attendants, and all the external conditions are properly ordered." As the over-employment of drugs gives way to juster views, the hygienic conditions and personal attendance on the patient are likely to be better cared for. The less the patient is annoyed with over-medication—painful and disgusting remedies—the more tractable he is likely to be, and the less likely to throw his medicine out of the window, where it will kill the chickens instead of the fishes. The more attention is likely to be paid to air and cleanliness and comfort, the more to the kind of nourishment and the modes and times of giving it. In proportion as the work of the apothecary diminishes the cares of the nurse are called upon to render disease endurable by all the arts known to a skilful attendant. Little things mean a great deal in the sick-room. "Will you have an orange or a fig?" said Dr. James Jackson to a fine little boy now grown up to goodly stature, and whom I may be fortunate enough to recognize among my audience of to-day. "A fig," answered Master Theodore, with alacrity. "No fever there." said the good Doctor, "or he would certainly have said an orange."

Now it is just in these little unimportant, all-important matters that a good nurse is of incalculable aid to the physician. And the growing conviction of the importance of thorough training of young women as nurses, is one of the most hopeful signs of medical advancement. So much has been done and is doing that the days of the Sairey Gamps and Betsey Prigs are numbered. I cannot help saying in this connection that the Registry of Nurses fortunately connected with the Boston Medical Library, itself of comparatively recent formation, is a blessing to our community which can hardly be over-estimated. What is there in the hour of anguish like the gentle presence, the quiet voice, the thoroughly trained and skilful hand of the woman who was meant by nature and has been taught by careful discipline to render those services which money tries to reward but only gratitude can repay? I have always felt that this was rather the vocation of women than general medical and especially surgical practice. Yet I myself followed a course of lectures given by the younger Madame Lachapelle in Paris, and if here and there an intrepid woman insists on taking by storm the fortress of medical education, I would have the gate flung open to her as if it were that of the citadel of Orleans and she were Joan of Arc returning from the field of victory.

I have often wished that disease could be hunted by its professional antagonists in couples,—a doctor and a doctor's quick-witted wife making a joint visit and attacking the patient,—I mean the patient's malady, of course,—with their united capacities. For I am quite sure that there is a natural clairvoyance in a woman which would make her as much the superior of man in some particulars of diagnosis as she certainly is in distinguishing shades of color. Many a suicide would have been prevented if the doctor's wife had visited the victim the day before it happened. She would have seen in the merchant's face his impending bankruptcy while her stupid husband was prescribing for his dyspepsia and endorsing his note; she would recognize the lovelorn maiden by an ill-adjusted ribbon – a line in the features,—a droop in the attitude,—a tone in the voice,—which mean nothing to him, and so the brook must be dragged to-morrow. The dual arrangement of which I have spoken is, I suppose, impracticable, but a woman's advice, I suspect, often determines her husband's prescription. Instead of a curtain lecture on his own failings he gets a clinical lecture,—on the puzzling case, it may be, of a neighbor suffering from the complaint known to village nosology as "a complication of diseases," which her keen eyes see into as much better than his as they would through the eye of a small-sized needle. She will find the right end of a case to get hold of, and take the snarls out as she would out of a skein of thread or a ball of worsted which he would speedily have reduced to a hopeless tangle.

I trust I have not dwelt too long on this point, which grew out of my consideration of the great change that has so largely substituted the careful regulation of all the conditions surrounding the patient for the drugging system derived from the practice of the English "Apothecaries." Like the Father of Medicine in the aphorism which I have quoted, we consider attention to these conditions entitled to precedence relatively to all active interference with the course of disease.

Yet we must not be ungrateful to the pharmacist for the useful agents, old and new, which he puts in our hands. Opium and cinchona appear in our modern pharmacopœia with all their virtues, but freed by chemical skill of the qualities which most interfered with their utility. Mercury is no longer considered a panacea, but it is still trusted for important special services. Most of the remedial plants have yielded their essential principles to chemical analysis and have got rid of the useless portions which made them bulky and repulsive. Iodine, bromine, salicine in their various compounds have, within the present century, conferred inestimable aid in the treatment of some of the most formidable diseases. Many other new remedies, such as carbolic acid, glycerine, chloral, have been added to the list of those which are of daily use in combating particular symptoms, or are adapted to certain exceptional conditions. The method of administering remedies by inhalation has been greatly extended, and the admirable invention of the process of subcutaneous injection—a method, I may remark, tried upon himself and made the subject of a thesis by the late Dr. Enoch Hale, a graduate of this school—has become next to etherization, the most rapid and potent means of subduing pain and other forms of suffering. I need not speak of medical electricity, which has proved so serviceable in the treatment of nervous and muscular affections.

I despair of enumerating all the improvements which have been effected in the various specialties into which the practice of medicine has become subdivided within these twenty or thirty years. The ophthalmoscope, the improved ear speculum, the rhinoscope, the laryngoscope—hold out their mirrors to enlighten us, or open their mouths to proclaim their own value. Diagnosis has reached a wonderful degree of accuracy; prognosis has become a terrible kind of second-sight which is not always handled carefully enough; treatment gains a little with every decade. The history of therapeutics records a succession of marches and counter-marches, with a slight onward movement as the total result of every completed revolution; slight, but precious to humanity.

I cannot pass over the most encouraging fact of the growth of medical libraries. We have a right to congratulate ourselves on the prosperity of that which has sprung into existence in this city within the last few years. It seems to me to mark the beginning of a new era in the medical history of the city. But what can I say of the immense library formed, but always forming, at Washington, and how can I sufficiently praise the work of Dr. Billings and his associates, one of the results of which comes before us in that colossal catalogue which is one of the best proofs of the advancing civilization of the great republic?

It was time for the Medical School of Harvard University—of that Institution of which Massachusetts must always be proud so long as she has anything to be proud of—it was time for this school to plant its chief edifice in a fairer position, and erect it on a broader foundation than those with which it has been so long obliged to be contented. Let us not be ungrateful to the memory of our earlier benefactors; to the State for the grant which proved of such value in its time; to the individuals who gave land and money when the former buildings were constructed. But the little Mason Street building was long ago outgrown, and that which succeeded it had in turn become wholly insufficient for the needs of the school.

You will pass from beneath this hospitable roof to the new edifice, in which, as we trust, many successive generations of medical students are to receive a large part of their instruction. As you enter its doors, as you survey its halls and lecture-rooms, its laboratories and their appliances, some of you may be ready to exclaim, What! All this to teach a student to cut off a limb or administer a potion?

The question is a natural one, and the answer is easy. The Art of Healing is supported, advanced, illuminated, by the various kinds of knowledge which are recognized as belonging to the Science of Medicine. And the Science of Medicine, like all other kinds of classified knowledge, is best taught, most easily and thoroughly learned, when taught systematically, because facts are most clearly perceived and most firmly retained in the memory when presented in their serial relations. The teaching of the various branches included in a complete medical course requires ample provision for its multiplied exigencies.

You will enter or look into more amphitheatres and lecture-rooms than you might have thought were called for. But if you knew what it is to lecture and be lectured to in a room just emptied of its preceding audience, you would be thankful that any arrangement should prevent such an evil. The experimental physiologists tell us that a bird will live under a bell-glass until he has substituted a large amount of carbonic acid for oxygen in the air of the bell-glass. But if another bird is taken from the open air and put in with the first, the new-comer speedily dies. So when the class I was lecturing to was sitting in an atmosphere once breathed already, after I have seen head after head gently declining and one pair of eyes after another emptying themselves of intelligence, I have said, inaudibly, with the considerate self-restraint of Musidora's rural lover—

Sleep on, dear youth; this does not mean that you are indolent, or that I am dull; it is the partial coma of commencing asphyxia.

You will see extensive apartments destined for the practical study of chemistry and of physiology. But these branches are no longer studied as of old by merely listening to lectures. The student must himself perform the analyses which he used to hear about. He must not be poisoned at his work, and therefore he will require a spacious and well-ventilated room to work in. You read but the other day of the death of an esteemed fellow-citizen from inhaling the vapors of a broken demijohn of a corrosive acid. You will be glad to see that every precaution is taken to insure the safety and health of our students.

Physiology, as now studied, involves the use of much delicate and complex machinery. You may remember the balance at which Sanctorius sat at his meals, so that when he had taken in a certain number of ounces the lightened table and more heavily weighted philosopher gently parted company. You have heard, perhaps, of Pettenkofer's chamber, by means of which all the living processes of a human body are made to declare the total consumption and product during a given period. Food and fuel supplied; work done. Never was the human body as a machine so understood; never did it give such an account of itself as it now does in the legible handwriting of the cardiograph, the sphygmograph, the myograph, and other self-registering contrivances, with all of which the student of to-day is expected to be practically familiar,

I do not see any room marked on the plan of the new building as intended especially for the use of the microscope. But that a proper apartment will be assigned to this use I feel assured. I have referred to the modern achromatic microscope as having created a new era in Medical Science. I have no time to tell what it has done for Anatomy, Physiology, and Pathology, besides its great services in other departments of knowledge. But to those who have never seen its miracles I can give an illustration, which they will find it hard to believe I did not borrow from some new Gulliver's Travels or from some Jules Verne's imagination. Yet what I shall say is the simplest truth in the world to any microscopic expert, and may be easily verified by any sceptic.

If we had to examine the structure of a human body by the naked eye,—or, as I will venture to call it, *gymnoscopic* or rather *gymnopic* inspection,—it would make a great difference whether our subject were of the natural dimensions or whether he were a Liliputian, or a Brobdingnagian. We should lose sight of many particulars in the structure of the Liliputian which we easily detect in a man of the natural size. We should find many things plain enough in the Brobdingnagian which we do not notice in the man of ordinary dimensions on account of their minuteness. Thus, for instance, we should find that man is shingled all over, or tiled, if you will—covered with scales, more literally, just as a serpent is. The statue of Liberty, the arm of which the cast in the square at New York has made familiar to us, the statue of Carlo Borromeo at Milan, that of Bavaria, or the new statue of Germania, any one of these changed to flesh and blood would be a great source of knowledge to a gymnopic anatomist. You will observe that the naturalist could examine only a small portion of one of these colossal figures at a time. Of course the same thing is true of the microscopic man I am going to describe. He must be examined in small fragmentary portions.

The individual from whom we will suppose the porion under examination to have been taken was, we will say, of short stature; a little more than five feet two inches in height, and weighing one hundred and twenty pounds. Our microscope, a rather powerful, but not extraordinarily powerful one, magnifies a thousand diameters. This fragment, then, thus magnified, represents an individual just one mile in height. He would ten times overtop the loftiest of the pyramids; twenty times the tallest of our steeples. He could bestride our good city from Long Wharf to Charles Street. His breadth and thickness being in proportion to his height, his weight would be one hundred and twenty thousand million pounds, equal to sixty million tons. He could take our State House up as we should lift a paving stone and fling it into the waters beyond Boston Lighthouse—cleaning out that palace of the people by a summary process quicker than the prætorian bands of Domitian or Commodus would have cleaned out a Roman Senate Chamber that dared to have an opinion of its own. Such is the microscopic man as we see him piecemeal in that wonderful instrument. It is the telescope of the microcosm—the master-key to the portals of a new universe, and the student must be carefully taught how to use it.

Among the various apartments destined to special uses, one will be sure to rivet your attention; namely, the Anthropotomic Laboratory, known to plainer speech as the Dissecting-Room. The most difficult work of a medical school is the proper teaching of practical anatomy. The pursuit of that vitally essential branch of professional knowledge has always been in the face of numerous obstacles. Superstition has arrayed all her hobgoblins against it. Popular prejudice has made the study embarrassing and even dangerous to those engaged in it. The surgical student was prohibited from obtaining the knowledge required in his profession, and the surgeon was visited with crushing penalties for want of that necessary knowledge. Nothing is easier than to excite the odium of the ignorant against this branch of instruction and those who are engaged in it. It is the duty and interest of all intelligent members of the community to defend the anatomist and his place of labor against such appeals to ignorant passion as will interfere with this part of medical education, above all, against such inflammatory representations as may be expected to lead to midday mobs or midnight incendiarism.

The enlightened legislation of Massachusetts has long sanctioned the practice of dissection, and provided means for supplying the needs of anatomical instruction, which, managed with decent privacy and discretion, have served the beneficent purpose intended by the wise and humane law-givers, without doing wrong to those natural sensibilities which are always to be respected.

During the long period in which I have been a Professor of Anatomy in this Medical School I have had abundant opportunities of knowing the zeal, the industry, the intelligence, the good order and propriety with which this practical department has been carried on. The labors superintended by the Demonstrator and his assistants are in their nature repulsive, and not free from risk of disease, though in both these respects modern chemistry has introduced great ameliorations. The student is breathing an air which unused senses would find insufferable. He has tasks to perform which the chambermaid and the stable-boy would shrink from undertaking. We cannot wonder that the sensitive Rousseau could not endure the atmosphere of the room in which he had begun a course of anatomical study. But we know that the great painters, Michael Angelo, Leonardo, Raphael, must have witnessed many careful dissections, and what they endured for art, our students can endure for science and humanity.

Among the large number of students who have worked in the department of which I am speaking during my long term of service,—nearly two thousand are on the catalogue as graduates,—there must have been some who were thoughtless, careless, unmindful of the proprieties. Something must be pardoned to the hardening effect of habit. Something must be forgiven to the light-heartedness of youth, which shows itself in scenes that would sadden and solemnize the unseasoned visitor. Even youthful womanhood has been known to forget itself in the midst of solemn surroundings. I well remember the complaint of Willis, a lover of the gentle sex, and not likely to have told a lie against a charming young person; I quote from my rusty memory, but I believe correctly:

> She trifled! ay, that angel-maid—
> She trifled where the dead was laid.

Nor are older persons always so thoughtful and serious in the presence of mortality as it might be supposed they would show themselves. Some of us have encountered Congressional committees attending the remains of distinguished functionaries to their distant place of burial. They generally bore up well under their bereavement. One might have expected to find them gathered in silent groups in the parlors of the Continental Hotel or the Brevoort House; to meet the grief-stricken members of the party smileless and sobbing as they sadly paced the corridors of Parker's, before they set off in a mournful and weeping procession. It was not so; Candor would have to confess that it was far otherwise; Charity would suggest that Curiosity should withdraw her eye from the key-hole; Humanity would try to excuse what she could not help witnessing; and a tear would fall from the blind eye of Oblivion and blot out their Hotel-bills forever.

You need not be surprised, then, if among this large number of young men there should have been now and then something to find fault with. Twice in the course of thirty-five years I have had occasion to rebuke the acts of individual students, once in the presence of the whole class, on the humane and manly sympathy of which I could always safely rely. I have been in the habit of considering myself at liberty to visit the department I am speaking of, though it had its own officers; I took a part in drawing up the original regulations which governed the methods of work; I have often found fault with individuals or small classes for a want of method and neatness which is too common in all such places. But in the face of all peccadilloes and of the idle and baseless stories which have been circulated, I will say, as if from the chair which I no longer occupy, that the management of the difficult, delicate, and all-important branch committed to the care of a succession of laborious and conscientious Demonstrators, as I have known it through more than the third of a century, has been discreet, humane, faithful, and that the record of that department is most honorable to them and to the classes they have instructed.

But there are better things to think of and to speak of than the false and foolish stories to which we have been forced to listen. While the pitiable attempt has been making to excite the feelings of the ignorant against the School and the University, hundreds of sufferers throughout Christendom—throughout civilization—have been blessing the name of Boston and the Harvard Medical School as the source from which relief has reached them for one of the gravest injuries, and for one of the most distressing of human maladies. I witnessed many of the experiments by which the great surgeon who lately filled a chair in Harvard University has made the world his debtor. Those poor remains of mortality of which we have heard so much have been of more service to the human race than the souls once within them ever dreamed of conferring. Dr. Bigelow's repeated and searching investigations into the anatomy of the hip-joint showed him the band which formed the chief difficulty in reducing dislocations of the thigh. What Sir Astley Cooper and all the surgeons after him had failed to see, Dr. Bigelow detected. New rules for reduction of the dislocation were the consequence, and the terrible pulleys disappeared from the operating amphitheatre.

Still more remarkable are the results obtained by Dr. Bigelow in the saving of life and the lessening of suffering in the new method of operation for calculus. By the testimony of those renowned English surgeons, Sir Henry Thompson and Mr. Erichsen, by the award to Dr. Bigelow of a sexennial prize founded by the Marquis d'Argenteuil, and by general consent, this innovation is established as one of the great modern improvements in surgery. I saw the numerous and patient experiments by which that priceless improvement was effected, and I cannot stop to moan over a scrap of integument, said to have been made imperishable, when I remember that for every lifeless body which served for these experiments a hundred or a thousand living fellow-creatures have been saved from unutterable anguish, and many of them from premature death.

You will visit the noble hall soon to be filled with the collections left by the late Professor John Collins Warren, added to by other contributors, and to the care and increase of which the late Dr. John Jackson of precious memory gave many years of his always useful and laborious life. You may expect to find there a perfect golgotha of skulls, and a platoon of skeletons, open to the sight of all comers. You will find portions of every human organ. You will see bones softened by acid and tied in bow-knots; other bones burned until they are as light as cork and whiter than ivory, yet still keeping their form; you will see sets of teeth from the stage of infancy to that of old age, and in every intermediate condition, exquisitely prepared and mounted; you will see preparations that once formed portions of living beings now carefully preserved to show their vessels and nerves; the organ of hearing exquisitely carved by French artists; you will find specimens of human integument, showing its constituent parts in different races; among the rest, that of the Ethiopian, with its cuticle or false skin, turned back to show that God gave him a true skin beneath it as white as our own. Some of these specimens are injected to show their bloodvessels; some are preserved in alcohol; some are dried.

There was formerly a small scrap, said to be human skin, which had been subjected to the tanning process, and which was not the least interesting of the series. I have not seen it for a good while, and it may have disappeared, as the cases might happen to be open while unscrupulous strangers were strolling through the Museum. If it has, the Curator will probably ask the next poor fellow who has his leg cut off for permission to have a portion of its integument turned into leather. He would not object, in all probability, especially if he were promised that a wallet for his pocket, or a slipper for his remaining foot, should be made from it.

There is no use in quarrelling with the specimens in a museum, because so many of them once formed a part of human beings. The British Government paid fifteen thousand pounds for the collection made by John Hunter, which is full of such relics. The Hunterian Museum is still a source of pride to every educated citizen of London. Our foreign visitors have already learned that the Warren Anatomical Museum is one of the sights worth seeing during their stay among us. Charles Dickens was greatly interested in looking through its treasures, and that intelligent and indefatigable hard worker, the Emperor of Brazil, inspected its wonders with as much curiosity as if he had been a Professor of Anatomy. May it ever remain sacred from harm in the noble hall of which it is about taking possession! If violence, excited by false outcries, shall ever assail the treasure-house of anthropology, we may tremble lest its next victim shall be the home of art, and, ignorant passions once aroused, the archives that hold the wealth of literature perish in a new Alexandrian conflagration. This is not a novel source of apprehension to the thoughtful. Education, religious, moral, intellectual, is the only safeguard against so fearful a future.

To one of the great interests of society, the education of those who are to be the guardians of its health, the stately edifice which opens its doors to us for the first time to-day is devoted. It is a lasting record of the spirit and confidence of the young men of the medical profession, who led their elders in the brave enterprise, an enduring proof of the liberality of the citizens of Boston and of friends beyond our narrow boundaries, a monument to the memory of those who, a hundred years ago, added a School of Medicine to our honored, cherished, revered University, and to all who have helped to sustain its usefulness and dignity through the century just completed.

It stands solid and four-square among the structures which are the pride of our New England Venice—our beautiful metropolis, won by well-directed toil from the marshes and creeks and lagoons which were our inheritance from nature. The magnificent churches around it let in the sunshine through windows stained with the pictured legends of antiquity. The student of nature is content with the white rays that show her just as she is; and if ever a building was full of light—light from the north and the south; light from the east and the west; light from above, which the great concave mirror of sky pours down into it; this is such an edifice.

The halls where Art teaches its lessons and those where the sister Sciences store their collections, the galleries that display the treasures of painting and sculpture, are close enough for agreeable companionship. It is probable that in due time the Public Library with its vast accumulations will be next-door neighbor to the new domicile of our old and venerated institution. And over all this region rise the tall land-marks which tell the dwellers in our streets and the traveller as he approaches that, in the home of Science, Arts, and Letters, the God of our Fathers is never forgotten, but that high above these shrines of earthly knowledge and beauty are lifted the towers and spires which are the symbols of human aspiration ever looking upward to Him, the Eternal, Immortal, Invisible.

REPORT OF A POST-MORTEM EXAMINATION IN A CASE OF RECURRENT HIP-DISEASE,

IN WHICH SUBCUTANEOUS OSTEOTOMY HAD BEEN SUCCESSFULLY PERFORMED EIGHT MONTHS BEFORE DEATH.

By H. R. WHARTON, M.D.,

SURGEON TO THE CHILDREN'S HOSPITAL, PHILADELPHIA; DEMONSTRATOR OF CLINICAL SURGERY, UNIVERSITY OF PENNSYLVANIA; ASSISTANT SURGEON TO UNIVERSITY HOSPITAL

The case from which the specimen represented in the accompanying drawing was taken was one of coxalgia, presenting marked angular deformity, which was relieved by a subcutaneous section of the femur below the lesser trochanter.[1]

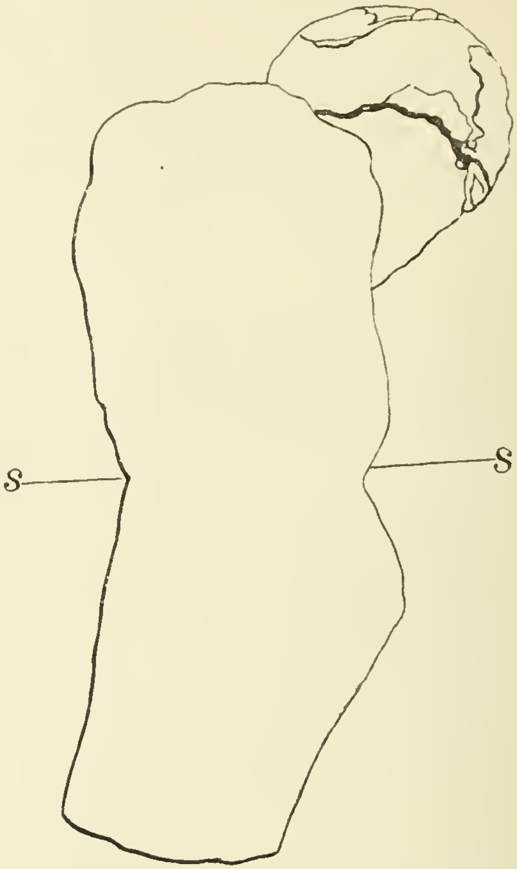
The patient, James C., aged nine years, was admitted to the Children's Hospital, July 31, 1882, suffering from coxalgia of the right hip which had been subjected to no treatment for some months before his admission to the hospital. The right thigh was found much contracted upon the pelvis, and adducted; he also suffered severe pain upon the slightest attempt to straighten the affected limb. He was treated by extension, and at the same time constitutional remedies were administered. His general condition improved markedly, but the faulty position of the limb still persisted, so that, as the active symptoms of the disease had disappeared, it was thought best to remedy this malposition by a subcutaneous division of the femur.

This operation I performed on November 25, 1882, and it was followed by a very satisfactory result in correcting the deformity. The patient, as soon as the union was firm at the seat of section of the bone, was allowed to get out of bed and walk about with the aid of a high shoe on the foot of the affected limb.

One morning, some months after the operation, the nurse, in dressing the boy, noticed a swelling in the neighborhood of the great trochanter of the affected limb, and called the attention of the house-surgeon to it, who discovered a large abscess, which, as it was pointing, he opened.

From this time, the patient grew rapidly worse. Abscesses formed at various points, above Poupart's ligament, in the right lumbar region just above the ilium, and a spontaneous dislocation of the head of the bone occurred backward on the dorsum of the ilium, and he finally died on August 15th from exhaustion. A post-mortem examination of the diseased hip-joint revealed the head of the bone lying upon the dorsum of the ilium, and surrounded by pus; the head of the femur was carious superficially at points, but a portion of the articular cartilage remained healthy in appearance; the change in the neck of the bone was not marked. The most extensive signs of disease were found in the acetabulum, which was entirely denuded of articular cartilage, was carious, and communicated with the cavity of the pelvis. The union of the femur at the seat of section was found firm, and the deformity resulting from the operation was slight, as can be seen by examining the accompanying wood-cut:

The history of the above case, together with the wood-cut of the specimen, is, I think, of peculiar interest, not only from the fact that I believe it to be the only specimen so far obtained showing the condition of the femur after a subcutaneous section with Adams's saw, for the patients who do badly after this operation generally die rapidly from exhaustion following the profuse suppuration, which interferes with union of the bone at the point of section, but also because it plainly shows that the operation recommended by Mr. Gant—section of the femur below the lesser trochanter—which was the one performed in this case, is one which is followed by very slight deformity at the seat of operation.



Upon this latter point, it must be acknowledged, some diversity of opinion exists, especially among English surgeons, some of whom state that Gant's operation merely substitutes one deformity for another; but an examination of the specimen will, I think, give the most important evidence upon this point, for it will be seen that the deformity resulting from the operation is very slight.

A question which might with propriety be asked is, Had the operation any direct connection with the final result of the case? I think not, for the wound of operation healed kindly; the patient was able to walk about, and was much improved in his general condition. The specimen shows firm union at the seat of section; the head and neck of the bone show little evidence of disease, and the most marked lesions are confined to the acetabulum and pelvis, whose indirect connection with the seat of operation would certainly negative any causal relation.

The symptoms of acute ostitis which so suddenly supervened in this case can be traced, I think, to a fall upon the diseased hip, which the boy acknowledged he had received while at play in the playroom, and of which he said nothing at the time, fearing it would necessitate his being confined to bed.

---

[1] Cases of Subcutaneous Osteotomy, American Journal of the Medical Sciences, July, 1883.

This case, although most unfortunate in its termination, has, I think, a very direct bearing upon that mooted point, the position at which to divide the femur, and seems to show that Mr. Gant's modification of Adams's operation is one that may be undertaken with a reasonable assurance of success as regards the correction of the deformity following certain cases of coxalgia.

1405 Locust Street, Philadelphia.

THE SIMULTANEOUS OCCURRENCE OF CHANCROID AND CHANCRE

By JOHN FERGUSON, M.A., M.D., L.R.C.P.,
ASSISTANT DEMONSTRATOR OF ANATOMY, TORONTO SCHOOL OF MEDICINE, TORONTO, CANADA.

That chancroid and the initial lesion of syphilis can occur at the same time in a person who has exposed himself has been both asserted and denied. The following very brief account of a case, of the genuineness of which there is no doubt from the circumstances, will set the possibility of this dual occurrence beyond doubt.

Mr. J. C., a student, who has been known to me for years, and on whose word the utmost reliance could be placed, called on me one morning and remarked that he thought he had been "caught." He told me that three nights ago he had gone out with another young man and that they had visited "two houses." He told me that he had never been with a woman previously to the night mentioned. This I can fully believe. That he never was out again I know for a fact myself.

When I saw him first there was considerable irritation, and by the end of a week from the date of his exposure a well-marked chancroid. I ordered him to remain in his room, perfectly quiet, which he did, and gave him a wash consisting of sod. bibor. ℥j, glycerini ℥ij, aquam ad ℥iv. With this he was told to sponge the sore often, and in the intervals to keep a pledget of cotton-wool, soaked in the lotion, applied. This went on well, and by the end of four weeks his chancroid could be regarded as really healed.

Some five or six days from the date of his last call upon me regarding his local sore he came again, and stated that he thought he felt a hard nodule on the opposite side of the penis, just behind the glans. This initial sore gradually took on the characters of the indolent ulcer, with a hard, widely extended base. In due time the inguinal glands enlarged, the rash on the skin appeared, and there were great loss of appetite, severe headache, much cachexia, and a good deal of fever. The case afterwards proved to be a very severe one indeed.

That there can be no doubt as to the real character of the two sores is clear to my mind, for the first was a most typical "soft sore," while the second was followed by constitutional syphilis. From my knowledge of the patient I can rely so fully upon his statements that there is really no doubt of the statement made by him that he "never was out in his life, excepting that one night." In the next place, he frequented two places of ill-fame. Now whether he contracted both diseases in one place, or one in one house and the other in the second, would be interesting to know. The patient succeeded in bringing to my office the woman he had been with in the first place. On examination I found she had a plentiful supply of chancroids, but no appearance of syphilis. It was after the hard sore had appeared on the young man that I sought and obtained this examination of the woman. In the interval that had elapsed since the student had been with her, she might have contracted her sores from some other person, but she asserted that she had the sores and was using a wash for them at the time when Mr. J. C. made her acquaintance. I succeeded in keeping track of this woman for nearly a year and never found the first evidence that she was a victim to syphilis.

We must conclude, then, that the young man contracted his local sores from the person above mentioned, and that his severer disease was due to the intercourse with the second woman. This second woman was a rather famous person, known as "Bell." Though I never could obtain an interview with her, I saw another student, suffering from syphilis, who stated that he got his disease from "Bell" about the same date as did Mr. J. C. This seemed to settle the question in my mind. How it may be with others I cannot say.

MEDICAL PROGRESS.

Kairin.—Since Dr. Filehne, a few months ago, introduced to notice the remarkable antipyretic action of kairin—an artificial alkaloid described as being the hydrochlorate of oxy-chinolin-ethyl—the drug has been given by others whose experience confirms that of the introducer. Thus Dr. Sassetzki (*St. Petersburger Med. Wochenschrift*, September 1st) states as his experience of its use in a case of typhus that kairin is a valuable antipyretic, doses of half a gramme reducing high fever to a normal temperature, which can be kept down by repeating the doses. The pulse falls together with the temperature, and the excretion of nitrogenous and phosphatic substances is lessened. The urine assumes a green color, which disappears very rapidly on ceasing the administration. It is curious that the fall of temperature in this case was not accompanied by sweating. No ill effects resulted from the drug. Another case is recorded by Dr. Knipping, of Neuwied (*Berliner klinische Wochenschrift*, September 10th), which may be briefly given here. A young woman, about twenty years of age, suffered from puerperal pyrexia for about nine days. On the fourteenth day after her confinement she was allowed to rise and take a bath. Next day she complained of pain in the left thigh, and symptoms of parametritis appeared, which were not controlled by the application of ice, leeching, etc., periphlebitis of the left leg also occurred with much irregular pyrexia, and the temperature reached nearly 105° F. On the twenty-fourth day there occurred periphlebitis of the right leg, and the case was further complicated by intestinal catarrh, bronchitis, and some dulness at the apex of the right lung. The morning temperature was 104°; evening, 105.4°, with very slight remissions; pulse 120 to 130, small and irregular. Quinine had been given in full doses without any influence, and the weakness of the patient precluded a resort to cold baths, so that on the thirty-fourth day, when the temperature reached 106.4°, and the heart was failing markedly, resort was had to kairin. It was given in doses of grs. viiss, in gelatine capsules, every hour. After the first dose the temperature fell to 102.2°, with profuse sweating; after the fifth, to 100.2°. The pulse did not correspondingly fall at first, remaining at 100. A reduction of the dose to grs. iv was followed by a rise in the temperature to 105.4°, with return of the bad symptoms, so that grs. viiss were again given hourly for four hours, when the temperature had fallen to 101.2°. For the next four hours grs. iv were given, with relapse of fever to 102.2° and 103°, again reduced to 100° by resort to the larger dose. The administration was continued for a week, and by the forty-first day the condition was much improved—temperature about 100.4°; and the intestinal and pulmonary symptoms had passed away. On now omitting the drug there was a slight rise in temperature, but this was easily controlled, and the case did well. In the seven days she had taken 220 doses of kairin without any toxic effects, beyond slight pricking sensations on the nose and forehead after the first dose. The urine became of a deep dark-green color, free from albumen and casts, the normal color returning if the drug was discontinued for twelve hours. The writer describes the sweating as being most marked, subsiding as soon as the kairin ceased to act and the temperature rose. He believes the drug in this case to have been the means of saving the patient's life, and insists upon the dose being repeated hourly if the antipyretic action is to be maintained.—*Lancet*, September 29, 1883.

SUBPERITONEAL INJECTIONS OF ALBUMINATE OF IRON IN CHRONIC ANÆMIA.—PROF. A. VACHETTA, having noticed the results obtained with this preparation when administered in the ordinary way, has endeavored to ascertain whether the peritoneum would not absorb it better, in larger quantities and more quickly than the mucous membrane of the stomach. From experiments on dogs, he concludes that the effects of albuminate of iron are more readily obtained by subperitoneal administration than by any other method, and that no inconveniences result from this mode of administration.—*Gazz. degli Ospitali*, No. 35, 1883.

KNEE-HÆMARTHROSIS.—At the late meeting of the British Medical Association, MR. JOHN FAGAN read a paper on this subject, and reported four cases. In referring to the diagnosis, he said that it should not be difficult if attention be paid to the following points: 1. The nature of the injury. 2. The time when the swelling appeared. 3. The character of the swelling. 4. The pain.

If a person sustain an injury to the knee, followed by swelling of the joint, it might be well to ascertain if there existed, prior to the injury, a hydrarthrosis, or any other form of enlargement. If swelling follow rapidly the receipt of an injury to a normal knee-joint, and this be limited to the synovial sac, as will be indicated by swelling of the pouch under the quadriceps muscle, and floating of the patella, he thinks the case may safely be diagnosed as one of hæmarthrosis.

He has noticed that very often there is but little pain on manipulation, sometimes there is no pain; the rule is, the pain is not severe. Very frequently accompanying hæmarthrosis there is a smart attack of synovitis. If the case has not been seen early, and there is no satisfactory history, it is difficult to determine which condition predominates. The doubt, however, will be cleared up by the progress of the case. If the case be one of synovitis alone, the swelling disappears under appropriate treatment; if it be due to blood in the joint, the pain and inflammation may disappear, but the swelling will remain. These facts were well established in some of his cases. Even without a history of enlargement rapidly following injury, if the swelling persist, and be not accompanied with much pain, one usually finds it to be due to the presence of blood in the articulation. Its distinctive characters, as compared with synovitis, are these:

Hæmarthrosis.

Swelling rapidly following injury.
No heat; little, if any, pain.
Joint can be moved.
Absence of fever.
Swelling does not subside under ordinary treatment, or does so only to a moderate extent.

Synovitis.

Swelling after a varying interval.
Heat and pain.
Joint usually fixed.
Fever, more or less.
Swelling subsides under appropriate treatment.

Regarding the treatment of this affection, those surgical text-books that take any notice of it, direct that the case should be treated with the view of promoting absorption of the effused fluid. Since he gave this subject consideration, and gained any experience in connection with it, Mr. Fagan says, without hesitation, that the proper treatment of the affection is to remove at once the fluid by puncture of the joint; by this means the foreign body is immediately got rid of, thereby preventing the possible train of serious symptoms that might follow its presence in the joint.

Up to the present time, he has treated fifteen cases in this manner, using the aspirator two or three times in the same case, and on no occasion has it been followed by the slightest unpleasant result. The way in which he carries out this treatment is to puncture the joint with the large needle of the aspirator, a little above and to the outer or inner side of the patella, whichever is more prominent; the needle is then directed obliquely under the patella. After the fluid is completely removed, he places a small pad of lint, saturated in friar's balsam, over the point of puncture, puts a bandage firmly round the joint, places the limb on a back-splint, and applies ice-bags. After a few days, if the swelling does not entirely disappear, he punctures again; and unless the case be complicated with some other form of injury, the joint is usually restored to its normal condition within a fortnight or three weeks.

Puncture of the knee-joint was looked upon as a hazardous practice some years ago. Now it is of frequent occurrence, and in the proper cases is followed with the most satisfactory results; and he expects that, after a little time, opening the joint to dispose of coagula that cannot be got rid of by the aspirator will be more frequently practised, and that this heroic but rational mode of treatment will cause less anxiety than puncturing did a few years ago.—*British Med. Journ.*, September 22, 1883.

VARIATIONS OF THE CHLORIDES IN DISEASES.—DR. BUROT read a paper on this subject before the late meeting of the French Association for the Advancement of Science, in which he showed a rapid method for estimating the quantity of the chlorides (the common method with nitrate of silver solution). Instead of using the graduated burette, the precipitating glass, and pipette, Burot inserts a tube, the extremity of which is in the form of a bowl, holding one cubic centimetre of urine. The urine is decanted and a small quantity of a solution of chromate of potash is added.

A burette, graduated in tenths of a centimetre, is used for decanting the solution of nitrate of silver. Each division corresponds to grs. xv of the chlorides per litre. The end of the reaction is indicated by the coffee and milk color due to chromate of silver.

Burot's observations lead him to admit eleven grammes of chlorides per litre as the normal, ten grammes being chloride of sodium, and one chloride of potassium. This proportion will vary, however, with the elimination, and with the causes which increase or diminish the secretory activity of the kidneys. It also varies in different states of disease. Diminution of the chlorides is important in view of the practical deductions which may be drawn from it. In chronic diseases, diminution only indicates feebleness of the digestive powers, unless there exists some other means of elimination, as diarrhœa, dropsy, etc.

In acute diseases, the diminution is proportional to the intensity of the disease, and the disappearance of the chlorides announces the presence of serous effusions or inflammatory exudations.—*Gaz. Méd. de Paris*, No. 35, 1883.

Acute Gonorrhœal Rheumatism.—In a paper on this subject in *Guy's Hospital Reports*, vol. xli., Mr. J. N. C. Davies-Colley suggests that there are several distinct affections confused together under the name gonorrhœal rheumatism, which he enumerates as follows:

1. *Gonorrhœal synovitis*, a chronic affection, occurring in the male, generally in the knee-joints. Very rarely it is acute, and goes on to suppuration.

2. *Gonorrhœal arthritis*, an acute affection, occurring in the female quite as often as in the male; as a rule, attacking at the outset several joints, and afterwards confined to one, most frequently the elbow-joint, affecting especially the fibrous tissues of the joint, and only secondarily the synovial membrane and cartilages.

3. *Gonorrhœal inflammation of fibrous structures not connected with the joints, e.g.*, the plantar fascia, sclerotic, iris, the peri- and endocardium; this gonorrhœal inflammation of the plantar fascia sometimes occurs in the acute form. Inflammation of the first three structures usually occurs in connection with chronic gonorrhœal synovitis. In the last two situations inflammations seem to be generally associated with gonorrhœal arthritis.

With regard to the second class, he says:

1. It usually occurs during the acute stage of gonorrhœa, or some purulent discharge from the genital organs, in adult patients under middle age.

2. It occurs as often in females as in males, if not more often. Of twelve cases recorded by the writer, nine were in females.

3. It may attack any joint, but most often the elbow-joint. Eight of the writer's twelve cases were in the elbow.

4. At first it attacks several joints, like acute rheumatism, and then confines itself, as a rule, to one.

5. Its seat is the fibrous tissue of the joint. There are great œdema, redness, pain, and tenderness. The ligaments are softened, and the cartilage may be disorganized. There is but little synovial effusion, and constitutional disturbance is but slight.

6. It may be confounded at first with acute rheumatism, later on with phlegmonous erysipelas, bursitis, lymphangitis, phlebitis, gout, and pulpy disease of the synovial membrane.

7. It rarely, if ever, suppurates, but is especially prone to set up fibrous anchylosis.

8. The best treatment is to cure the discharge, keep the joint perfectly still, and apply uniform pressure as long as the acute stage lasts, and then to use passive motion.

Floating Kidney.—Prof. Senator's conclusions recently published in the *Charité Annalen*, based upon the records of thirty-two cases, agree in almost every particular with those to be found in Landau's *Wanderniere der Frauen*. Senator terms the affection "ectopia renis." He found 1 in every 139 sick women to be subject to floating kidney, independently of age or social station. Disappearance of the fat around the capsule of the kidney can hardly be a cause of this condition, for there is little or no such fat in children, amongst whom floating kidney is very rare, and men are as liable to emaciation as women, yet floating kidney is much less frequent amongst men than in women. The absence of fat, as Senator most pertinently observes, does not cause floating kidney, but facilitates diagnosis. The causes are more probably to be found in the condition of the generative organs and defects of attire. Repeated pregnancy, causing pendulous abdomen, is a very probable cause; and uterine displacements are considered by Landau to influence the position of the kidney. The same authority attributes displacement of the kidney to tumors and hydronephrosis, but Senator has never observed these pathological conditions in any of his cases. Tight-lacing is considered as a highly probable cause of floating kidney, as Mr. Clement Lucas observes in his paper on surgical diseases of the kidney, published in this week's *Journal*, and would account for the greater frequency of displacement of the right kidney, which, in a tight-lacing woman, is subject to prolonged pressure by a large solid body, the liver. The greater length of the right renal artery favors displacement of the right kidney. To make diagnosis as certain as possible, the patient should first be placed on her back; the abdominal walls must then be thoroughly relaxed by passive elevation of the lower extremities. In examining the right lumbar region, the surgeon or physician should stand on the same side, and place the left hand on the loin posteriorly, and the right on the abdomen; in examining the opposite side, these tactics must be reversed. Prof. Senator appears to prefer this method to Landau's, for if the medical attendant stand on the opposite side of the patient, with the position of the hands reversed, Senator believes that the displaced organ is more likely to be pushed aside, and thus elude detection.—*Brit. Med. Journ.*, Sept. 29, 1883.

Method of Reduction in Dislocations at the Elbow.—Mr. J. E. Kelley gives the following method for reducing dislocations at the elbow-joint, especially in cases where assistance cannot be readily obtained:

The operator sits on a corner of a table, at the end of which the patient is placed upon a chair. The injured limb is drawn under the surgeon's proximal thigh, which rests, close to the joint, on the anterior surface of the humerus, while the olecranon is accurately placed on the anterior surface of the lower third of the distal femur, and the proximal foot is "hitched" behind the other leg, which is flexed firmly against the frame of the table. In order to obtain the most favorable fulcrum, the surgeon fixes his proximal elbow against the antero-internal aspect of his corresponding thigh, and, grasping the wrist of the patient with both his hands, reduction is effected by the simultaneous and coöperative action of the muscles of the arms, back, and thighs. Fixation and counter-extension are supplied by the powerful thighs of the operator, and coaptation is effected, with great nicety, by the backward pressure of the proximal femur against the anterior surface of the humerus, while the distal femur forces the olecranon forwards. Owing to the accuracy with which it can be applied, this power, which is incalculably greater than that afforded by the pressure of the fingers and thumbs (Boyer), is sufficient, when the forearm is steadied, to reduce an ordinary dislocation without the aid of extension. Additional adjusting influence is exercised by the inner side of the proximal thigh, which, by pressing against the anterior surface of the forearm, liberates the coronoid process from its position behind the lower extremity of the humerus, and allows the greater sigmoid cavity to resume its normal relation to the trochlea. Extension is supplied by the muscles of the upper extremities acting round the fixed point provided by the elbow of the surgeon, and, when his body is thrown backwards, additional force is derived from the muscles of the back, the glutæi, and the other extensors of the thighs. This power may be applied at various angles in rapid and easy succession, an advantage which the surgeon experienced in the treatment of dislocations cannot fail to appreciate.

In the lateral modifications of the posterior luxations the reduction is generally effected by the same manœuvre which is employed for the simple form of dislocation, but should special coaptation be necessary, it is at the disposal of the operator, as, when aided by the powerful constraining pressure of the thighs, the proximal hand can supply sufficient traction and stability, while the other is unoccupied and in the most advantageous position to apply any additional manipulation, which may, if desirable, be afforded by an assistant. If the condition be such that the full extending force of both arms be required, the isolated rural surgeon can, with a little ingenuity, render himself independent of professional aid by fixing the bone of the arm or forearm, which is displaced inwards, by a bandage passing round his own loins, and by making lateral traction on the bone or bones displaced outwards, by another bandage attached to his foot, and passing over his knee, as over a pulley. By this simple apparatus the instinctive movements, which are essential to the reduction of the simpler luxations, are utilized for the treatment of the more complicated forms.—*Dublin Journ. Med. Science*, July, 1883.

Extirpation of the Kidney.—M. Ollier has performed this operation three times. In the first case, the operation was performed on account of pyonephrosis in a young woman, believed to be due to obstruction of the pelvis of the kidney by calculi. The extirpation was rendered difficult by adhesions of the capsule to the adjacent parts, and it was found necessary to decorticate the organ. Though the operation was long and tedious there were no untoward symptoms, and the patient recovered. The patient now complains of pain in the liver and left iliac fossa, and at two periods there has been excessive salivation, amounting to more than a quart in half a day.

The second operation was performed on account of a cyst containing about four gallons of fluid. The patient died on the third day.

The third case was one of sarcoma of the kidney. All went well until the tenth day, when the child died suddenly in attempting to raise itself from the bed.—*Gaz. Hebdom.*, No. 36, 1883.

Relations between Diseases of the Abdomen and the Right Heart.—The clinical researches of MM. Potain and Tessier and the recent memoir of M. Rendu, on this subject, are already familiar to many. Passerini now adduces a new confirmation of the close relations between visceral diseases and the heart. In three cases of peritoneal effusion, a cardaic insufficiency was soon characterized by prolongation of the first sound and augmentation of the second. This sound disappeared after evacuation of the liquid. Paserini considers this as dependent upon ischæmia of the abdominal veins compressed by the liquid, and also upon the obstruction to the thoracic veins. This explanation is confirmed by Larcher and Depaul, who have observed prolongation and augmentation of the first sound in pregnant women. Ovarian cysts and large tumors of the abdomen are sometimes accompanied by the same phenomenon. It seems, then, that it can be produced by mechanical compression of the abdomen.—*Gaz. Hebdom.*, No. 36, 1883.

Treatment of Phthisis.—Dr. E. P. Hurd, of Newburyport, Mass., in the *Boston Medical and Surgical Journal* (September 20, 1883), discusses the medicinal treatment of phthisis under the three heads of (I.) the germicide treatment, (II.) the constitutional treatment, (III.) the symptom treatment.

As regards the first, he says it would be presumptuous scepticism to gainsay all the testimony in support of this direct medication. Some benefit is doubtless often derived; the cough is allayed, local congestions arrested, putrefaction of the bronchial secretions prevented, and respiration facilitated. There is, however, no evidence that inhalations, sprays, atomizations, or fumigations have any efficacy in destroying the micro-organisms whose multiplication and whose ravages are supposed to be such important *secondary* factors in the disease. He says *secondary*, for he looks upon the constitutional diathesis as of *primary* importance. If the soil be not first fit for the bacillus, it will not find a habitat there. If it be *fit*, there is no direct medication known to science which will prevent the development, growth, and multiplication of the parasite. It cannot, then, be too strongly urged that the hygienic and tonic medication constitutes the best germicide medication, and that pure, dry, bracing out-door air is the best antiseptic.

The constitutional treatment of phthisis comprises all those remedial agents which assist nutrition and promote systemic vigor. Chief among these are cod-liver oil, the phosphates and hypophosphites, bitter tonics, alcohol, and arsenic.

He has seen the best results from the oil when large quantities were taken, say four or five ounces a day. In whatever stage of the disease, where cod-liver oil is well supported, amelioration always attends its use. Unfortunately, however, in this stage of softening, and in febrile conditions, it is, as a rule, not borne.

Of the various emulsions in the market, he has had the best success with that of Phillips', which certainly contains the oil globules in a very minute state of division. He has seen this emulsion taken with benefit—and for a long time—by patients with delicate stomachs which revolted against the pure oil.

As regards the hypophosphites and phosphates in phthisis, there is probably nothing specific about them. Alone they have never cured and never can cure consumption. They doubtless have an important subordinate place in the therapeusis of this disease, aiding nutrition, and possibly being appropriated, to some small extent, in supplying the waste of the organic phosphorus compounds.

Lumbricus in the Liver.—Dr. Oks, of Rasgrad, Bulgaria, describes in *Vratsch*, the case of an almost moribund phthisical patient, who was seized with vomiting and icterus. The liver was much enlarged. After death, the usual appearances of advanced phthisis were discovered. All the biliary ducts were dilated, and the common duct was occupied by a large female lumbricus; one extremity of its body hung free into the duodenum. Deep in the substance of the liver a smaller male lumbricus was found, impacted in a biliary duct. This is a rare, but not entirely unknown, complication of a parasitic disease.—*British Medical Journal*, September 29, 1883.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

Communications are invited from all parts of the world. Original articles contributed exclusively to The Medical News will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

Subscription Price, including Postage,

Per Annum, in Advance, ... $5.00.
Single Copies, ... 10 cents.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

Address, HENRY C. LEA'S SON & CO.,
Nos. 706 & 708 Sansom Street,
Philadelphia, Pa.

SATURDAY, OCTOBER 20, 1883.

FORMS AND TREATMENT OF ANGINA PECTORIS.

Dr. Henri Huchard, in the course of an elaborate disquisition on "Angina Pectoris" ("Des Angines de Poitrine," *Revue de Médecine*, August, 1883), classifies the several pathogenetic influences in five groups: The organic form; the nervous; the reflex; the diathesic; and the toxic. These causal conditions admitted, the therapeutical indications are at once manifest. It may be well to clear the ground by a proper definition of the pathogeny of each class.

By the organic form is meant an ischæmia of the heart-muscle, the result of calcification and narrowing, or complete obstruction of the coronary artery. The nervous form is that condition of the cardiac nervous mechanism which has its origin in the state of the nervous system accompanying hysteria, neurasthenia, hypochondria, exophthalmic goitre, and in the masked epilepsy which assumes the objective type of angina pectoris. The reflex form, as the term implies, is a disturbance at some point in the sphere of distribution of the pneumogastric nerve, reflected over its cardiac branches. Irritation of the peripheral nerves at other points may, under some circumstances, be referred to the heart, and induce paroxysms of angina pectoris. The examples of diathesic origin occur in gout, rheumatism, diabetes, and syphilis. Lastly, the toxic cases are caused by the abuse of tobacco, tea, coffee, and, indirectly, of alcohol, etc.

If the limits of the pathogenetic influences inducing angina pectoris be enlarged to include all the factors above mentioned, the severe definition heretofore given of the malady must be correspondingly modified. An entirely functional state must be admitted to exist, and, indeed, must be regarded as relatively and actually of more frequent occurrence. That form characterized as organic, in which various morbid conditions of the heart exist, are by Huchard entitled *true* angina pectoris, and the functional disorders *false* angina pectoris. The former is the malady described by Heberden, Fothergill, Stokes, and other classical English authorities.

In few maladies are the improvements in our therapeutical resources more conspicuous. In the use of the most effective remedy for the relief of the paroxysm, an admirable illustration is given of the remarkable value of the contributions made to therapeutics by physiological investigations. We refer to the use of the amyl nitrite in this affection—an addition to scientific medicine which we owe to Dr. Lauder Brunton. Remarking the high tension of the vessels in certain cases of angina pectoris, Dr. Brunton made the fortunate deduction that this condition might be quickly relieved by amyl nitrite, which promptly lowers vascular tension. All the world knows how completely successful the expedient has proved in actual practice. This explanation of the relief afforded by the remedy is not universally admitted. For example, Filehne holds that the relief is due to paresis of the vagus, and Dr. George Johnson that the arrest of the pain in the cardiac nerves is the real factor, the rise in the vascular pressure being secondary to this pain, since the same result follows from irritation of the sensory nerves in any part of the body. Huchard offers an explanation of the good effects of amyl nitrite which seems to us eminently satisfactory. He thinks that the remedy acts by increasing the circulation in the cardiac muscle, which is much impeded by spasm or calcareous changes in the coronary artery, and that it lessens the work of the heart by dilating the peripheral vessels. Not all cases of angina pectoris are accompanied by peripheral vascular spasm, and hence this explanation will not satisfy all the requirements of a perfect theory.

If the curative effect of amyl nitrite is not explicable in a satisfactory manner, its value is none the less firmly established, although failures have been reported. The most facile mode of inhalation is by means of delicate glass vesicles—perls—which may be broken in a handkerchief and readily inhaled with slight loss. Nitroglycerine corresponds in action, and may, therefore, be substituted in some forms of the malady. It is less prompt, and the susceptibility to its action is so varied that some preliminary trials are necessary to determine the proper dose. Whilst nitroglycerine is much inferior to amyl nitrite for the relief of the paroxysms, it has a very important place as a remedy in those cases of the functional disorder characterized by repeated seizures at short intervals.

The remedy next in importance is morphine subcutaneously. Huchard maintains the thesis that morphine diminishes the contractile energy of the heart, and lessens the vascular tension by dilating the peripheral vessels. Not to mention the mass of opinion in opposition to this view, it will suffice to give the observations of Schüller, who studied the effects of morphine on the vessels of the pia-mater *in situ*, and ascertained that this agent first, and briefly, dilates the vessels, but this is soon followed by decided contraction. The unquestionable good effects of morphine in angina pectoris must, therefore, be sought on other grounds. The two chief reasons for its utility are the relief of pain, and the slowing of the heart movements, permitting a more abundant supply of blood to the heart muscle. The best results in the severest cases, are said to be had from a combination of these remedies by the inhalation of amyl nitrite and the subcutaneous injection of morphine.

When the heart's action is very feeble, as appears to be the condition of the organ in some examples of angina pectoris, the subcutaneous injection of ether, and the intravenous injection of ammonia, are highly useful. In such cases, also, atropine may render important service. The inhalation of ethyl bromide, cautiously carried on, may also prove in a high degree efficacious. This agent has also been employed with excellent results, by the hypodermatic method, in place of ether.

With the means now at our disposal, the treatment of the paroxysms of angina pectoris is most effective. It is, however, more desirable to prevent the attacks. This fortunate result may be attained by the adaptation of remedies to the various pathogenetic conditions. Have we to deal with true angina pectoris—with the organic form? Are there also at work in the causation of the attacks any of those influences concerned in the production of the pseudo affections? Is there a nervous, a diathesic, a toxic, or a reflex element added to the existing organic basis of the seizures? It would seem needless to assert that all causes of disturbance included under these heads, and all unfavorable hygienic influences of every kind, should be withdrawn. Our space will only permit some references to the remedies properly so-called. As in the organic form the condition of chronic arteritis is the chief source of mischief, it becomes exceedingly important to arrest the progress of this destructive change. None of the measures hitherto proposed, unless the treatment by carbonate of soda—the suggestion long ago made by Bretonneau is an exception—has exercised any remedial influence. We are, therefore, fully aware of the assumption involved in our recommendation, of the carbonate and iodide of ammonium given conjointly with cod-liver oil as the most effective treatment for chronic endarteritis. Huchard concludes that the iodide of potassium or sodium is entitled to rank first as a preventive remedy, and he gives the details of six cases illustrating the remarkable value of this plan of medication. We prefer, to the iodides alone, the combination above referred to, for the following reasons: In chronic endarteritis, when the structural changes in the walls of the vessel encroach materially on the lumen, and retard the blood-current, fibrinous deposits take place, and finally thrombi form. The persistent administration of ammonia is the most effective means of preventing these formations by maintaining the alkalinity of the blood. The iodides contribute to this result. Cod-liver oil with the iodides is probably the best remedy for chronic endarteritis. Besides, by improving the nutrition generally, it tends to give stability to nervous matter. *Sanguis moderator nervorum* is an aphorism of Hippocrates. Arsenic serves a double purpose: as a means of stimulating the nutritive functions and as a moderator of reflex excitability. We have seen cases in which it gave more sustained relief than any other remedy. Under such circumstances, enormous doses are taken with impunity. An apparent tolerance is established, and the large doses, so far from causing gastric disturbance, increase the appetite, improve the nutrition, and induce a condition of mental comfort comparable to that of a favorably acting narcotic. With this mental quietude coincides a calm state of the reflex excitability.

It is in the office of a preventive remedy that nitroglycerine serves so important a purpose. It should be given daily, to maintain the state of diminished vascular pressure. Iodide and bromide of ethyl by inhalation, in quantity far short of that necessary to cause anæsthesia, may also be used daily when attacks are frequent. The bromides also have an important function when reflex excitability is to be moderated.

The diathesic and toxic cases are improved or cured by the removal of the causes, and by treatment addressed to the functional nervous disturbance resulting therefrom.

KNEE-HÆMARTHROSIS.

IN a paper read at the recent meeting of the British Medical Association, and published in the *British Medical Journal*, of September 22, MR. JOHN FAGAN, of Belfast, calls attention to the nature, diagnosis, and treatment of knee-hæmarthrosis, which, he asserts, is not noticed in surgical textbooks as an independent affection, and if mentioned as a complication of fracture or some other serious injury, there is no special guidance to its diagnosis and therapeutics. An idea of the comparative frequency of the lesion may be formed when it is stated that it has been observed in one of the hospitals with which Mr. Fagan is connected, and which contains about eighty surgical beds, twenty times during the past five years.

Extravasation of blood into the knee-joint may be caused by sudden muscular strains, severe contusions, and wrenches of the articulation, through which the mucous ligament and other vascular fringes are lacerated. This form of the complaint constitutes the typical, uncomplicated variety of the lesion, and is of rare occurrence. Another and more frequent form is associated with serious injury to the joint, and varies in degree from a simple fracture of the patella or a fissured fracture of the femur into the articulation, to that of a compound fracture or dislocation, being in the last two events only of secondary importance. In certain forms of the simple fractures mentioned, the fragments remain in close apposition, and the blood is retained in the synovial cavity, through which the lesion belongs virtually to the typical variety. When, however, the fragments are widely separated, or there is much laceration of the synovial membrane, blood is effused both within and without the sac, and, while this condition modifies the symptoms and prognosis, it does not change the mode of treatment.

In all cases of uncomplicated hæmarthrosis, the blood remains fluid for an indefinite period, and in one case of fractured patella and in one of fracture of the lower end of the femur into the joint, fluid blood was aspirated, respectively, in four days and fourteen days after the injury. Absorption of the blood, when it forms the bulk of the swelling, is rarely met with; hence it is useless to institute a plan of treatment directed to that end.

The diagnosis of the affection is not difficult, and is based upon the following points: Swelling rapidly following an injury to the normal knee-joint, and limited to the synovial sac, as indicated by enlargement of the pouch under the quadriceps muscle; mobility of the joint; absence of heat and febrile action; little, if any, pain; and resistance to ordinary methods of treatment. In synovitis, the swelling comes on after a varying interval; the joint is usually fixed; heat, pain, and more or less fever are present; and the enlargement subsides under appropriate measures.

The treatment consists in removing the fluid at once with the aspirator, putting a bandage firmly around the joint, placing the limb on a posterior splint, and applying bags of ice. If, in a few days, the swelling do not entirely disappear, the joint should be punctured again. All of the fifteen cases treated in this manner recovered, without an unpleasant symptom, in from two to three weeks.

THE ANTAGONISM BETWEEN PARALDEHYDE AND STRYCHNINE.

IN a recent issue, we called attention to the valuable hypnotic and anodyne qualities of paraldehyde. The Italian PROFESSOR CERVELLO, to whom we owe this new remedy, has continued his researches, and has recently demonstrated an antagonism of action between paraldehyde and strychnine. His research included three forms of procedure: 1. After a dose of strychnine, a non-lethal quantity of paraldehyde was given. 2. After a dose of paraldehyde, a lethal quantity of strychnine was administered. 3. Both agents were simultaneously used. As a control experiment, the same animals were subjected to the effects of these agents alone. In this way a criterion was established by means of which the narcotic power of paraldehyde and the toxic activity of strychnine could be judged. By this method he demonstrated that paraldehyde arrested the action of strychnine, after the manifestations of poisoning began, or prevented the appearance of toxic symptoms. The antagonism was manifested in what order soever these agents were administered, and when they were given together. Cervello ascertained that it is not necessary to the antagonism that the quantity of paraldehyde given should be above the merely physiological limit, a relatively small quantity sufficing to neutralize the effects of a large dose of strychnine. In a rabbit weighing 1665 grammes (about three and a half pounds), four milligrammes of nitrate of strychnine (more than a lethal dose) were injected, and the symptoms of poisoning vanished under the action of a small dose (less than a drachm) of paraldehyde. To another rabbit, narcotized by a drachm nearly of paraldehyde, six milligrammes of nitrate of strychnine were given, and the animal survived. Strychnine appears to have no influence over the course of the narcotizing action exerted by paraldehyde, for the duration of the narcotic effect is practically the same when strychnine has and when it has not been given. There is, however, a difference as to the time when the narcotic effect produced by paraldehyde manifests itself—strychnine retarding the action, but not altering its character. The seat of the opposing actions is the spinal cord, strychnine increasing and paraldehyde lessening the reflex excitability of the gray matter of the medulla oblongata.

LATERAL CLOSURE OF VEIN-WOUNDS.

DURING the past twelvemonth efforts to popularize partial closure of wounds of veins have been made by PROF. BRAUN, of Heidelberg, and DR. L. S. PILCHER, of Brooklyn, whose papers on the subject may be found respectively in vol. xxviii., *Archiv für klin. Chirurgie*, and the *Annals of Anatomy and Surgery*, for August, 1883. In support of their views as to the safety of the measure, they refer to Von Wattmann, Von Walther, Bérard, Denonvilliers, Richet, Follin, Hueter, and Von Linhart.

Lateral closure includes ligation, forcipressure, and suture, of which the first is the most generally applicable. As stated by Braun and Pilcher, it should be reserved for the jugular, subclavian, axillary, and femoral veins; but, as a sufficient number of cases upon which to base positive conclusions as to the comparative safety of lateral and complete closure has been recorded of the internal jugular alone, our remarks will be confined to that vessel.

The internal jugular vein has been tied laterally eighteen times, of which three ended fatally from secondary hemorrhage. The wound has been closed with forceps twice, both of which recovered, but forcipressure was resorted to in one after a lateral ligature had failed to retain its hold. The suture has been employed twice, both having been successes as regards bleeding. Leaving out of the question the four examples of suture and forcipressure, it will be seen that of nineteen lateral deligations three were fatal, and one failed to accomplish the object through the slipping of the thread. Hence the measure was unsuccessful in nearly one case in every five.

The same trunk has been completely included in a ligature upwards of fifty times, without a single death from hemorrhage, and without a single premature detachment of the thread. These facts speak for themselves, and they utterly upset all the sophistic arguments that have been advanced in favor of lateral deligation, which, upon the authority of Malgaigne, Von Langenbeck, Pirogoff, C. O. Weber, Von Mosetig, Rose, Blasius, H. Fischer, Billroth, Bardleben, G. Fischer, Boeckel, Nicaise, Dussutour, Tillaux, the elder and younger Gross, Agnew, Ashhurst, Lidell, and Markoe, should be abolished from practice as a dangerous expedient. The plea entered by Pilcher for the catgut thread is not warranted by experience, and his supporter in other points expressly states that the silk ligature is preferable on account of the greater firmness of its knot and its consequent less liability to slip.

THE CENTENNIAL OF THE HARVARD MEDICAL SCHOOL.

In 1783, one hundred years ago, John Warren, Benjamin Waterhouse, and Aaron Dexter founded the Medical School of Harvard University. Last Wednesday the Centennial Anniversary of this occasion was appropriately celebrated, and by a happy coincidence at the same time the University dedicated to its service the most beautiful and thoroughly equipped building, now in use for the purposes of medical education, to be found on this Continent.

The Centennial Oration was delivered by Dr. Oliver Wendell Holmes, who, after many years of faithful service in the Chair of Anatomy, has lately retired from active teaching, and on this occasion, probably for the last time, has made a formal address on medical topics. The oration was carefully prepared, and the large audience, which included representative men from different parts of the country, listened with eager attention to the scintillations of wit which fell from the mouth of the poet-anatomist. The address we present in full to our readers through the generous courtesy of *The Boston Medical and Surgical Journal.*

The celebration was appropriately concluded by the presentation to the University of a portrait of Dr. Holmes and a bust of Dr. Bigelow, who, by their faithful professorial teaching, as well as by their conspicuous contributions to literature and the healing art, have rendered eminent service to the University during a goodly portion of the century which it has now completed.

THE MORBID CHANGES IN MYXŒDEMA.

Very few opportunities have been afforded for the study of the morbid anatomy of myxœdema. The "cretinoid state" of Sir William Gull, the mucoid degeneration of Ord, and the pachydermic cachexia of Charcot rather suggest the cutaneous appearances than throw light on the pathological conditions. Recently M. Henrot, of Rheims (*Le Progrès Médical*, Sept. 15, 1883), has given an account of the appearances in a case observed by him, and as the changes were carefully studied, it may be useful to lay before our readers the more important results of this examination.

M. Henrot emphasizes the fact that there were no alterations in the skin to account for the characteristic appearances. He found in the cerebrum a considerable hypertrophy of the pituitary body and of the pineal gland. The pneumogastric nerves, the glosso-pharyngeal, the brachial plexus, and the ganglia and fibres of the sympathetic had undergone a notable increase in size. Changes also were found in the meninges of the spinal cord comparable to those which occur in chronic alcoholism. M. Henrot hence concludes that myxœdema consists essentially in a return to the embryonic condition of the subcutaneous, submucous, and general connective tissue under the influence of the hypertrophic changes which occur in the sympathetic system and its annexed organs, the pituitary and pineal bodies, leading to the excessive production of mucin, and the infiltration of the affected organs with this material.

SOCIETY PROCEEDINGS.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

Stated Meeting, Thursday Evening, Sept. 13, 1883.

THE PRESIDENT, JAMES TYSON, M.D., IN THE CHAIR.

DR. CHARLES W. DULLES presented a specimen of very large

ULCER OF THE STOMACH, WITH UNUSUAL FEATURES.

The specimen which I have to show you came from the body of a patient of Dr. Edward L. Anderson, who had had Dr. J. H. Musser to see her in consultation during life, and who asked my assistance in making the *post-mortem* examination because of Dr. Musser's temporary absence from the city. To the clinical notes of Dr. Anderson and my notes of the autopsy, Dr. Musser will, no doubt, add his own impressions of the case, which has appeared to me to be of singular interest and instructiveness.

The following are Dr. Anderson's notes:

Mrs. M., aged 35 years, husband living, the mother of five children, one of whom died of stricture of the pyloric or cardiac end of the stomach. Both her parents died before their fiftieth year.

At my first visit, May 12, 1883, she was confined to bed, and stated that since the birth of her last child she had not been well, having more or less dyspepsia and growing steadily worse for the last six months. She complained of a constant burning pain in the region of the stomach, which nothing seemed to relieve. She vomited daily, sometimes immediately after a meal, but often not until evening, when it seemed to her that all the food she had taken during the day would be ejected. The matter vomited was intensely sour, dark, and frothy, having the appearance of yeast. There was always pain after vomiting, and at all times irregular pains over the abdomen. She was anæmic, emaciated, and had a weak but regular pulse. Upon physical exploration I could find no tumor. Her heart and lungs were normal, and, as I afterwards learned, the urine likewise. The abdomen was resonant. She was placed on a milk diet, with pepsin and ten drops of sulphurous acid every three hours. She took two quarts of milk daily, and did not vomit until the twenty-second of May; a period of ten days. On this day she vomited but a small quantity of food. May 23, the period of her menstruation (though not menstruating from April until the time of her death), she ate, on her own responsibility, a fritter for supper. This indiscretion brought on an attack of vomiting and sufficient prostration to occasion considerable alarm to her family and cause them to send for me. I found her much exhausted, only able to speak in monosyllables, with a pulse of one hundred and four, and respiration forty. She complained of intense, burning pain in the stomach. External heat and sulphurous acid internally gave relief. This was the first time I was able to see the vomited matter, and I found it to be digested blood, about two quarts in amount. Dr. J. H. Musser kindly examined the material microscopically and found blood-corpuscles, pus-globules, and epithelial cells. I was told that she had vomited similar material prior to my first visit. The vomiting was repeated on May 25, 26, 27, and 28, and several times there were free hemorrhages. She was treated with bismuth and carbolic acid, with enemata of milk, whiskey and eggs, and inunctions of cod-liver oil. Hemorrhages occurred again on June 6, 7, and 8. On June 10, Dr. J. H. Musser saw the case in consultation; he thought he detected a tumor. We came to no positive diagnosis, but wavered between carcinoma and ulcer. It was only when the patient was placed in the knee-elbow position that a tumor could be felt, and this a little to the right of the median line. The treatment was changed to one drop of hamamelis every twenty minutes, and a pill containing one-quarter of a grain of oxide of silver three times daily. June 17 and 18, hemorrhages again occurred, but from this time until her death, about six weeks later, there were no more hemorrhages, little inclination to vomit, and very little pain. This was notwithstanding the fact that, I have reason to believe, for about a month before her death she paid no particular attention to her diet, while the only part of the treatment carried out was the taking of the oxide of silver pill. About three weeks before her death a troublesome cough set in, but it was easily controlled by opium. Her death followed a large meal and free draughts of coffee and water. The act of death was quiet and gradual, unaccompanied by pain or alarm.

Autopsy.—Sept. 2, 1883. Body of Mrs. M., aged 35; thirty hours after death; rigor mortis absent; body much emaciated; right hand puffy with œdema; bruise over middle of right shin. Examination of thorax, abdomen, and pelvis.

There was no fluid in either pleural cavity. Both lungs were attached at the upper part to the parietal pleura, by adhesions which broke down easily. The upper lobe of each lung was pretty well solidified with chronic catarrhal deposits, and quite soft. In each upper lobe there was a cavity. That in the right lung was as large as a hen's egg; that in the left about the size of a pigeon's egg. Both were ragged, and contained dirty grayish detritus. The lower lobes of both lungs contained a number of small nodules of caseous degeneration.

The heart was very small and firm, about the size of a goose-egg. Its valves were normal, and it contained but a small quantity of fluid blood in its right cavity.

The abdomen contained about a third of a pint of slightly turbid serous fluid. There was not the slightest injection of the peritoneum anywhere, nor any other evidence of peritonitis. The pelvic organs were all normal in appearance, except the uterus, which, though of normal size, was in a state of marked retroflexion. The bladder contained about two fluidounces of urine. There was no omental apron. The liver was of normal size and appearance. The gall-bladder was normal in appearance, and contained about half a fluidounce of saffron-colored bile, but no gall-stones. The spleen was normal. The kidneys were of normal size, rather hard, their capsules adherent, their surfaces a little granular. On section, their cortex was found somewhat diminished. The suprarenal capsules were very tough, the right more so than the left. The pancreas was of normal appearance at its left end, but at its right it was attached to the stomach, and was decidedly indurated. Here it was imbedded in a quantity of delicate adhesive bands, which united into a bundle its own duct, the end of the ductus communis choledochus, and the pyloric end of the stomach. The intestines were collapsed and empty, except the duodenum, which contained a small quantity of thick, bile-stained chyme.

The stomach itself presented the features of the greatest interest. It was much enlarged by dilatation; its walls were thin and pale; its vessels along the greater curvature much enlarged and full of dark blood. It occupied a standing position from above downwards, and from left to right. It contained about *two quarts* of grumous, sour-smelling fluid ingesta, and with this it was not nearly filled. At the upper part of the pyloric entrance it bore a firm, puckered induration, looking like a cicatrix, about two-thirds of an inch in diameter. Close by this was a large ulcer, about two and a half inches long, and over an inch wide, with indurated, thickened, and in part perpendicular edges. This ulcer passed through all the coats of the stomach; nevertheless, the large quantity of fluid contents of this viscus had not escaped from its cavity because the ulcerated part of the stomach was applied against the adjacent pancreas and attached to it by adhesions. This attachment, however was extremely delicate, and would not bear the gentlest handling; it gave way while the viscera were still in the abdomen, upon an attempt being made to lift the pancreas up, while the stomach was held aside. This disclosed what seemed to be a loose connective-tissue mesh between the stomach and pancreas, in which a small quantity of the ingesta was found.

The pyloric orifice of the stomach was at the edge of the induration surrounding the ulcer, and it was so contracted as to barely admit the passage of a grooved director through it.

Dr. Henry M. Fisher presented a case of

TUBERCULAR ULCERATION OF THE INTESTINE, WITH TUBERCULAR INFILTRATION OF THE LUNGS AND SPLEEN.

E. H., æt. 43, married, was admitted to the Episcopal Hospital July 16, 1883. The following notes were taken by Dr. George M. Boyd, the resident physician:

The patient states that she has been sick since last April. Her trouble began with vomiting and purging, which it seemed impossible to check. No cough was complained of, and there appeared, on admission, to be no marked dulness in percussion over either lung, but, in consequence of the patient's statements, a careful physical examination of the lungs was not made. She was very pale and much emaciated. At first, almost all nourishment was rejected, but after a few days the stomach became more tolerant of ingesta.

Pain was complained of in the left inguinal region, where there seemed to be an undue degree of fulness; but the pain was relieved by poulticing, and the diarrhœa was relieved to a certain extent by opium and astringents. Four or five thin, dark, and watery passages occurred every twenty-four hours, in spite of treatment. Sometimes small clots and shreds of coagulated blood were seen in the passages.

The diarrhœa became again more profuse, and the emaciation more extreme. About a week before her death the patient began to complain of cough, and auscultation then revealed tubular breathing and gurgling below the right clavicle.

Death occurred on August 30th. The post-mortem examination was made fifteen hours after death. Rigor mortis hardly yet well established. The body is extremely emaciated, the omentum being almost destitute of fat.

Heart: Weight four ounces; tissue pale.

The apices of both lungs present numerous cheesy nodules, with catarrhal pneumonic thickening. The right lung presents at its apex a cavity with smooth walls of the size of a pigeon's egg.

Spleen: Weight, two and a half ounces; its section shows numerous cheesy nodules.

Left kidney: Weight, two ounces; capsule adherent, and cortex diminished. Right kidney: Weight, four ounces.

Liver fatty.

Small intestine almost empty and contracted; its mucous surface is everywhere injected, and about eighteen inches from the ileo-cæcal valve it presents two or three small round ulcerations, which do not penetrate quite to the peritoneal investment. Mesenteric glands everywhere swollen, and veins dilated. The large intestine presents throughout its entire extent thickening of its submucous layer and other indications of chronic inflammation. The inflammation has caused in the descending and a portion of the transverse colon complete, or almost complete destruction of the mucous membrane for a space of about three feet. The muscular layers are thickened, and the mesenteric glands swollen, and there is some thickening and undue opacity of the walls of the vessels, but no tubercular granulation can be detected with the naked eye.

Dr. Fisher also presented a

CASE OF CANCER OF THE LIVER.

The patient, S. A., æt. 65, single, was admitted to the Episcopal Hospital July 31, 1883.

The following notes were made by Dr. Claxton, the resident physician: While at work, six weeks ago, the patient began to experience pain in the epigastric and right hypochondriac regions. Two weeks later, he noticed that he was jaundiced, and that there was a lump (or swelling) in his abdomen.

Upon admission to the hospital, the patient was much emaciated and very feeble; skin and conjunctivæ intensely jaundiced, of a deep saffron hue.

There was marked bulging noticed in the right hypochondriac and epigastric regions. The tumor, which could be plainly felt through the thin abdominal wall, was found to extend four inches below the xiphoid cartilage and two inches to the left of the linea alba.

The mass occupying the right hypochondriac region was found to be distinctly nodulated and very hard. Some of the nodules appeared to be umbilicated. The patient presented a markedly cachectic appearance; tongue thickly coated with a dirty yellowish-brown fur; his bowels were constipated, and there was anorexia.

Purgation failed to influence the size of the tumor. The patient complained of insomnia, but did not seem to suffer much. Mental action was sluggish. The patient became rapidly weaker, and for fully a week before his death it was noticed that his extremities were very cold and full. Three days before his death his pulse had become so weak as to seem almost imperceptible. Death occurred on August 16th.

The post-mortem examination was necessarily hasty, as the body was removed from the hospital within two hours after the patient's death. The new growths appeared to involve, however, only the liver and the pancreas. The common bile-duct was completely occluded by a hard nodular mass, which had its apparent origin in the pancreas. Above the occlusión the cystic duct and the gall-bladder were distended with dark, olive-green bile. The liver weighed five pounds six and a half ounces. Section of the organ showed complete infiltration with cancer nodules, and little or no normal hepatic tissue could be seen. The spleen was markedly atrophic, weighing one and a half ounce. The kidneys were deeply stained with bile, and seemed somewhat contracted. The heart was very small, and its muscular tissue flabby.

OBITUARY RECORD.

Brigadier-General Charles H. Crane, M.D.,

SURGEON-GENERAL U. S. ARMY.

In our last issue, we gave a short notice of the death of Surgeon-General Charles H. Crane, U. S. Army, which took place at his residence, in Washington, D. C., on the morning of October 10, 1883, in the fifty-ninth year of his age. He had been suffering for several weeks with an abscess near the root of the tongue, which had opened and formed an ulcer which extended forwards. The immediate cause of death was hemorrhage from perforation of one of the lingual arteries.

General Crane was the son of Colonel Ichabod B. Crane, of the First U. S. Artillery, and was born in Rhode Island, July 19, 1825. He graduated in Arts, at Yale College, in 1844, and received the degree of Doctor in Medicine at Harvard, in 1847. He at once entered the army, being appointed an Acting Assistant Surgeon the same year, and commissioned as Assistant Surgeon on February 14, 1848.

He served with the Second U. S. Artillery in the Mexican War, and was also in the Florida War. At the close of this, he went to the Pacific Coast, where he remained on duty until the end of 1856; was then transferred to New York City, where he remained, as Attending Surgeon, examining recruits, and as Assistant to the Medical Purveyor, until 1859; accompanied General Scott to the Pacific Coast, September, 1859; was promoted to a Surgeoncy in May, 1861; Medical Director, Department of the South, to July, 1863; in the Surgeon-General's Office until appointed Assistant Surgeon-General, in July, 1866; Brevet Brigadier-General for faithful and meritorious services during the war, and appointed Surgeon-General July 3, 1882. He leaves a wife and one son.

General Crane was greatly esteemed by those who were intimate with him, these being mostly the older officers of the army. He was an excellent executive and administrative officer, and his sudden and untimely death is a heavy loss to the Department.

The following circular has been issued from the Headquarters of the Army:

General Orders, No. 70.

Headquarters of the Army,
Adjutant-General's Office,
Washington, October 10, 1883.

The following order has been received from the War Department:

It is with regret the Secretary of War announces to the Army the decease of Surgeon-General Charles H. Crane, who died at his residence, in this city, at 6 o'clock A.M. to-day.

General Crane was appointed Acting Assistant Surgeon in November, 1847, and his first duty was to accompany a detachment of recruits to join the army in Mexico. He was appointed Assistant Surgeon February 14, 1848, and served with the Second and Fourth Artillery in Mexico and Florida.

In 1852, he was ordered to the Pacific Coast, where he took part in several expeditions against hostile Indians, rendering distinguished service in an expedition against the Indians near Rogue River, Oregon, in 1856. From December, 1856, to January, 1862, he was Attending Surgeon and Assistant to the Medical Purveyor at New York City. In 1859, he accompanied General Scott in his diplomatic mission to the Pacific Coast. He was promoted Major and Surgeon May 21, 1861. On duty as Medical Director, Department of Key West, Florida, and Medical Director, Department of the South, to July, 1863; and Medical Inspector of Prisoners of War in August and September, 1863. From September, 1863, he was on duty as executive officer in the Office of the Surgeon-General; promoted Colonel and Assistant Surgeon-General July 28, 1866, and appointed Brigadier-General and Surgeon-General on July 3, 1882.

General Crane received the brevets of Lieutenant-Colonel, Colonel, and Brigadier-General for faithful and meritorious services during the War of the Rebellion.

The foregoing notation of the long and faithful service of General Crane simply formulates his official record as an honorable and distinguished officer of the Army. In the hearts of his many friends another record exists — the outgrowth of his manly worth, earnest devotion to duty, fidelity in friendship, and generous sympathies — that will serve to keep his memory cherished so long as one remains.

The officers of the Medical Department will wear the usual badge of mourning for six months.

By command of General Sherman.

NEWS ITEMS.

BOSTON.

CELEBRATION OF THE ONE HUNDREDTH ANNIVERSARY OF THE FOUNDATION OF THE MEDICAL SCHOOL OF HARVARD UNIVERSITY, AND DEDICATION OF ITS NEW BUILDING, OCTOBER 17, 1883.

(Specially reported for The Medical News.)

The Centennial exercises were begun at eleven o'clock in Huntington Hall, Massachusetts Institute of Technology, in the presence of a large audience.

President Eliot said:

Ladies and Gentlemen: We are met to celebrate the beginning of the second century of the medical school's existence, and the simultaneous completion of its new building.

It is a hundred years since John Warren, Benjamin Waterhouse, and Aaron Dexter were installed as Professors of Anatomy and Surgery, Theory and Practice, and Materia Medica, respectively, and without the aid of collections or hospitals, began to lecture in some small, rough rooms in the basement of Harvard Hall, and in a part of little Holden Chapel at Cambridge. From that modest beginning, the school has gradually grown until it counts a staff of forty-seven teachers—ten professors, six assistant professors, nine instructors, thirteen clinical instructors, and nine assistants working in the spacious and well-equipped building which we are shortly to inspect, and commanding every means of instruction and research which laboratories, dispensaries, and hospitals can supply.

Out of our present strength and abundance, we look back to the founding of the school, and its slow and painful development. We bear in our hearts the three generations of the teachers who have served this school with disinterested diligence and zeal. We recall their unrequited labors, their frequent anxieties and conflicts, and their unfulfilled hopes; we bring to mind the careful plantings and the tardy harvests reaped at last, but not by them that sowed.

We meet, indeed, to rejoice in present prosperity and fair prospects, but we would first salute our predecessors, and think with reverence and gratitude of their toils and sacrifices, the best fruits of which our generation has inherited.

The medical faculty of to-day have strong grounds for satisfaction in the present state of the school; for they have made great changes in its general plan and policy, run serious risks, received hearty support from the profession and the community, and now see their efforts crowned with substantial success. By doubling the required period of study in each year of the course, instituting an admission examination, strengthening the examinations at the end of each year, and establishing a voluntary fourth year of instruction, which clearly indicates that the real standard of the faculty cannot be reached in three years, they have taken step after step to increase their own labors, make the attainment of the degree more difficult, and diminish the resort of students to the school.

They have deliberately sacrificed numbers in their determination to improve the quality of the graduates of the school. At the same time, they have successfully carried out an improvement in medical education which required large expenditures. This improvement is the partial substitution, by every student, of personal practice in laboratories for work upon books and attendance at lectures.

The North Grove Street building, erected in 1846 or '47, contained only one small laboratory for students —that of anatomy. We shall shortly see that the new building contains a students' laboratory for each of the five fundamental subjects—anatomy, physiology, chemistry, histology, and pathology, and that a large part of the building is devoted to these working-rooms.

It was a grave question whether the profession, the community, and the young men who, year by year, aspire to become physicians and surgeons would support the faculty in making these improvements. The answer can now be recorded. The school has received by gift and bequest three hundred and twenty thousand dollars in ten years; it has secured itself in the centre of the city for many years to come by the timely purchase of a large piece of land: it has paid about two hundred and twenty thousand dollars for a spacious, durable, and well-arranged building; it has increased its annual expenditure for salaries of teachers from twenty thousand dollars in 1871 and '72, to thirty-six thousand dollars in 1882 and '83; its receipts have exceeded its expenses in every year since 1871 and '72, and its invested funds now exceed those of 1871 by more than one hundred thousand dollars.

At the same time the school has become a centre of chemical, histological, and sanitary research as well as a place for thorough instruction; its students bring to the school a better education than ever before, they work longer and harder while in the school, and leave it prepared, so far as sound training can prepare them, to enter, not the overcrowded lower ranks of the profession, but the higher, where there is always room.

The Faculty recognize that the generosity of the community and the confidence of the students impose upon them reciprocal obligations; they gladly acknowledge themselves bound to teach with candor and enthusiasm; to observe and study with diligence, that they may teach always better and better; to illustrate before their students the pure scientific spirit; and to hold all their attainments and discoveries at the service of mankind. Certainly the medical faculty have good reason to ask to-day for the felicitations of the profession and the public.

Nevertheless, the governors, teachers, graduates, and friends of this school have no thought of resting contented with its present condition. Instructed by its past, they have faith in its future. They hope, they know, that the best fruits of their labors will be reaped by later generations. The medical profession is fortunate among the learned professions in that a fresh and boundless field of unimaginable fertility spreads out before it.

Its conquests to come are infinitely greater than those already achieved. The great powers of chemistry and physics, themselves all new, have only just now been effectively employed in the service of medicine and surgery. The zoölogist, entomologist, veterinarian, and sanitarian have just begun to contribute effectively to the progress of medicine. The great achievements of this century in medical science and the healing art are all prophetic. Thus, the immeasurable deliverance of mankind from smallpox is an earnest of deliverance from measles, scarlatina, and typhoid fever.

Within forty years anæsthetics and antiseptics have quadrupled the chances of success in grave surgical operations, and have extended indefinitely the domain of warrantable surgery; but in value far beyond all the actual benefits which have thus far accrued to mankind from these discoveries, is the clear prophecy they utter of greater blessings to come. A medical school must always be expecting new wonders.

How is the medical science to be advanced? First, by the devoted labors of men, young and old, who give their lives to medical observation, research, and teaching; secondly, by the gradual aggregation in safe hands of permanent endowments for the promotion of medical science, and of the sciences upon which medicine rests.

Neither of these springs of progress is to fail us here. Modern society produces the devoted student of science as naturally and inevitably as mediæval society produced the monk. Enthusiastic devotion to unworldly ends has not diminished; it only manifests itself in new directions. So, too, benevolence and public spirit when diverted by the teachings of both natural and political science from many of the ancient forms of benevolent activity, have simply found new and better modes of action.

With thankfulness for the past, with reasonable satisfaction in the present, and with joyful hope in the future, the medical faculty celebrate this anniversary festival, welcoming their guests, thanking their benefactors, and exchanging with their colleagues, their students, and the governing boards mutual congratulations and good wishes, as the school sets bravely out upon its second century.

And now, ladies and gentlemen, I have the pleasure of presenting to you our oldest professor and our youngest, our man of science and our man of letters, our teacher, and our friend Dr. Holmes.

Dr. Holmes then delivered his oration (see page 421).

Dr. Francis Minot then presented a portrait of Prof. Holmes, in behalf of the donors. He said:

Mr. President: "Many alumni of the school, beside many of its present students, have desired that a permanent memorial of their beloved teacher, Professor Oliver Wendell Holmes, should be placed in the new college building, in token of their gratitude for the great services which he has rendered to many generations of his pupils. By his eminent scientific attainments, his sound method of teaching, his felicity of illustration, and his untiring devotion to all the duties of his chair, he inspired those who were so fortunate as to come under his instruction, with the importance of a thorough knowledge of anatomy, the foundation of medical science.

In the name of the alumni and students of this college, I have the pleasure of presenting to the medical faculty, a portrait of Prof. Holmes, painted by Mr. Alexander, to be placed in the college in memory of his great and invaluable services to Harvard University, to the medical profession, and to the community.

Hon. Samuel A. Green, M. D., in behalf of the donors, then presented a bust of Prof. Henry J. Bigelow. He said:

The pleasant duty has been assigned me, Mr. President, to present to you, as the head of the corporation of Harvard College, in behalf of his many friends, this animated bust of Professor Henry J. Bigelow.

The list of subscribers comprises about fifty names, and includes nearly all the surgeons of the two great hospitals in this city; several gentlemen not belonging to the medical profession, but warm personal friends of Dr. Bigelow; a few ladies who had been his patients, and all the surgical house pupils who had ever been connected with the Massachusetts General Hospital, during his long term of service at that institution, so far as they could easily be reached by personal application.

The bust is given on the condition that it shall be placed permanently in the new surgical lecture-room, which corresponds to the scene of Dr. Bigelow's long labors in the old building. It has been made by the eminent sculptor Launt Thomson, of New York, and is a most faithful representation of the distinguished surgeon. It outlines with such accuracy and precision the features of his face and the pose of his head that nothing is wanted, in the opinion of his friends, to make it a correct likeness.

I need not, in the presence of this audience, name the various steps by which Dr. Bigelow has reached the high position which is conceded to him as freely and fully in Europe as it is in America; but I cannot forbear an allusion to some of his original researches.

His mechanism of the reduction of a dislocated femur by manipulation was a great discovery in surgical science, and follows as a simple corollary to the anatomical facts which he has so clearly and minutely demonstrated. His operation of rapid lithotrity has deprived a painful disease of much of its terror, as well as of its danger.

Nor should I overlook on this occasion his quick and ready discernment of the importance of Dr. Morton's demonstration of the use of ether as a safe anæsthetic, which took place at the Massachusetts General Hospital, in the Autumn of 1846. The discovery of this greatest boon to the human family since the invention of printing was fraught with such immense possibilities that the world was slow to realize its magnitude; but by the clear foresight and prudent zeal of Dr. Bigelow, shown in many ways, the day was hastened when its use became well-nigh universal.

Dr. Bigelow has filled the chair of surgery in this medical school during thirty-three years, a period of professional instruction that rarely falls to the lot of any teacher, and he now leaves it with the honored title of Professor Emeritus. During this long term of service he has taught through his lectures probably not fewer than 1800 students who have graduated at the Harvard Medical School, and perhaps 7500 more who have taken their degrees elsewhere; and by these thousands of physicians now scattered throughout the land, those of them who survive, Dr. Bigelow is remembered as most eminently a practical teacher—active in his profession, clear in his instruction, and enthusiastic in his investigations, he always had the happy faculty of imparting to his students a kindred spirit and zeal.

> "Haud inexpertus loquor."

The audience then adjourned to the Medical College on Boylston St., where

THE DEDICATORY SERVICES

were held.

After prayer, **President Eliot** said: On behalf of the President and Fellows of Harvard University and of the Medical School, I now declare this building to be henceforth devoted to the advancement of medical science, and to the improvement of the art of healing.

Mr. Henry Lee, in behalf of the donors of the building, said:

Mr. President: Thanks for your invitation to be present on this interesting occasion,—the hundredth anniversary of your Medical School, and the dedication of a new building of fair proportions well adapted to your wants, as far as a non-professional can judge.

You have assigned to me the honorable task of speaking for the contributors to the building fund.

I little thought, as I used to gaze with awe at that prim, solitary, impenetrable little building in Mason St., and with the aid of imaginative companions, conjure up the mysteries within, I little thought that I should ever dare to enter, and explore its interior; nor have I yet acquired that relish for morbid specimens which characterized my lamented kinsman, who devoted so many years to accumulating and illustrating your pathological collection.

It was an ordeal to a layman, Mr. President, especially to one who has reached the sixth age, to be so forcibly reminded, as one here is, of the

> "—— last scene of all
> That ends this strange, eventful history,
> Sans teeth, sans eyes, sans taste, sans everything."

And it is a further ordeal to assume to speak for others, whose motives for aiding you I may not adequately set forth.

This I can say, that we are citizens of no mean city; that private frugality and public liberality have distinguished the inhabitants of this "Old Town of Boston" from the days of the good and wise John Winthrop, whose own substance was consumed in founding this colony, to the present time.

Down through these two centuries and a half, the multiform and ever-increasing needs of the community have been discovered and supplied, not by the Government, but by patriotic citizens, who have given of their time and substance to promote the common weal, remembering "that the body is not one member, but many, and that the members should have the same care one for another."

It is this public spirit, manifested in its heroic form in our civil war, that has made this dear old commonwealth what we all know it to be, despite foul slanders. Far distant be the day when this scene of brotherhood shall be lost.

Purple and fine linen are well, if one can afford them; but let not Dives forget Lazarus at his gate.

> "Ill fares the land to hastening ills a prey,
> Where wealth accumulates, and men decay."

Whatever doubts may arise as to some of our benevolent schemes, our safety and progress rest upon the advancement of sound learning, and we feel assured that the increased facilities furnished by this ample building for acquiring and disseminating knowledge of our fearful and wonderful frame, will be improved by your brethren.

Some of the papers read before the International Medical Congress in London, two years ago, impressed me deeply with the many wants of the profession.

And who are more likely to have their wants supplied? For the physician is not regarded here as in some countries, as the successor to the barber surgeon, and his fees slipped into his upturned palm as if he were a mendicant or a menial.

Dining with two Englishmen a few years since, one an Oxford professor, the other the brother of a lord, I was surprised to hear their views of the social standing of the medical profession, and could not help contrasting their position here, where, if not all autocrats, they are all constitutional, and some of them hereditary, monarchs, accompanied by honor, love, obedience, and troops of friends.

But, however ranked, physicians have the same attributes the world over. I have had occasion to see a good deal of English, French, German, and Italian physicians under very trying circumstances, and have been touched by their affectionate devotion to their patients.

The good physician is our earliest and our latest friend; he listens for our first and our last breath; in all times of bodily distress and danger, we look up to him to relieve us.

"Neither the pestilence that walketh in darkness; nor the sickness that destroyeth in the noonday deters him."

"Alike to him is time or tide,
December's snow or July's pride;
Alike to him is tide or time,
Moonless midnight or matin prime."

The faithful pursuit of any profession involves sacrifice of self; but the man who calls no hour his own, who consecrates his days and nights to suffering humanity, treads close in the footsteps of his Master.

No wonder, then, that the bond between them and their patients is so strong; no wonder that we respond cheerfully to their call, in gratitude for what they have, and in sorrow for what they have not been able to do to preserve the lives and to promote the health of those dear to us.

And how could money be spent more economically than to promote the further enlightenment of the medical profession?

What better legacy can we leave our children, and our children's children, than an illumined Medical Faculty?

Dr. Henry W. Williams, in behalf of the Medical Faculty, then said:

Friends of the Harvard Medical School: For a hundred years the medical faculty of Harvard College have earnestly sought to discover, and striven faithfully to teach whatever might exalt the condition, relieve the woes, and prolong the service of those minds and bodies, through which man lives, and moves, and is. Year by year they have seen their horizon of knowledge extended, and their sphere of duty enlarged. But, though zeal and self-sacrifice have not been wanting, their efforts to be useful have been continually hindered, because of imperfect facilities and scanty resources.

All is changed; in this, more wonderful than Aladdin's palace, risen from the sea, and which has already endured the wrath and mercy of the flames, we see a fulfilment of our hopes, and the means and assurance of future success.

Thanks to generous benefactors, there will no longer be a lack of room or of appliances for our needs; our work will go on under fairer auspices, and we can offer to disciples of the healing art fitter opportunities, and ampler aid in their studies.

As spokesman of the Faculty on this occasion, so full of felicitation and of promise, I would I could give to their message a host of tongues, to adequately thank those whose great flood of bounty has thus favored and endowed us.

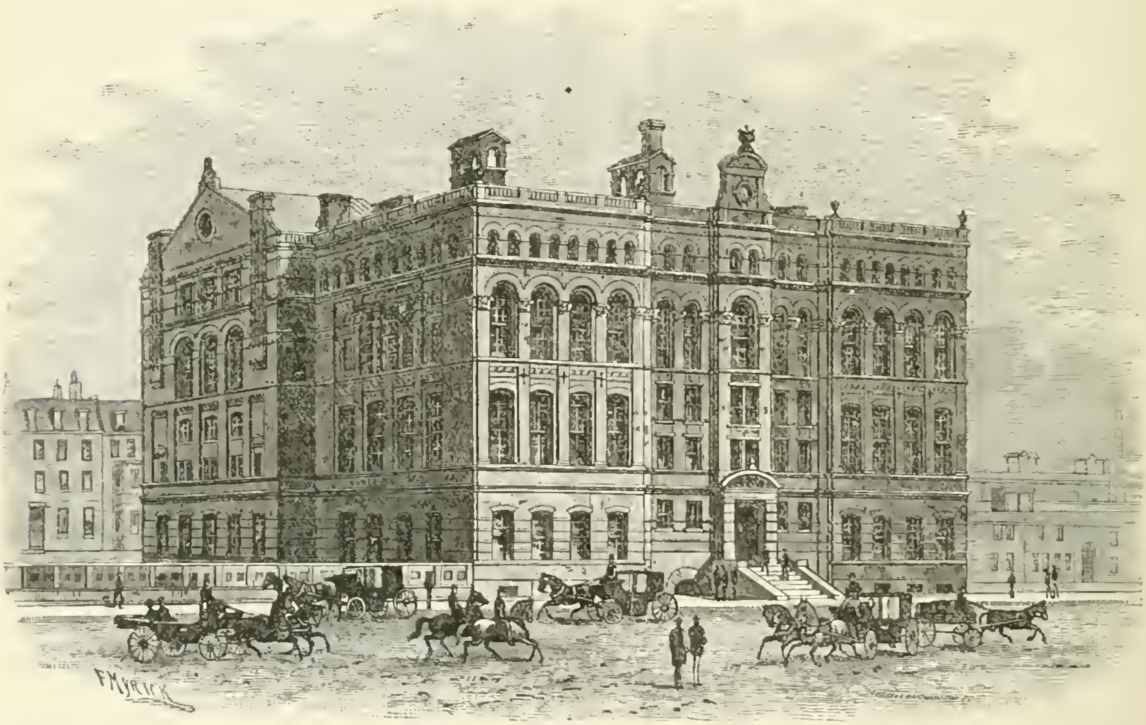
In occupying this beautiful and convenient structure, we shall ever feel that this place is dignified by the giver's deed; and we rejoice the more because we know that this gift of $300,000 has been bestowed by those who are accustomed to use their own eyes in their estimation of merit, and that it signifies a hearty approval of our endeavors, and shows that medical science, as it is to be here embodied and taught, shall have a warm and generous support.

In accepting this more than princely gift, as a token that the value and necessity of well-educated physicians to every community are felt and acknowledged, we hail the privilege of goodly fellowship in which the donors and ourselves have become co-workers to the end that blessings to the whole land may arise and be memorized in this institution; and we trust that the efforts of the faculty to advance the knowledge, train the judgment, and perfect the skill of those entering our profession will ever continue to deserve countenance and help.

At the conclusion of the exercises, a handsome collation was served, and the building was then inspected.

In the evening, the Medical Faculty entertained their guests at Young's Hotel.

Fig. 1.



The Harvard Medical College.

A DESCRIPTION OF THE NEW BUILDING ERECTED FOR THE MEDICAL SCHOOL OF HARVARD UNIVERSITY.

In order to secure for each student that direct personal supervision and instruction, forming such a marked feature of the courses offered, especially in the thorough laboratory training, which is so essential in securing a broad foundation for future clinical work, larger and better equipped rooms were required than could be obtained in the old school-building. A comparison of the plans with their detailed description will give a clear appreciation of the facilities afforded to the departments of anatomy, physiology, and chemistry, and of the carefully arranged rooms for the lectures on therapeutics, materia medica, and those branches of medicine and surgery which can be taught away from the bedside of the patient.

The comfort and convenience of the students have been carefully considered, as will be seen from the ample provision made for a study, coat-room, smoking-room, and lavatories.

The building is situated in Boston, at the corner of Boylston and Exeter Streets, in the new part of the city which is destined to be its educational centre, and which now contains numerous handsome structures, both public and private. It is at nearly equal distances from the Massachusetts General Hospital, the City Hospital, the Boston Dispensary, and the Children's and Women's Hospitals, with their rich stores of clinical material available for the purposes of teaching.

The corner position, and the reservation of a large open area on the east, will always insure good light and air to the building, which has a frontage of one hundred and twenty-two feet towards the north on Boylston Street, and of ninety feet towards the west on Exeter Street. It is handsomely built in the style of the renaissance, freely treated and developed in brick, trimmed with red sandstone and terra cotta. Decorative panels of the latter material, inscribed with the names of men great in the annals of medicine, Hippocrates, Sydenham, Paré, Celsus, Vesalius, Galen, Haller, Hunter, Harvey, and Bichat, are placed in the facade. It has four lofty stories topped by a sky-line of stone balustrades and low gables, the latter marking structural divisions of the interior. The main front on Boylston Street has three pavilions, of which the central is slightly recessed. In the interior, the material used and the plan of construction are those which the experience of the present day has shown to be the best proof against fire, all the walls being of brick without furrings, with occasional minor partitions of concrete building blocks. The floors and roof are of "mill construction," and made of three-inch planks, laid flatwise upon heavy square beams, which form the constructive and decorative divisions of all the ceilings, there being no inclosed spaces in any part. On the under side these ceilings and beams are throughout encased with plaster on wire lathing, and embellished with stucco mouldings and cornices, to serve as a protective envelope in case of fire. In order to avoid columns, the larger rooms are crossed by heavy compound trusses of iron, also encased in plaster, and into these are framed the wooden floor beams.

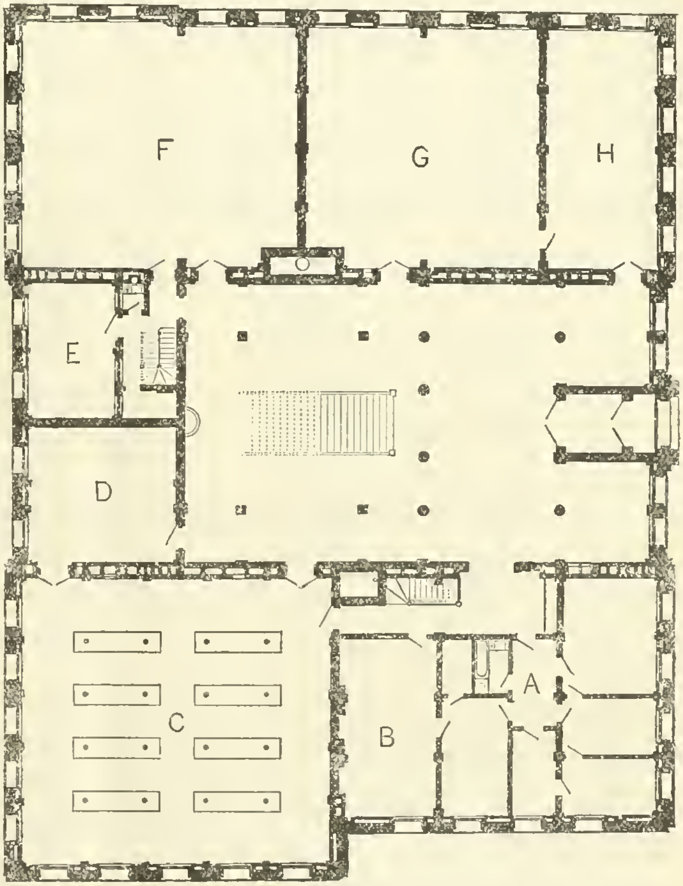
The building is finished throughout in natural woods polished, and the walls are handsomely painted in warm colors.

Heating and ventilation are accomplished by means of large stacks of steam radiators, which warm the fresh air as it passes over them to be distributed throughout the building. The air is removed by a series of flues connecting with a central shaft in which an upward current is maintained by means of heated coils of pipe. An additional amount of direct heat is furnished by small radiators placed in each room.

Both hot and cold water are supplied wherever needed, and the entire building is abundantly lighted with gas.

The plan, in general, is that of a large central hall, lighted from above, containing the main stairway, about which the different rooms are grouped. Adjoining this are two brick wells extending from the cellar to the roof. In one of them is a stairway giving access to the instructors' rooms, and which can be used as a fire-escape if necessary. In the other is the elevator for passengers and freight, with doorways opening at the several landings of the stairways, and others communicating with the various rooms connected with the laboratories and lecture-rooms. Four floors and a basement are required for the various rooms.

Fig. 2.

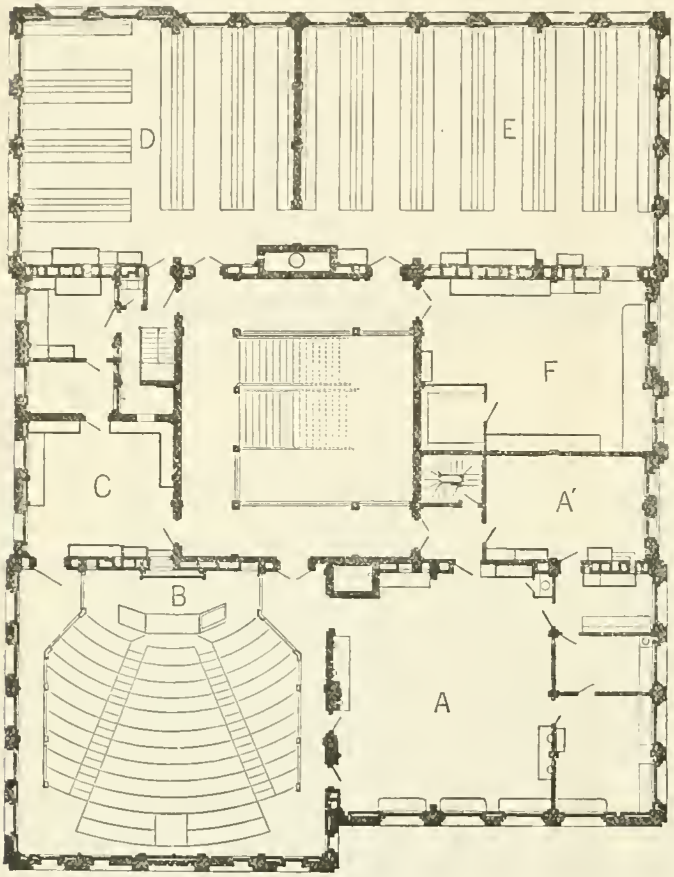


A. Janitor's apartments. B. Coat-room. C. Reading-room. D. Smoking-room. E. Ante-room. F. Lecture-room. G. Library. H. Faculty-room.

GROUND FLOOR.

The main entrance to the building is into the central hall from Boylston Street. In the interior, over the main entrance, has been placed a handsome marble tablet on which are inscribed the names of the medical alumni who fell in the War of the Rebellion. On the left or easterly side of the wall is an archway leading to a window opening into the *Janitor's Apartments* (Fig. 2, A), where letters and packages for the students are received, and where bells and speaking-tubes connecting all parts of the building unite.

FIG. 3.



A. Laboratory, Physiology. A′. Mechanic' sroom. B. Lecture-room. C. Ante room, Chemistry. D. Laboratory, Medical Chemistry. E. Laboratory, General Chemistry. F. Chemical Supply-room.

From the southeast corner of the central hall opens the *Students' Reading-room* (Fig. 2, C), having an area of about sixteen hundred square feet, and amply provided with tables for reading and writing. Connected with this, as well as with the south side of the hall, is a smaller room (Fig. 2, D) where conversation and smoking will be allowed.

Leading from the janitor's window to the reading-room is a narrow corridor, from which the students' *Lavatories*, etc., in the basement are reached, while the remainder of the latter is used for the heating apparatus and storage. The coat-room (Fig. 2, B) also opens from this entry.

A large room and adjoining ante-room (Fig. 2, F and E) have not been especially assigned as yet, but will be used for lectures or recitations as occasion may require.

Occupying the centre of the westerly side is the room for the general *Library* (Fig. 2, G), with ample space for its valuable medical classics and the more recent books which are added from time to time. Next to this on the north is the room for the faculty (Fig. 2, H), where its meeting will be held and the school records preserved.

SECOND FLOOR.

A broad flight of iron stairs leads to the second floor, which is entirely devoted to the *Departments* of *Physiology* and *Chemistry*, with their laboratories and lecture-room. The physiological laboratory (Fig. 3, A) occupies a space forty by thirty feet in the centre of the eastern side. It will be provided with the most approved apparatus for illustrating lectures and for students' use. Opening into the laboratory on the north are rooms for the professor and his assistants, as well as one especially fitted for chemical manipulation. Adjoining the laboratory on the west is a room for the mechanic (Fig. 3, A′) who takes care of the laboratory and makes needed repairs. Above is a room for a special library and study for the department. The laboratory is directly connected with the lecture-room (Fig. 3, B), beneath the seats of which are rooms for special and optical experiments.

The *Chemical Department* occupies the entire western side of this floor. The large laboratory, having over two hundred desks, is divided to accommodate the classes in general and medical chemistry (Fig. 3, D and E), and will be provided with spacious hoods, steam-baths, and all modern apparatus. The room for the professor is on the south, opening into the laboratory on one side, and into a preparation-room (Fig. 3, C) adjoining the lecture-room on the other. Special analyses will be conducted in the half-story over C and the adjoining rooms. The laboratory assistants' room, from which supplies of chemicals and apparatus will be distributed to the students, is situated upon the north side (Fig. 3, F). An assistant will be at hand to aid students in the laboratory throughout the day.

The students' entrance to the lecture-room (Fig. 3, B), is from a landing half-way between the second and third floors. This room, which will accommodate about two hundred persons, is furnished with raised seats, planned after a careful comparison of the most approved models. A large blackboard and screen for diagrams are placed against the wall.

THIRD FLOOR.

The third floor contains the *Amphitheatre* for the lectures on *Anatomy* and *Surgery*, the Warren Anatomical Museum, and two large rooms for medical lectures and recitations.

The seats of the amphitheatre (Fig. 4, B) are arranged in the manner implied by the name, for the purpose of giving each student an unobstructed view of the demonstrations. The same general model of seat has been used here as in the room below, but so modified as to meet the special requirements of the teaching. The room is thirty feet in height and lighted from above as well as from the sides, and will accommodate about three hundred students.

On the south side are the rooms for the professor and demonstrator of anatomy (Fig. 4, C); while connecting with the floor of the amphitheatre by a short passage are the rooms for the surgical department (Fig. 4, B′) and curator of the museum (Fig. 4, A′). Direct access to the museum is also to be had from the floor of the lecture-room.

The room intended for the *Warren Anatomical Museum* (Fig. 4, A) extends eighty feet along the north side of the building, is forty feet in width, and has a height of eighteen feet. The collection is placed in cases against the wall and in alcoves, divided into two tiers by a light gallery extending round the room. The cases themselves are handsomely made in the manner best adapted to prevent the entrance of dust and insects, and the specimens number over seven thousand.

The two lecture-rooms (Fig. 4, D and E) opening from the westerly side of this floor are especially intended for exercises which do not require extensive demonstration or experiment. The seats are placed on the floor level, while the lecturer occupies a raised platform, behind which are the screen and blackboard. Separating these, but connecting with both, is an ante-room (D′) where diagrams and other illustrations can be kept.

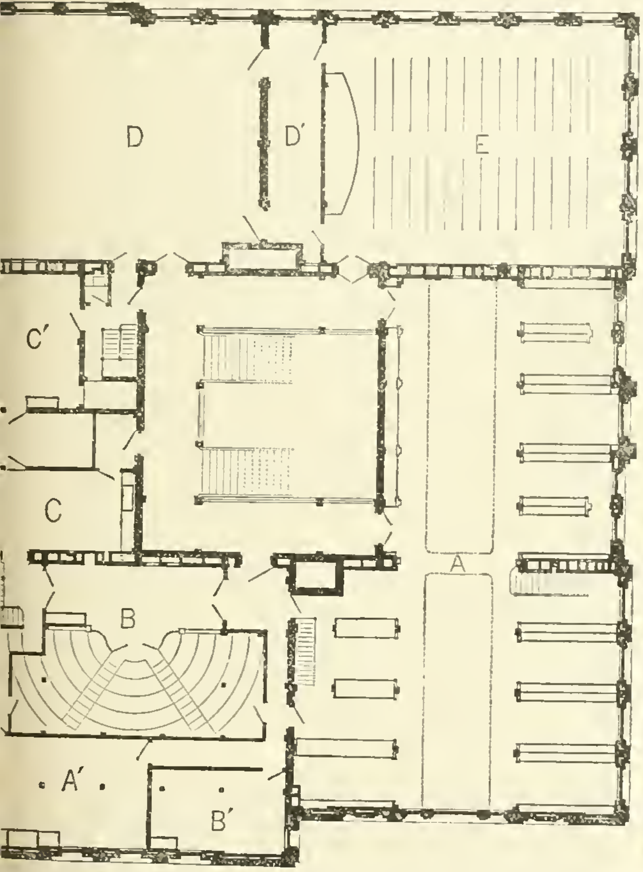
FOURTH FLOOR.

In the southeast part of the fourth floor two large doorways give access to the upper part of the amphitheatre, and it is through these that the students enter (Fig. 5, B).

Occupying two-thirds of the western side of this floor is the large room for practical anatomy (Fig. 5, E). Large skylights give abundant direct light upon the tables for classes, while the windows lining the sides of the room serve the same purpose for special students working at benches placed beneath. The floor slopes slightly, and is waterproof. Boxes for books, instruments, etc., with separate lock and key for the students' use, are placed against the wall.

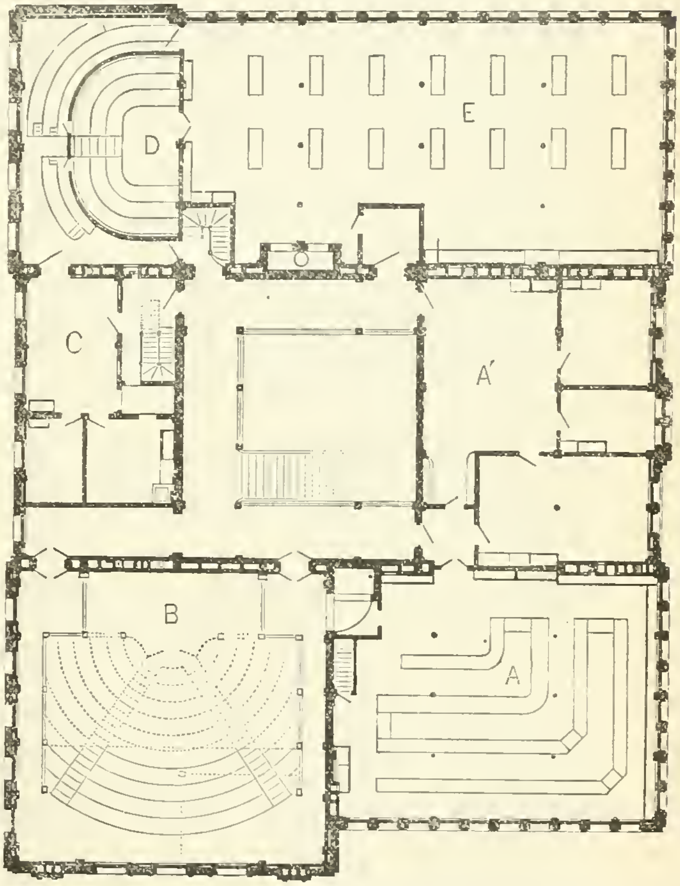
A small amphitheatre (Fig. 5, D) opens from this. Here operative courses in surgery and obstetrics will be held, and special demonstrations given. In close proximity are the rooms for the demonstrator and his assistants (Fig. 5, C).

Fig. 4.



Museum. A′. Curator's room. B. Amphitheatre. B′. Ante-room. C. onstrator's room. C′. Demonstrator's room. D. Lecture-room. D′. -room. E. Lecture-room.

Fig. 5.



A. Laboratory, Pathological Anatomy and Histology. A′. Laboratory, Experimental Pathology. B. Amphitheatre, Upper Half. C. Ante-rooms, Anatomy, Surgery, and Obstetrics. D. Amphitheatre, Operations and Demonstrations E. Practical Anatomy.

The pathological laboratory is entered from the northeast corner of the building (Fig. 5, A). It has been arranged with special reference to the exhibition of recent morbid specimens and for microscopical work. A private stairway leads to the museum, so that specimens for comparison or illustration can always be easily obtained. A series of continuous tables occupy the centre of the room, along which specimens can be passed for inspection after they have been demonstrated. The height of the tables has been regulated with special reference to the use of microscopes, as the classes in normal and pathological histology will also work here. Placed beneath the windows are tiers of boxes, where the instruments are to be kept. Two large open sinks are provided for general use, and one, smaller and covered with a hood, for use in demonstrations.

Four smaller rooms (Fig. 5, A′) connect with this laboratory, where advanced students or graduates can make special investigations under the direction of the professor of pathological anatomy.

From this brief description it will be seen that facilities are offered to the student for the thorough study of medicine in all its branches. The new laboratory arrangements are not excelled in this country, and the well-appointed rooms for lectures and recitations afford every means for the collection and display of illustrations. These greatly increased conveniences for laboratory and didactic instruction are supplemented by the numerous and varied opportunities for the observation and study of clinical cases, so amply provided at the different general and special hospitals and dispensaries.

Yellow Fever at Pensacola.—Surgeon-General Hamilton received, on October 12th, a telegram from Lieutenant-Commander Welch at the Navy Yard, Pensacola, Fla., reporting the last case of yellow fever there to be convalescent. Unless there are signs of further cases of fever during the next ten days, General Hamilton says that the quarantine against that section will be abolished.

A dispatch received on October 13th reported that the last case of yellow fever had been discharged, and that there were no signs of any new cases.

The Fever in Alabama.—A dispatch of October 13th states that Surgeon Stone, of the Marine-Hospital Service, stationed at Savannah, has been ordered by the Surgeon-General to proceed to Brewton, Ala., and investigate the alleged epidemic at that place. The Louisiana State Board of Health has been requested to send a competent inspector to act with Surgeon Stone in the investigation.

Since last Saturday night there have been five deaths from the prevailing fever at Brewton. Five new cases were reported during that time. Fever experts have arrived there, but have, as yet, reached no decision as to the nature of the disease.

Yellow Fever at Havana.—A telegram of Oct. 13th states that D. M. Burgess, Sanitary Inspector of the United States Marine-Hospital Service at Havana, reports that during the month of September there were 562 deaths in that city. Sixty deaths were from yellow fever, forty-four of which occurred among the mercantile shipping and private individuals, and the remainder in the military hospital. There were twenty deaths from yellow fever at Havana during the week ending Oct. 5. The wharves are markedly infected, and shipping going to them now runs the risk of becoming invaded by the disease.

Yellow Fever at Vera Cruz.—A report from Vera Cruz of Sept. 27 says that no yellow fever has recently occurred among the shipping at that port.

Smallpox in New Orleans.—For the weeks ending September 29th and October 6th there were, respectively, six and three deaths from smallpox in New Orleans.

Typhoid Fever in Connecticut.—Much anxiety is felt at Waterbury regarding the health of the city. There were sixteen deaths from typhoid fever in August, nine in September, and several this month. There are at this time many persons sick, and the prevalence of disease is attributed to the low water-supply, and the opening of the streets for new sewers.

Koch's Investigations of Cholera.—Dr. Koch, of the German Commission which went to Egypt to investigate the cholera epidemic, reports that he has discovered that cholera is due to a living thread-like microscopic organism, resembling that seen in cases of phthisis.

Gift to the Vermont University.—Mr. John P. Howard has announced his intention of giving a new building for the medical department of the University of Vermont, and of refitting the old building for a gymnasium. The cost will be about $40,000. This will make over $400,000 that Mr. Howard has given to the University and the city within ten years.

French Association of Physicians.—The Presidency of the Section of Medicine of this body has been conferred upon M. Nicaise, for 1884. The next Congress of the Association will be held at Grenoble.

Honors to Professor Lister.—Professor Lister, who recently spent some days in Pesth, was warmly welcomed on the part of the medical faculty of the University there. The professors gave a banquet in his honor, and the students arranged a torchlight procession to the great surgeon. At the banquet, which took place at the Queen of England Hotel, all the professors were present. The dinner over, the students, several hundred strong, appeared before the hotel with torches, a deputation was sent up, and Mr. Lister and his wife, followed by the professors, came out on the balcony. They were received with much cheering. After an address in Hungarian by one of the students, another addressed Mr. Lister in English, asking to be the interpreter of the feelings of his fellow-students in offering their homage. Mr. Lister replied in German, thanking the students for their welcome.

Harvey's Remains.—On last Thursday the remains of the illustrious surgeon and physician, Harvey, were to be removed from a vault under Hempstead Church, and placed in the Harvey Chapel in a sarcophagus furnished by the Royal College of Physicians.

Malady of the Count de Chambord.—The disease of the late Count de Chambord, according to M. Vulpian, who saw him in consultation, was characterized, from an anatomical point of view, by ulcerations of the gastric mucous membrane, and especially of the mucous membrane of the œsophagus; from a clinical point of view by a collection of symptoms which inevitably led to the diagnosis of cancer of the stomach. There was also degeneration of the kidneys.

Garfield Memorial Hospital.—The erection of the new Garfield Memorial Hospital in Washington began last week. On the ground recently purchased by the Hospital Association at the head of Tenth Street, there is already a brick dwelling-house commanding a fine view of the city. This house is two stories high, and has ample rooms, and will be used as the dwelling of the officers and attendants at the Hospital.

West Virginia State Board of Health.—Dr. Geo. H. Carpenter, of Moorefield, has retired from the State Board of Health of W. Va., to accept the place vacated by Dr. N. D. Baker, of Martinsburg, on the Board of Directors of the Asylum for the Blind and Deaf at Romney, while Dr. Baker has taken Dr. Carpenter's place on the State Board of Health. The exchange of places was made by Governor Jackson to accommodate the wish of Drs. Baker and Carpenter.

Student's Club-room at Guy's Hospital.—Among the recent improvements made at this hospital for the accommodation and convenience of students, is the formation of a club and refreshment room, which enables the industrious student to obtain a mid-day meal without going out to one of the dining and coffee-houses in the neighborhood. The entrance fee is merely nominal, and the food cheaper and better served than that to be obtained elsewhere. Experience has shown that, so far from being a lounging-room for the idle, those who frequent the club are industrious men who desire to save the time lost in going outside the walls of the hospital. The club was opened last winter as an experiment, but its popularity has greatly increased, and a very large proportion of the students now avail themselves of its advantages.

Trichinosis in Saxony.—Reports from London, of Oct. 16, state that an outbreak of trichinosis is reported at Ermsleben, Russian Saxony. One hundred and eighty persons are suffering from the disease, and four deaths therefrom have occurred.

Foot and Mouth Disease in England.—Notices in the *Gazette* show that the foot and mouth disease in England is gradually disappearing.

Cholera Congress at St. Petersburg. — The *British Medical Journal* of September 29th, says that there is reason to believe that a Medical Congress will be held in St. Petersburg during the present month, for the purpose of discussing all matters connected with cholera. MM. Charcot and Pasteur and other European authorities are said to have promised to be present.

International Sanitary Code.—We learn that the European powers have signified their agreement to the proposal of the Italian Government to summon a conference at Rome, with the object of making sanitary regulations, and drawing up an International Sanitary Code. Signor Mancini, Minister for Foreign Affairs, will shortly address a circular to the Powers on the subject.

Cholera Chemically Considered.—M. Ramon de Luna has given expression to his views on cholera at a recent meeting of the Académie des Sciences. He believes that the cause of cholera is always to be found in the atmosphere; that it exerts its action exclusively through the respiratory passages; that it is especially during the passive condition of the individual, particularly during sleep, that its incubation takes place; that the microbe or ferment acts chiefly on the blood corpuscles, preventing proper oxidation, and so leading to gradual suffocation; that the only remedy which was ascertained to do any good was the inhalation of the fumes of nitrous acid mixed with air; and that the same agent is of prophylactic value against cholera. These conclusions are given as the result of practical successful experience.—*Lancet*, Sept. 29, 1883.

The Gresham Lectures.—The Gresham Lectures, delivered in Gresham College, Basinghall Street, by Dr. E. Symes Thompson, discussed the subject of Nursing. The first lecture treated of observation and watchfulness, the administration of medicine, methods of feeding, and how to prepare peptonized foods, etc.; the second, of knowledge and judgment, the application of external remedies, and the prevention of needless suffering. The third lecture dealt with purity and impurity, the purification of house and patient, and the various forms of, and methods of employing, antiseptics. The fourth lecture was devoted to firmness and authority, the removal of restraints during convalescence, the importance of change of air, invalid furniture, and, finally, an account of a visit to the Hygienic Exhibition at Berlin in August, 1883.—*Lancet*, Sept. 29, 1883.

Quarantine on Vessels from Mediterranean Ports.—Quarantine on arrivals from Mediterranean ports has been reduced at Malta to periods ranging from four to ten days, minus the actual duration of the voyage. Arrivals from Greece are admitted to free pratique, but the quarantine regulations are still enforced against those from Egypt. In French ports, vessels from Syria are now subjected to only twenty-four hours' quarantine of observation, and at Odessa and Kertch, quarantine for vessels with clean bills of health has been reduced to three days' observation, counting from departure from Constantinople.

Epidemic Religious Excitement.—The *Journal de Ploërmel* reports a curious example of one of those outbreaks of epidemic nervous disorder which were characteristic of the Middle Ages, but are now rarely heard of. Of fifty pupils of the Girls' Congregational School of Saint Marlo des Trois Fontaines, upward of thirty-five have been attacked by a nervous disorder having all the symptoms of St. Vitus' dance. The school has been closed by order of the local authorities. —*British Med. Journal*, Aug. 18, 1883.

New Surface Thermometer.—M. Burq has recently completed a new surface thermometer, made of a small ivory case, in the lower part of which is solidly encased the tube for the mercury. There is a scale, minutely divided, with a needle pointer which indicates the maximum position in a series of observations. The inventor designed it to indicate the thermic effects of metallic applications, though it will probably be a valuable aid in studying local variations of temperature.

Generous Recognition.—It is said that the Emperor of Brazil has given Prof. Lacerda $20,000 for his discovery of permanganate of potassium, hypodermically injected, as an antidote for the bite of the cobra.

New Medical Academy in Siena. — Under the Presidency of Prof. G. Marcacci, a new society has been formed in Siena for the advancement of medical science, under the title "Societa fra i Cultori della Scienze Mediche."

Magnesia in Beer.—As a custom of adding magnesia to beer to preserve it is now becoming general, a word in time from the medical profession may avert what threatens to become a danger to health. Formerly, to preserve beer, only salts of lime and the alkalies were used; these imparted harsh and soapy tastes respectively. As magnesian compounds are not so perceptible (when in beer) to the taste, their use in brewing is replacing that of lime. Pure beer itself contains more magnesia than can be taken with impunity by many constitutions, the addition of further quantities under names known to the trade as "antacid," to correct beer, "C and D," to preserve it, "concentrated Burton water" to harden brewing water, may easily increase the amount to an injurious quantity. Brewers do not inquire into the nature of the chemicals now largely used by them, and cannot be aware of their effects. It is time that they were reminded that the continual drinking in a popular dietetic of salicylic acid, magnesia, vegetable bitters, etc., is a question which concerns the public health quite as much as their own profits. Drinking-waters containing excessive quantities of magnesia are frequently condemned;

beer can disguise more, and should be closly watched. In obscure cases of purging, it will be well for the medical adviser to bear in mind the possible, but hitherto unsuspected, presence of excessive quantities of magnesia in beer.—*British Medical Journal*, September 18, 1883.

MANAGEMENT OF MEASLES.—The Board of Health of Boston have issued the following circular of recommendations for the proper management of measles:

When a case of measles occurs, put the patient in a room apart from the other inmates of the house, and allow no person to enter such room, except the nurse and physician. Have the sick chamber properly warmed, exposed to the sunlight, well aired and relieved of all unnecessary furniture and other articles which cannot be cleansed without injury.

All clothing removed from the patient, or the bed, should be at once placed in boiling water, or in a tub of disinfecting fluid—three pounds of sulphate of zinc and one and a half pounds of common salt to each ten gallons of water. Water-closets and privies in the house should be disinfected frequently with a solution of copperas—two pounds to a gallon of water. Every kind of filth in or about the house should be removed, and disinfectants freely used.

Children in the family should not attend school, or mingle with other children, until the patient has wholly recovered, and all infected articles have been disinfected.

On the recovery or death of the patient, the most thorough disinfection should follow. The room and all articles in it should be at once subjected to the fumes of burning sulphur as follows: Close the room tightly, and burn two pounds of sulphur to each thousand cubic feet of space.

After four or six hours, open the room, and expose it to free currents of air.

Anything that can be boiled without injury may be so treated. The walls and ceilings should be dry-rubbed or lime-washed, and the floors washed with some disinfecting liquid. When death occurs, the body should be immediately placed in a tight coffin, with disinfectants, and the coffin tightly and finally closed.

No public funeral should ever take place at the house where the patient has died, until the coffin has been tightly sealed, and the most thorough disinfection has taken place.

Nurses ought to be particularly careful to remove all infection from themselves and their clothing before leaving the house.—*Sanitary Engineer*, September 13, 1883.

HEALTH IN MICHIGAN.—Reports to the State Board of Health, for the week ending October 6, 1883, indicate that influenza, diphtheria, and intermittent fever have increased, and that dysentery, typho-malarial fever, pneumonia, and cholera morbus have decreased in area of prevalence.

Including reports by regular observers and others, diphtheria was reported present during the week ending October 6, and since, at twenty-six places, namely, Calumet, Coldwater, Clarence, Clam Lake, Detroit, Ensley, Grand Rapids, Ida, Jackson, Kalamazoo, Kendall, Lansing, Manistee, Manton, Monroe, Mt. Pleasant, Nashville, Newberry, Niles, Pontiac, Petersburg, Saginaw, Sault Ste Marie, Somerset, Utica, and Whitehall. Scarlet fever at twenty places: Bingham, Belvidere, Detroit, Dorr, Edmore, Fentonville, Grand Rapids, Ithaca, Jackson, Lowell, Manistee, Manton, Monroe, Mendon, Nashville, Pierson, Saginaw, Somerset, Summit, and Whitehall. Measles at four places: Charlevoix, Grand Rapids, Otsego, and Union City.

MEMORIAL TABLET TO M. THUILLIER.—A tablet commemorative of the public services of M. THUILLIER, and his untimely death of the disease whose nature and causes he had accompanied M. Pasteur to Egypt to investigate, will be placed in the Normal School at Paris, of which he was a graduate.

OBITUARY RECORD.—The death at the age of eighty-four is announced of DR. WILHELM BAUM, of the University of Göttingen. He became the senior of the medical faculty on Wöhler's decease, and had long held the chair of surgery, which is now occupied by Kœnig. He was considered in Germany as one of the school of conservative surgery to which Langenbeck and Stromeyer belong.

DR. JAMES A. SEWELL, of Quebec, Dean of the Medical Faculty of Laval University, died on October 2d, aged 73. He was a graduate of Edinburgh, and had practised in Quebec for half a century.

NOTES AND QUERIES.

CORRIGENDUM.

In our issue of October 6th, page 387, second column, twenty-seventh line from bottom, for "A paper was then read by Dr. E. Bock," read "by DR. EDWARD BORCK," of St. Louis.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM OCTOBER 8 TO OCTOBER 15, 1883.

HAMMOND, JOHN F., *Colonel and Surgeon.*—Leave of absence on surgeon s certificate of disability granted April 2, 1883, extended six months on surgeon's certificate of disability.—*Par. 7, S. O. 231, A. G. O.*, October 8, 1883.

SWIFT, EBENEZER, *Lieutenant-Colonel and Assistant Medical Purveyor.*—Under the provisions of section 1 of the act of Congress approved June 30, 1882, is, by operation of law, this day retired from active service, and will proceed to his home.—*Par. 4, S. O. 231, A. G. O.*, October 8, 1883.

HARTSUFF, ALBERT, *Major and Surgeon.*—Granted leave of absence for fifteen days.—*Par. 2, S. O. 205, Department of the Missouri*, October 6, 1883.

HUNTINGTON, DAVID L., *Major and Surgeon.*—By direction of the President, will, until further orders, take charge of the office of the Surgeon-General of the Army, and perform the duties pertaining thereto.—*Par. 3, S. O. 234, A. G. O.*, October 11, 1883.

MEACHAM, FRANK, *Major and Surgeon.*—Assigned to duty at Fort Douglas, Utah.—*Par. 3, S. O. 109, Department of the Platte*, October 6, 1883.

STERNBERG, GEORGE M., *Major and Surgeon.*—Granted leave of absence for one month to date, from October 6, 1883, with permission to go beyond the limits of the Department, and to apply for extension of one month.—*Par. 3, S. O. 134, Department of California*, October 4, 1883.

CRONKHITE, H. M., *Captain and Assistant Surgeon.*—Assigned to duty at Fort D. A. Russell, Wyoming.—*Par. 3. S. O. 109, Department of the Platte*, October 6, 1883.

WEISEL, DANIEL, *Captain and Assistant Surgeon.*—Assigned to duty at Fort Fred. Steele, Wyoming.—*Par. 3, S. O. 109, Department of the Platte*, October 6, 1883.

ARTHUR, W. H., *First Lieutenant and Assistant Surgeon.*—Assigned to duty at Fort Douglass, Utah.—*Par. 3, S. O. 109, Department of the Platte*, October 6, 1883.

STRONG, NORTON, *First Lieutenant and Assistant Surgeon.*—Assigned to duty at Fort Washakie, Wyoming.—*Par. 3, S. O. 109, Department of the Platte*, October 6, 1883.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

ORIGINAL LECTURES.

LOCOMOTOR ATAXIA.

A Course of Three Lectures delivered before the Cincinnati Medical Society,

By PHILIP ZENNER, A.M., M.D.,

OF CINCINNATI, OHIO.

LECTURE II.

PATHOLOGY.

Gentlemen: In considering the pathology of this disease, we will have to speak of both the locality and nature of the pathological changes, and in how far the latter enable us to explain the symptoms presented. In order the more intelligibly to approach this subject, permit me first to speak briefly of our present knowledge of the functions of the spinal cord. Notwithstanding great advances of late years, that knowledge is still extremely meagre. For in the way of anatomical, experimental, and pathological researches, through which this knowledge is acquired, there are great and serious obstacles. The anatomist can trace the nerve-roots, whose functions are known, such a short distance into the cord as not thereby to determine the function of any of its integral parts. The physiologist by his experimental studies has been enabled to determine, with a considerable degree of certainty, that parts of the anterior columns convey motor impulses. But as to the posterior columns he has come to far less definite results. Schiff concludes, from his experiments, that the posterior white columns convey tactile sensations, that the posterior gray matter conveys sensations of pain. But herein he is not upheld by all physiologists. Ludwig and Woroschiloff, from recent experiments, have concluded that the lateral columns also contain sensory fibres, but their experiments were made on rabbits, and their results cannot, without further consideration, be accepted as true for man.

Our knowledge of the cord has recently been greatly advanced by the investigations of Flechsig; his results were obtained from a study of the development of the cord. He observed that some nerve-fibres become enveloped with their medullary sheaths earlier than others, the two being easily distinguished by their color; the one white, the other more translucent or colorless. He was thus enabled to determine that whole strands of nerve-fibres became medullated at different periods; some in the early months of fœtal life, others being not yet completely medullated at birth. From this, as well as some other considerations, he concluded that the cord was composed of a number of different nerve-bundles which were anatomically and functionally distinct; these different nerve-strands he terms systems. Those which are earliest medullated, appear to contain only short fibres, either short continuations of the spinal roots or fibres connecting one part of the cord with the other; those medullated latest appear to contain long fibres which connect the cord with higher intracranial centres.

On one of the accompanying figures I wish to point out these several systems. On the first figure is merely represented the usual appearance of a section of the cord. Between the anterior fissure and the posterior roots are the antero-lateral columns; between the posterior fissures and roots, the posterior column divided by a slight sulcus (in the cervical region) into the external or Burdach's column, and the internal or column of Goll. On the second figure are delineated, in a diagrammatic manner, the systems of Flechsig. Those remaining white are the various systems containing short fibres. The darkened ones contain long fibres, and are respectively the pyramidal tracts connecting the central convolutions in the brain with the muscles; the cerebellar strands connecting, probably, Clarke's column in the cord with the cerebellum; and Goll's column, of which we will speak again.

These results of Flechsig are largely corroborated by the studies of secondary degenerations. It is well known that when nerve-fibres are cut off from their trophic centres, they will degenerate throughout their whole peripheral extent. Thus, after lesions of the internal capsules, the pyramidal tract will degenerate throughout its whole extent in the cord. After section of the cord, experimental or otherwise, the systems containing short fibres degenerate for a short distance above and below the seat of section. But we wish here to speak of secondary degenerations of the posterior columns, and this for two reasons; because these columns especially interest us in our studies to-day, and because Flechsig, in his researches, was enabled to throw less light upon this part than upon other portions of the cord; only finding Goll's column with distinctness in the upper parts of the cord. After disease of the cauda equina, secondary degeneration has been observed in the lumbar region, involving the greater part of the posterior column, while in the dorsal and cervical regions it is limited to Goll's column. This secondary degeneration can be traced as far as the medulla. Singer has experimentally evoked the same changes through section of the posterior roots of the sacral and lumbar nerves. These observations lead us to conclude that fibres of the posterior roots, after penetrating the gray matter of the cord, pass upward in Goll's column as far as the medulla oblongata. Lesions of higher portions of the cord of the dorsal and cervical portions, as well as some recent experiments of Kahler, inform us that the posterior root-fibres in these parts also ascend in Goll's column, but are contained in the more external and anterior part of that column. These facts are illustrated on this plate (presented to the Society), on which are represented the sections at various levels of the cord, in five cases of secondary degeneration reported by Schulze. In three of these the primary lesion was in the lower; in two, in the upper portion of the cord.

These various studies, those of Flechsig on the development of the cord, and those of secondary degenerations, enable us to map out separate nerve-strands

which are, at least in a degree, anatomically and functionally distinct. And now let us ask, do pathological processes ever attack and limit themselves to one or more of these systems? They do; and such are termed systematic diseases. Thus, amyotrophic lateral sclerosis attacks the lateral columns and, their probable terminations, the ganglion cells of the anterior cornua, and causes paralysis and atrophy of muscles. We will not mention other systematic diseases which have been more or less definitely determined, but ask—Is or is not locomotor ataxia a systematic disease? Is it a diffuse myelitis which only accidentally limits itself to the posterior columns, or does it primarily attack and limit itself to certain bundles of nerve-fibres, which are anatomically and functionally distinct? Before attempting to answer this question, let me first briefly state what are the pathological changes in this disease. We find what is usually termed gray degeneration. On section of the cord at an early period of the disease, the diseased areas are observed to be of a gray or grayish-red color, thus contrasting with the normal white tissue. Often the changes cannot be observed on the fresh section, but are easily brought out after hardening in chromic acid preparations. At a later period there may be complete atrophy and shrinking of the diseased parts. The microscope reveals, at an early period, an increase of the neuroglia, granular cells, enlarged Deiter's cells, etc., and swelling or atrophy of some of the nerve-fibres, both axis-cylinders and medullary sheaths. At a later period the neuroglia is converted into a fine, wavy, dense connective tissue, and the nerve-fibres have largely disappeared.

As to the locality of these changes. They are in the posterior columns, in the posterior nerve-roots and posterior gray matter, in both of which diseased changes are probably found at a very early period. At a later period they may even attack the lateral columns and the ganglion cells of the anterior cornua.

What is the origin of these changes, and what their more exact localization? It has been supposed that the disease begins as a meningitis, and only secondarily affects the cord. This theory was based on the fact that in advanced cases thickening and degeneration of the pia mater in the posterior portion is almost always observed. But, as in several cases in which the cord could be examined at an early period of the disease no meningitis was found, this origin cannot be accepted. The changes in the meninges are probably secondary to those in the cord.

Let us study the more exact localization of the disease in the posterior white columns. A number of cases have been reported in which the diseased changes of an early period were very carefully examined. I know of only four such cases, one of Pierret, one of Westphal, and two of Strumpell, in each of them the patient dying of some other disease while the locomotor ataxia was still in its early stages. In each of them the disease was most marked in the lumbar region, where it appears to have had its origin. It was here limited to a portion of Burdach's column. In higher parts of the cord the disease of Burdach's column was less extensive, while in the highest part it limited itself to the column of Goll. I here present you the plates representing the disease on different sections of the cord in the cases of Pierret and Strumpell. I present you also a number of plates (nine cases of Strumpell's), representing the disease at a more advanced period. If you will carefully study these plates, you will observe that certain parts of the posterior columns are always attacked, that other parts are almost as universally spared; for instance, in the lumbar region the most anterior parts of the posterior columns, in the cervical region the most external posterior portion, are always spared. In these two anatomical sections, which I present to you, the one from the lumbar, the other from the cervical region, you will again see that about the same parts are spared. You will also observe that both in these anatomical sections, as well as in all the plates presented, there is an almost exact symmetry of the disease on the two sides. These facts, the symmetry of the disease, its beginning in certain parts, its attacking certain parts and sparing others, cannot be explained by a diffuse myelitis, and are sufficient, I believe, to prove that we have to do with a systematic disease. But it is more difficult to define the system or systems attacked. The most easy and natural explanation is, that the disease begins in the posterior root zones, in that part of Burdach's columns where fibres from the posterior roots penetrate the gray matter, possibly attacking at the same time the nerve-fibres in this part, and their continuation in the roots and in the gray matter. It begins, then, in this posterior root zone as a primary disease, perhaps first in lumbar, later in dorsal and cervical regions. And from this primary source the disease extends inwards and upwards; inwards to the gray matter, and even in those rare cases where the ganglion cells of the anterior cornuæ are involved, Charcot believes that it is through an extension of the disease along some fibres of the posterior roots. Possibly the disease in the lateral columns is also to be thus explained. Upwards the disease extends into Goll's column, thus reaching to the medulla.

While this seems the easiest explanation, it is not universally accepted. Strumpell believes that we have to do with a combined systematic disease, and that both Burdach's and Goll's columns, are each primarily affected. It must be acknowledged that we know too little concerning primary or secondary degenerations to be able to distinguish them from one another by mere appearances. Then we must remember a surmise of Westphal, that the posterior column is composed of a number of different systems, and perhaps one after another of them is attacked in this disease.

Another question we must consider is, What is the nature of the disease? Is it an interstitial or a parenchymatous myelitis, or is it primarily merely a degeneration of the nervous elements? We have seen that both the neuroglia and the nerve-fibres are affected, and the mere appearance does not enable us to determine in which the changes were primary. But if we have to do with a systematic disease, this can only be accounted for by a primary disease of the nerve-fibres. But whether this primary disease be an inflammation or a degeneration, our present knowledge does not enable us to determine.

And now we approach the second part of our subject, how far we can explain the symptoms by the pathological changes. What we have already said of our knowledge of the functions of the cord will lead you to infer that such explanations will be largely conjectural. Charcot explains the main symptoms in this way. The disease, when limited to a part of Burdach's column, produces the lightning pains; when it extends to the posterior cornua and roots, it produces ataxia; when it involves the gray matter and posterior roots, it produces marked anæsthesia. This explanation, plausible as it appears, is largely arbitrary. And it may be more nearly correct to attribute the symptoms at these various periods rather to the intensity than the exact locality of the diseased areas. While the disease is very limited those nerve-fibres are only irritated which, when the disease becomes more extensive, are now destroyed.

We may in a general way state that the pains, parasthesias, etc., are due to irritation, the anæsthesia to destruction of fibres of the posterior roots, either in the roots or in some part of the cord. Paralysis is due to involvement of the lateral columns, muscular atrophy to disease of ganglion-cells in the anterior cornua. As to the explanation of the symptoms on the part of genital functions, bladder, rectum, or of the trophic changes we are still entirely in the dark.

Most interest has been taken in the explanation of the prominent symptom, the ataxia, and concerning this various theories have been promulgated. One is that it is due to disturbances of the reflexes, and therefore to a loss of control on the part of the cord. Another is that on account of the impairment of sensation, cutaneous, muscular, etc., centripetal impressions from the periphery to the coördinating centres in the brain are not properly received, and therefore the guiding influence of the latter imperfect. In other words, on account of deficient knowledge of the limbs there is a loss of the power of controlling them. According to a third theory, there are in the cord, in addition to the fibres conveying the motor impulses, another set of fibres from the coördinating centres, which serve to regulate muscular actions, and these coördinating fibres are destroyed in this disease.

I do not wish to give the various arguments for or against these various theories. Each is far from being established, and there are serious objections to all. But it seems to me, rather than supposing a special set of motor fibres in addition to those which convey motor impulses, far easier to believe that there is a loss of control from peripheral sources, either on the part of the cord through impairment of the reflexes, or on the part of the coördinating centres through impairment of conscious sensations, or from both causes at the same time.

As to the involvement of the cranial nerves, the amaurosis, ocular paralysis, etc., we can give no definite explanation. No anatomical connection has been found between these nerves and the disease in the cord, and probably none exists. We can more easily believe that there is some general condition which at the same time predisposes certain parts of the cord and certain cranial nerves to disease.

For one symptom we can give a more definite explanation, that is the absence of the patellar tendon-reflex. Westphal has long supposed that this was due to disease of the posterior columns in the lumbar region. He was recently enabled to carefully examine the cord in a case where the disease was at such an early stage that no other symptom but the absence of the patellar tendon-reflex was apparent, and he here found the pathological changes limited to a portion of Burdach's column and most marked in the lumbar region. In the two cases of Strumpell's already mentioned, the disease was also in its early stage, there was an absence of the patellar tendon-reflex, and pathological changes were found in the same part of the cord. And now we know why this is usually the first symptom of locomotor ataxia, because the pathological changes usually begin in that part of the cord which produces it.

NEW ENGLAND MALARIA—FROM WHENCE?

By EZRA M. HUNT, M.D.,
OF TRENTON, N. J.
PRESIDENT OF THE AMERICAN PUBLIC HEALTH ASSOCIATION.

The occurrence of malaria in certain parts of the United States more frequently than heretofore, and in some sections not constantly disturbed thereby, has given rise to some hypotheses as to causation which invite and deserve the careful analysis of every student of etiology. Whenever we are called upon to deal with a dyscrasia in which it is admitted that the morbific principle is unknown, there is great temptation to that excursus of scientific imagination, to which even scientists are sometimes prone. Like most beguiling infatuations the scholar is lured in a most inquisitive and intoxicating way into the arbor of his delightful reverie, until the very enchantment of his myth leads him to cajole himself with the idea that he is still in the region of facts, and has arrived in his delectable land by a new road surveyed with the exactest care, and laid out in accord with the precise rules of a logical analysis.

One need only to turn from some of these new and modern views to the records of the authors and practitioners who have for a century been dealing with malaria, to see how the minority hypotheses of the past are reproduced in the present.

We are first informed that there are many marshes and lowlands rich in vegetable decay in which malaria has never been known to prevail. If this were a new fact, it might have some influence in modifying a belief in the paludal relations of malaria.

But this fact is no more prominent now than it has been during the whole period in which this disease has in many countries, and under diverse circumstances, been subjected to the most careful judgment and experience of the medical profession. Malaria, says Bartholow, is called "marsh miasm," because of the abundance of this poison about marshes. But not all marshes produce malaria. The "Dismal Swamp," for example, is free from marsh miasm, "although apparently well adapted to produce it."

It is because nearly all observers and authors have all along been able to admit this, and yet maintain the view of the connection of marshes with malaria that we have one of the best historical evidences of the correctness of this view. Having given full weight to all these facts, experience has yet confirmed a verdict as to this marsh relationship.

Another statement, of which again so much is made as to give it an air of novelty, and so a force against an old truth, is that malaria occurs on the hilltops as well as in the valleys.

Score upon score of such facts were also in possession of our medical fathers and ourselves, and were given due consideration in making up the judgment of historical experience (see *Dictionary of Medicine*, Quain, 1882, article Malaria).

So long as the doctrine of the diffusion of gases or the fact of prevalence of winds lasts, so long will it occur that particles of disease will be wafted; that by proximity or varying direction of winds or changes introduced by the removal of forests, the cutting of channels, the changes of seasons and of temperature, and the greater travel of the people of the hills to the valleys, there will be the increase of occurrences which have been well understood and accounted for before this, and of which the vacillating increase is equally susceptible of explanation.

It was long ago found that changes made by man high up in the hills gave rise to some of the same conditions once confined to the valleys; that artificial channels of conveyance have been made from sources near at hand; that the malarial zone is moved above some old isothermal line not by the change of latitude, but by a change of temperature and of vegetation which is equivalent thereto, and so the apparent advance has been a coming down of the hills to the conditions of the valleys, rather than a change in the conditions of malarial distribution. The same is true of the next leading statement, viz., that malaria is found to prevail in latitudes where it was once unknown.

It is intensely interesting to turn back to the authorities of the last fifty years, and find whole pages of close statement, which show how well these and similar facts have been considered and given their due weight and proper explanation. The sustained view was held not because they were not cognizant of these facts; not because they had settled to a belief which nothing could shake, but because the opinions entertained accounted for the largest number of facts and were not nullified by explicable variations.

Indeed, the tendency to deny the influence of any local cause, for any disease on the part of the resident community, is one as old as the days of Hippocrates, and could never have been expected to be overlooked by a certain inventive race to the north of Mason's and Dixon's line.

The only really new thing which has given an impetus to the hypothesis as to the migratory or portable character of malaria is that which relates to the cryptogamic origin or particulate entity of many diseases. As soon as the view fairly took shape that even such a disease as this depended on a specific plant-life, so soon it was an easy generalization that all marshes do not produce the same forms of plant-life; that some might not happen to have the special one that causes malaria, and that in places where it did occur you must not merely prove a marsh, stagnant water, abnormal decay and heat, and a rising miasm, but you must also show that this particular marsh has this particular plant. Hence, it is probable that, for a score or more of years, yellow fever, typhoid fever, typhus fever, diphtheria, and several other diseases, whenever occurring in a foul locality, will be insisted upon by a very respectable minority as not being in any way connected with local conditions, but as having arrived from somewhere else. In certain rare instances it will be true; in certain other instances they will arrive through channels provided by the locality; in most, they will depend for their virulence and for their continuance on the pabulum of local conditions. In all such, if not before native, they will become so, because they find all the conditions they found in their own habitats. Oftener they will find themselves among their own species of plant-life, and that they have but added to the intensity of the malaria-breeding atmosphere. Just as it may be true of some very common marsh-plant that it may not be found in some particular locality where you would expect to find it, it is equally true that you are almost certain to find it indigenous there; but if you do not, it is very sure to become so. Also, that if you would be rid of it, your expectation of riddance and relief is far better in changing the adaptation of soil and locality thereto than in trusting to its not getting in from an adjacent township or State.

The prominent argument that has been more recently put forth in favor of the independence of malaria of local and paludal conditions, is that malaria has appeared in places where it was unknown; that it seems to have cycles of appearance, and to be intermittent in its continuance. Also, it is claimed that its steady progress can be traced as by a moving wave, one year after another reaching places in succession, and so showing a foreign origin.

The appearance in places before unknown is so easily accounted for by the changed conditions of locality, of forest and soil, of excavation and infilling, of rain-fall and water-courses, of climate—and especially temperature—of moisture and winds, of neglect or cultivation, of immigration and increase of travel and population, that these seem quite adequate to explain many of the asserted facts.

The intermittency of prevalence very readily impresses some minds, since it is very natural to reason that causes constant in operation will have a constancy of result. But when we come to know that malaria is greatly related to changing conditions of season; that the conditions of low lands are constantly being modified by the height of the level of soil-water, and by its varying alteration in different seasons; that plant-life varies much in exuberance from season to season, and that a few days of excessive temperature or dryness may be the deciding point, it is not wonderful that there is not more uniformity of result, and that the varying seasons and conditions do not register the same number of cases. We have seen an instance in which for years there has seemed no prominent result from alluvial deposits and interrupted water-courses, in which, owing to the killing of vegetation by peculiar midsummer heat and drought, nine-tenths of the people of a population of three thousand have been seized with various forms of malarial disease, and where the demonstration was too palpable and too stultifying to permit the hypothesis of invasion.

I have lived and practised in a district where bilious fever prevailed extensively in the year 1828. Gradually there came to be a cessation of periodic fevers. I had practised for twenty years in that locality, scarcely seeing a case of intermittent but for a single year, and yet twice in the last ten years seeing seasons of great prevalence of the disease.

I can point to an inland town where malaria was never known until some six or eight years since, but where it now prevails extensively from year to year, and yet it has never occurred to account for it by invasion. How it *invades* is well described by Dr. Chapin, of Providence, Rhode Island, in the Fourth Report of the Rhode Island State Board of Health, 1881, pp. 223 and 224, where it is shown how local causes have accumulated in many places once exempt, and how a marsh which has long existed has become stagnant or fever-producing by more recent changes and climatic variations. Also by Dr. Snow, as quoted in Sixth Report of the New Jersey State Board of Health, pp. 12, 13.

To most observers the yearly conditions had been the same until closer investigation of course and changes had been made. The hypothesis of the progressive travel of malaria has been so pressed into prominence that this deserves a careful study. This cannot be better reached than by an examination of the field in which it has been especially claimed to be illustrated.

The term Yankee has very properly ceased to be a term of reproach, and become one significant of high inventive genius and ready wit. It has never been more aptly and acutely displayed than in the energy and sophistry with which it is attempted to show that Connecticut has been invaded by malaria from New Jersey, and places to the south and west. Plausible explanations have been sought, and deductions made on an insufficient number of data, so that very clever physicians have kept watch while week by week and year by year it has come from the salt meadows of New Jersey and the dark jungles of New York, reached the pure and elevated shore of the Sound; the non-miasmatic highlands along the lofty banks of the Connecticut River; the sparkling, dashing water of the straight-running, unalluvial, roaring Housatonic, and actually insinuated itself amid the mountain fastnesses of Milk Street, and the Springfield tablelands.

We readily admit that to this there has been great temptation. There were enough loose facts from which to frame a hypothesis, and the sharp interests of manufacturers made it very easy to be self-deceived.

It would never do to admit that the busy mills and manufactories were producing malaria as well as merchantable fabrics. It is in evidence that almost every quarter of a century, since mills began to run in New England, has been signalized by some important lawsuit in which the most recent and plausible hypothesis has been made available to shift the etiology of malaria. As we now have the doctrine of germ portability, it is easy to assume that all evils come from afar, and to construct an artificial wave-chart out of a few facts and abundant evolution of inner desire. While we cannot doubt the honesty of these hypothetical inventors, we do not find that the facts are presented in such way or with sufficient data to command assent.

While it is no doubt true, as it has been true in other States, that the disease is not equally prevalent at all times; that it appears often in a place north or south, or east or west, of another before it appears in that place; it is also true that there may be causes not remote in distance or in time to account for this.

We do not claim that there are no mysteries attending malaria, but they are such as obtain as to many other diseases. John Simon did not do despite either to pathology or to experience when he spoke of a whole class of diseases as filth diseases. Yet he would in very many cases be totally unable to define the exactness of relationship, and might be bothered now or then by the statements of many a one as to a place in which, notwithstanding the apparent conditions, no form of filth disease had occurred. Neither a cessation nor sudden recurrence of malaria should confound the great class of witnesses who recognize a connection between enforced conditions of vegetable decay amid moisture and heat as having a causal and prolific relation to periodic fevers.

These may be transferred from place to place, over a larger expanse of territory than once conceived, since more rapid transit may occur to things as well as men. There may continue to be in the future, as in the past, swamp conditions in which undisturbed nature has so harmonized and adjusted relations that the very growth and decay are conservative of health.

But this does not set aside the fact that the habitat of malaria is still just where it has been supposed to be, and that the only radical remedy, therefore, is to preserve the water-courses, or compensate for the disturbance; to study and regulate the soils and water by proper and efficient drainage; not to make great changes by the felling of forests, the blocking-up of streams, the construction of roads, or the methods of artificial vegetation, without recognizing that such disturbances must have adjustments, or else the disturbed equilibrium will tell on the health of the vicinity.

Let us now examine into the alleged invasion of New England by malaria. We need not refer at length to the evidence that malaria showed itself in early days native and to the manor born, and earlier than in any other known localities in America.

The monograph of Dr. Oliver Wendell Holmes, published in 1846, is so full in its detail, and so accurate in its historical references, as scarcely to need additional testimony.

The sanitary report as to epidemics in Massachusetts, made in 1850 by the commissioners appointed relative to a sanitary survey of the State, refers to various outbreaks, and gives some details. We trace it along at such connected intervals as 1634, 1647, 1655, 1658, 1668, and as recognized as indigenous to Connecticut in 1671 and 1678. In 1683 it was at Cambridge and Salem. (See *Boston Med. and Surg. Journal*, Jan. 26, 1853.) The summary of Dr. Bronson gives evidence of its endemicity at Fairfield, Norwalk, and other points, so, as he says, "*there is good reason to believe that the towns along the Sound were affected during the seventeenth century.*" It is to be remembered, too, that just at the last half of the seventeenth century, settlers were constantly arriving in New Amsterdam, and the Dutch and English and Scotch were emigrating to New Jersey, without any signs of it there. It had not as yet settled down from New England upon Long Island, New York, or New Jersey. Indeed it is quite probable that Gov. Cartaret owed much of his success in promoting emigration from New England to New Jersey to the greater healthfulness of the latter, and because the people were seeking riddance from the local periodic fevers which had not been prevalent with the early settlers in the Middle States.

For a time, at the beginning of the eighteenth century, we do not hear so much of the disease, because the smallpox came into such prominence, and probably because malaria had become so indigenous as not to excite so much attention. Yet we hear of it in 1725 as so serious as to give rise to a litigation lasting until 1730, when the dam on Bantam River, near Litchfield, was removed. In 1750 the Bethlehem epidemic followed the draining of the pond. We have frequent references to sickly seasons from 1740 to 1760, in which there is good reason to believe that the fevers were of this type. Thus, in connection with the terrible Pepperell fever of 1755, Butler's *History of Groton* says: "The cause of the Pepperell fever was thought to be the miasma arising from decayed vegetable matter. The swamp or meadow of John Shattuck, near Henry Jewett's, had been overgrown with bushes and various vegetables; and in order to kill them, and bring the land into a state of cultivation, a dam was built, and the swamp overflowed with water. When the water had been drawn, and the vegetable-matter exposed to a summer's sun, the stench was very offensive, and extended for several miles around" (see Shattuck, p. 68).

We have no map showing by what lines this great sickness advanced from New Jersey and New York until it struck Pepperell swamp in 1755.

From 1764 to 1780 we are told that there were many years of sickness, but we have few facts preserved to show its extent. The famous suit as to New Milford in 1799, however, is valuable as bringing out the fact that for long years before, and so often and in so many places, malaria had occurred at intervals for a half-century, as not to satisfy the jury that this one mill-dam was the cause. Places are named and particulars given. The excellent summary of Dr. Chamberlain, in the fourth report of the Connecticut Board of Health, pp. 142–147, commencing, "On the other hand," . . . and ending with the sentence, "These items are only given to aid in proving malarial diseases to have been permanently endemic in the region in question, which also includes portions of Litchfield County," would of itself be enough to show the prevalence of malarial fever with as great constancy through the period up to 1860 as is common in those States in which malaria has been claimed as so endemic as to be a source of it. The description by Dr. John Warren of the Boston and Sheffield fevers of 1796 shows that a very great portion of those taken sick were situated near extensive flats, and that Hubbard's Pond and the repeated Sheffield fever were associated (see Shattuck, pp. 71 and 72). But, besides this, we find that all Connecticut and the westerly part of Massachusetts, about the year 1800, were busily discussing—as they are now—"whether overflowing lands for mill-ponds or other purposes generated a malaria which was unfavorable to health" (see Shattuck, *Sanitary Report*, 1850, p. 73). Indeed, if any one should start the hypothesis that Massachusetts and Connecticut were the original habitats and breeding-places of malaria for the United States, and that by winds and by New England emigration the disease had reached adjacent States, he would need no better description than is to be found in the *Memoirs of the Connecticut Academy of Arts and Sciences*, vol. i. p. 131, being the account given by the Hon. David Daggett of the Ruggles trial (January, 1800), in the court of Litchfield County, Connecticut. It related to a mill-dam which had long caused malarial fevers. Saulsbury, Colebrook, Roxbury, Kent, Great Barrington, West Stockbridge, and most of the towns of the Housatonic, were then, or before, named as habitats of the fever, while it had always, as far as runneth the memory of man, been the disease of New Milford. Already the interests of capital had begun to oppose the theory of its relation to overflowed lands, since many a New Englander was looking for a mill-site. It is no doubt true that, after the great prevalence of malaria in Connecticut and Massachusetts for several years, about up to 1805, there was not so epidemic a prevalence of it, and other diseases seem to have been more general. Yet from the records of medical societies, of courts, and of medical men, there seems to have been just about the same prevalence as in the Middle States. Thus, we notice that in 1822 reporters for the different counties in the State of New Jersey speak of a prevalence of "intermittents" *after an exemption* of twenty years.

In 1835, a circular was extensively distributed in Massachusetts, inquiring into the history of intermittent fevers. Dr. Bowditch, in his *Hygiene in America* (1877), says: "In reference to Massachusetts, I will report that there is no evidence of any disease generally distributed over the State, having ceased to exist. . . . It is admitted, however, that intermittent fever *formerly* prevailed in certain localities where now it is not known. This is due undoubtedly to the cultivation and drainage of the soil." This accords with the statement of Bartholow, in his *Practice of Medicine*, that "the telluric and other conditions favorable to the development of malaria exist largely in this country along the Atlantic seaboard as far north as Boston." It had the same history of prevalence and absence from 1750 to 1850 that is recorded of numberless localities.

Where the population had become fully acclimated, and there was little or no immigration, and little change of vegetation, of forests, of water-courses, and no upheavals or excavations, there was, no doubt, notable absence of the disease. On the other hand, the lines of new population, of improvement, and those where mill-dams and other changes were made in due time recorded the effect during a period somewhat limited by the shortness of the warm season. The Housatonic kept well up with the Delaware and Long Island Sound. The Connecticut River was more prolific in chills than the Hudson River, near New York City (see description of the Housatonic in Holmes' "Prize Essay"). It would be well for those who dispute the effect of local causes in high latitudes to read the report of the Board of Health of Ontario, Canada, on "The Malaria Epidemics of 1882 in Coboconk and Madoc" (see Annual Report of Provincial Board of Health, Ontario, 1882). Its facts are most significant and illustrative as to how malaria may originate even in New England.

So far as we understand the views of those who would discredit the paludal hypothesis and adopt the wave or migratory view, the present malarial wave began its surging about the year 1860, although it was not until 1865, or about the period of the return of thousands of troops from the war, and great interchanges in the internal life of New England, that, to use the words of another, "Each year saw new territory invaded" (see Chamberlain, p. 144).

A paper in the last Report of the State Board of Health of Connecticut (1882), pp. 205–211, is accompanied by a map to show the extent and direction of the annual progress of "the present malarial epidemic during the past twenty-three years." The map is based upon a classification which differs from that of the same report the year before in *fifty or more names of localities or years of occurrence.* In the former year, the Secretary of the State Board of Health of Connecticut had so interpreted his statistics as to have concluded that, "*although not endemic generally in Connecticut, intermittent fever was present in some part of the State, saving the western and southern, nearly if not quite every year since colonial times.*" That is true, and if one cares to study even these records and others in our knowledge, it will be found that the southern part of Connecticut must nearly have touched the Massachusetts line, and the western part extended quite east of the Connecticut River, and that its lesser prevalence in Eastern Connecticut is to be accounted for without resort to the second author's hypothesis of "successive waves, and later by the concentric lines of its annual progress," which, the author says, indicates an advance in one definite direction independent of any known or recognized influence, whether atmospheric, telluric, magnetic, or climatic. To find out how dependent on some of these it had been, he needed only to have turned to the paper of Gen. Veilé, in the former report of the Board, in which he accurately states a sufficient number of facts as to many of these localities, and also as to causes of its occurrence and progression because of changes made. From page 228 onward, there are some very exact statements as to the obstruction of whole lines of water-courses by railroads, and of changes in inland and higher towns, which do much towards explaining the advance both in territory and in prevalence.

We thus find that local causes had accumulated all along the Connecticut shore of Long Island Sound, and penetrated as really and as progressively up the rivers and into the hills as malaria had done.

The author, after a series of statistics so incomplete as to be misleading, projects an original map to show the ærial and telluric significance of this wave hypothesis; how by successive gyrations it has lighted from afar on the hitherto unsmitten New Milford, the cleanly North Adams, and actually affected the valley of the Housatonic.

The map of Paris which Mark Twain constructed for the diversion of strangers, and which had numerous certificates as to its boldness of conception and originality of design, may be profitably studied side by side with this excursus, which is fortified by graphic and linear delineation of the most vagrant character. Then the author, without giving the names of observers or their own statements, and with but one and a half pages of comment not based on any complete analysis of statistics, proceeds to say "*that we may be sure that ague is not produced by heat, moisture, or decay arising from ponds, reservoirs*, swamps, or low ground overflowed by freshets, or exposed by evaporation," however handy the hypothesis may be for the (p. 206) daily use of "talkative laymen and lazy physicians." The author seems all along to have forgotten (p. 207) what had occurred all this time along the southern border of Massachusetts.

The article on mill-dams and other water obstructions in the Report of the Massachusetts Board of Health for 1872 has many local facts that do not look like a foreign invasion.[1]

While it is quite true of towns in Connecticut, as everywhere else, that we do not quite see always why one town has more intermittent than another, why some regions are comparatively exempt, yet we do see that malarial fever in Connecticut and Massachusetts is no new thing. We think many other localities can, in a general way, trace lines of direction, as when it prevails in one place, and favoring winds transmit it to another before a local condition has caused it. But from any evidence before us, we fail to see that there has been an "invasion" of successive waves, "north-east by north," slightly curving to the left, "for fifteen years, then a lateral radiation; that it first touched shore on Long Island Sound in two places, with a third invading point at Milford." *New Milford*, we are told in the one report, was reached in 1876, and by the other in 1877, whereas the disease had been indigenous in both places far back, although not being found each year. Dr. Knight, of New Haven, declared it *never altogether* disappeared from the lower Housatonic, and that it was sporadic as far up as Northampton.

Yet notwithstanding these and scores of other facts, this map projects its contour lines; seeks to make them all converge to its hypothesis, and reaches its climax when it says: "Now, by following it [these lines] backward, we naturally reach that part of Long Island where ague was rife from 1850 to 1860, and, continuing the course, it carries us to New Jersey." *It is not too much to suppose that it came over from Long Island and New Jersey, etc., and possibly further south, etc.*

"Not too much to suppose that it came over." Innocent New England, where no fever yet was born. *Invaded*, and never productive of chills and fever. I admire this constructive ingenuity. It fits in so admirably with the desire of mill-owners; it is profitable as a diversion to juries and courts, who would find excuse for prevalent evils by declaring that they come from afar. It is a hypothesis around which can be marshalled a host of phantasies and analogies. The shaking martyrs of the Connecticut and Housatonic can now pass from the cold stage into the hot and the sweating stage, declaring that chills and fever were never heard of until a wavy breeze of pestilence struck the high and healthy shore of the Sound, and invaded the lofty rivers, the upland marshes, the sunny forests, and the dry mill-swamps of New England. A marked exception to the imaginary wave line which occurred in several towns twelve years too soon is accounted for by the nearness of that part of Connecticut to Westchester County, New York, "*where ague is perennial, and may have received its impulse.*"

---

[1] See also as specimens, Notes on Health of Towns in Massachusetts, 1872; Actor, p. 306; Cantor, 1870, p. 310. How often was the word typhoid used in a loose sense for fevers that were really malarial? See Halifax Huntington, p. 316, 1872, and very many such cases in the Yearly Notes on Health of Towns, also Drainage for Health, 1873, Mass. Rep., and various other evidences of local periodic fevers in the "Health of Towns" for each year.

In this brief study of graphics, we confess to have come across a series of interesting facts which incline us to a far different hypothesis. It is that the Housatonic River in particular and Connecticut specially were the original habitats of this great pest.

As iron filings gather around a horse-shoe magnet, facts seem to be gathering to show that the Middle States were for scores of years free of malaria, while it was desolating, or irritating, or demoralizing the people of Massachusetts and Connecticut; that finally it was introduced by the migration of New England people and by the winds on the shores of Long Island; that it reached then Staten Island and the shores of New Jersey. The Dutch population of New Amsterdam and of Bergen County long withstood the general effects, but finally it obtained a foothold in Westchester and Hudson Counties. The great portion of this State is still exempt, and where it does prevail it is often with long intervals, and there is a strange correspondence between the dates of this malarial wave and its progress southward through the State. We yet may be able to show that the occasional marshes of New Jersey do not breed malaria until it is introduced from places further north. While we must not fail to protect ourselves by the most thorough drainage and by attention to all the laws of health, is it not high time that we appeal to the general government to make such a sanitary survey of the lands, marshes, and rivers of New England as will map out the malarial districts, and then call upon our New England brethren, by drainage and free water-courses, to deliver not only their own regions, but all the Middle States, from those risks of dissemination and extension of malarial particles to which they have so long exposed them?

While we do not at present commit ourselves to this hypothesis to all the extent which possibilities or probabilities might admit, and have not yet constructed an accompanying map, we do claim that the New England invasion hypothesis, which, we are happy to say, has been accepted by comparatively few students and statisticians among medical practitioners, is not sustained. There is need either to fall back upon the effect of local conditions or to construct a hypothesis which, if less comforting down East, will be nearer in accord with local facts and with he conclusions of skilled and well-tried observers.

POISONING BY TWO DRACHMS OF ARSENIC; RECOVERY.

By H. B. HEMENWAY, M.D.,
OF KALAMAZOO, MICHIGAN.

W. O., male, married, colored, age twenty-six years, hostler, generally strong and healthy, went, Monday morning, August 27, 1883, to a drug-store, and bought two drachms each of tartaric acid, powdered cubebs, and arsenic. He said that one of his horses was lame, and that he wanted to make a liniment for his foot. About eleven o'clock he took all of the arsenic and twenty-five grains of the tartaric acid, with suicidal intent. He soon after drank some water, and then vomited. He said that he vomited very little, but one of those in the house said he threw up about a quart of frothy mucus. After that first time of emesis, he did not throw up more until after the physician saw him at one o'clock P. M. At that time, the patient was lying upon his back, with eyes shut, frothing at the mouth. Temperature normal, but had complained of being cold. Pulse 80, full and strong. Ordered ℥ss of mustard, to be given in water. This produced free emesis, but the family were not satisfied, and repeated the dose in the absence of the physician. At two P. M., the doctor gave freely of the sesquioxide of iron, and also six fluidrachms of castor oil. At four and a half P. M., no movement of the bowels having occurred, ʒiss of magnesii sulph. were given. Patient complained of burning pain in the pit of the stomach, extending also, though less intensely, over the entire abdomen, and behind the sternum to the throat. Head clear; said his tongue felt thick. Before seven o'clock in the evening, he had had several movements from the bowels. Urine passed freely. Ordered milk diet.

August 28. — 9 A. M. Patient passed a very good night, but did not sleep much until morning. Pulse 70, and weaker than the day before. Complained of chills, but temperature was normal. Complained of cramps in the abdomen and in the legs. Pain in the small of the back, on the right side. (When the patient vomited the day before, he lay upon his left side. The probability was, therefore, that the pain in the back was due to the straining at the time of emesis.) There was no headache. Patient complained of the thick and heavy feeling of his tongue. Urine higher colored than normal. No movements of the bowels since seven P. M. the day before. In the afternoon, ordered another dose of salts for him, which brought on three movements. No appetite.

29th.—9. A.M. Pulse 50, weak, and not full; patient complained of feeling weak; hands trembled; tried to sit up, but his head felt so light he laid down again immediately; had slept a little through the night; cramps troublesome in the legs; pain great in the right side of the back; patient restless and constantly picking at the bed-clothes; general tenderness over the abdomen; urine passes freely; no fulness around the eyes.

℞.—Tr. Digitalis,
Tr. Nucis Vomicæ, . . . āā ♏iij.
To be taken once an hour while awake.

4 P.M.—No special change.

30th.—9 A. M. The patient had passed a good night, slept well, and had taken a smoke of tobacco; appetite returning; still very weak; pulse 60, fuller, and stronger than the day before; great trembling of the arms and hands. The abdominal tenderness was not so great; cramps in the limbs and pain in the back still continue.

From this time until the patient was discharged, September 3d, he continued to improve rapidly, so that on the last-named day he came to the office, nearly a mile from the house. Though not as strong as usual, he was feeling pretty well.

From the beginning of the case to the end, there was no headache, no abnormal fulness around the eyes, no suppression of urine, but the urine was higher colored than usual. For the first two or three days there was some thirst. The most prominent symptoms in the case were the slow and weak pulse, muscular tremors, cramps, abdominal tenderness, and burning pain.

One other point in the case may be instructive. As has already been said, the patient bought two drachms each of arsenic and tartaric acid. The first article was put up in two papers; upon the outer one of these was the label "Arsenic—Poison," with the name of the druggist. For some reason, possibly because of the breaking of the paper containing the tartaric acid, after he had taken the arsenic he emptied the tartaric acid into the paper bearing the arsenic label. The man's sister-in-law snatched this package from him and delivered it to the physician as soon as he came. The physician went immediately to the drugstore and found what had been purchased, and then weighed the tartaric acid to find how much had been taken. Both arsenic and tartaric acid are white, and though they are quite easy to distinguish between, yet being labelled "arsenic," in his haste he did not doubt that it was arsenic, and it was not until the evening visit that he discovered his mistake. In this instance no harm resulted from the error, but under some circumstances the result might have been different.

GALVANIZATION IN ACNE PUSTULOSA.

BY E. STUVER, B.SC., M.D.,

OF RAWLINS, WYOMING TERRITORY.

MR. C. A. P., æt. nineteen years, formerly of Boston, Mass., consulted me on October 12, 1882, and gave the following history: For about six months he has been troubled with an eruption on the forehead, cheeks, nose, and in a less degree on the chest. The eruption consists of quite a number of papules, about the size of a split pea, which inflame, suppurate, and in a week or ten days subside, leaving dark-colored cicatrices. This was soon followed by a new crop, and the same process repeated. Although he had used numerous remedies, the disease continued to increase in gravity, each crop consisting of a greater number of larger sized papules and pustules.

At the time of consultation, the following condition was noted: Face covered with numerous, large, inflamed papules and pustules, the intervening portions of cuticle being of a dark-rose color, and having a decidedly unctuous appearance. A number of dark-colored cicatrices and a great many comedones, especially about the nose, were noticeable. General health good, and no other trouble discoverable. His diet was carefully regulated, and the following treatment prescribed:

After carefully washing the face with some mild soap, ℞.—Hydrargyri chloridi corrosivi, grs. iv; Spts. vini rectificatæ dil., f℥j; Aquæ destillatæ, q. s. ad. f℥viij.—M. To be applied twice daily. And ℞.—Pilulæ arsenici iodidi (each) gr. $\frac{1}{100}$; one or two after each meal. This treatment was faithfully followed until October 28th, when no improvement being manifest, it was determined to try galvanism.

From October 28th to November 28th inclusive, thirteen applications of a current from six increased to ten cells of a Bartlett galvanic battery were made in the following manner: The positive sponge-covered electrode was placed over the stylo-mastoid foramen, or in that region, and the negative electrode brushed over the affected parts of the corresponding sides. After an application of this kind, lasting from five to ten minutes, the developing papules were touched by a conical-pointed electrode connected with the negative pole, the sponge-covered positive electrode being placed near the spot operated on; the most prominent comedones were then expressed, and finally the sponge-covered electrodes were applied for a few minutes as in the beginning. This order of application has several advantages, of which the following may be mentioned: the application of the sponges to the face as the first step brings into greater prominence the developing papules, as well as the comedones, which latter are more easily expressed after than before this application, owing doubtless to the contraction produced in the muscular elements of the skin. The final application of the sponges is for the purpose of increasing the tonicity of the sebaceous follicles, which is most effectually accomplished after the removal of their secretion.

There was some improvement during the month, but not very marked. The eruption began to be more discrete, and the papules, with their supervening pustules, smaller in size and more limited in duration; the skin also began to assume a more healthy appearance. While the application of the small conical electrode directly to the developing papules did not always prevent their further development and pustulation, it nevertheless had this effect on a considerable number of them, and in all cases exerted a decidedly beneficial influence in diminishing their size and abridging the duration of the eruption.

During December eight applications were made, with somewhat slow but constant improvement. In January, 1883, five applications were made, and the improvement was very marked and satisfactory. In February the current was applied four times, and the last application made March 6th, at which time the eruption had entirely disappeared, and the skin was of a very excellent color indeed.

I saw the patient July 2d, and found him free from the eruption, and highly gratified with the excellent results of the treatment.

THE VALUE OF PICRIC ACID AS A TEST FOR ALBUMEN.

BY CHARLES A. COOKE, M.D.,
AND
RALPH B. WATKINS, M.D.,
RESIDENT PHYSICIANS AT BAY VIEW ASYLUM, BALTIMORE, MD.

In making a series of observations on the character of urine in *malarial* cases at Bay View Asylum, picric acid and heat and nitric acid were used as tests for albumen.

After examining quite a large number of cases, we observed that while heat and nitric acid gave negative results in every instance, unless complicated by organic disease of the kidneys, picric acid invariably gave the albumen reaction. We concluded that there must be some other agent causing the precipitate. Cinchonidia, being the uniform remedy prescribed, was judged to be the factor. Acting upon this suspicion, we instituted a series of experiments to corroborate our theory.

Experiment 1.—We made solutions of sulphates of quinine and of cinchonidia in water (grs. iv–℥j), to each of which a small quantity of picric acid solution (1 to 56, sp. gr. 1010) was added. In each case, a yellowish-white, albuminous-looking precipitate was immediately formed. A solution containing $\frac{1}{120}$ of a grain gave a decided precipitate, and one containing $\frac{1}{180}$ of a grain a perceptible cloud. Heat and nitric acid failed to produce a reaction in each case.

Having established the above facts, we verified our theory by clinical application.

Experiment 2.—The urine of each of twenty-five patients was carefully examined before and after taking six grains of sulphate of quinine, or of cinchonidia. We found that heat and nitric acid failed to give a reaction in every instance, and that picric acid, although failing to cause a precipitate previous to the administration of the drug, invariably caused one nine or ten hours after.

Experiment 3.—To prove that the precipitate produced by picric acid was quinine, and not albumen, we made a solution of quinine and egg-albumen in water, which was boiled and filtered.

To a portion of the filtrate picric acid was added, and a decided precipitate was thrown down. Dil. acetic acid, alcohol, and tr. iodine—Herapath's test for quinine—were added to the remainder and heated. On cooling, the copper-green crystals were deposited. Picric acid was then added to the supernatant fluid, and no precipitate was produced.

In view of the free use of quinine and cinchonidia and their elimination by the kidneys, the above proven fact becomes of much importance, and seriously affects the value of picric acid as a test for albumen, especially so as the appearance of the albumen reaction, and of that produced in non-albuminous solutions in which quinine exists, cannot be differentiated by the naked eye.

Quinine must now be added to the objections set forth by Rayner W. Batten, of Gloucester, in the *Lancet* for November 11, 1882, to wit: 1. That an excess of albuminous urine dissolves the precipitate formed by picric acid. 2. Potassium salts are precipitated by it. These three objections, we think, weaken the claim of Dr. Johnson, of London, in regard to the superiority of picric acid as a test for albumen in urine.

Bay View, Oct. 1, 1883.

ON MASSAGE: ITS EFFECTS AND INDICATIONS.

BY A. HEILBRUNN, M.D.,
OF PHILADELPHIA.

This method of treatment, which has only been recently revived, was known to Hippocrates, Galen, and Celsus for these authorities praised the value of the effects of massage in all diseases of the joints, both acute and chronic. In a work published in 1557, Oribasius endeavored to give a physiological explanation of the results obtained by massage. In the last decade, expositions of massage have been published in a few medical journals, the clearest and perhaps best of which is contained in a lecture of Professor von Mosengeil, of Bonn, in the Congress of the German Society of Surgeons, which may be found in *Langenbeck's Archiv für klinische Chirurgie*, vol. xix.

The credit of the revival of this method of treatment is chiefly due to Dr. Johann Metzger, of Amsterdam, who made a great reputation through the methodical employment of massage according to scientific rules, as well as by the brilliant results of his treatment. Besides him, Esmarch, in Kiel, and Mosengeil, in Bonn, are the most celebrated representatives of this method of cure on the Continent. I pass over the technique of massage, presuming that its principles are theoretically known.

The practice of massage requires, first of all, the possession of a soft, fleshy hand, as a hard and rough hand is not adapted for its exercise. The different manipulations must be frequently exercised, requiring also great patience and perseverance on the part of the physician; for the results are not immediate, but appear, especially in chronic diseases, only gradually. In comparison with other methods of treatment, however, such as electricity, mineral waters, hot baths, etc., they are quicker and more evident to the patients.

In many acute diseased conditions, such as distortions, contusions, etc., the ameliorating effect is almost immediate, which is not the case after the ordinary application of ice. In addition to which, the disturbance of the functions of the parts is corrected soon after the employment of the massage. The rule hitherto practised of ordering absolute rest of the injured parts, and the application of firm bandages to secure immobility, is not necessary when massage is employed.

Since the manipulations of massage, as intimated above, require great practice, it cannot be exercised by every physician, but must be committed to those who devote special attention to it, as in the case of electrotherapy and hydrotherapy, the indications, contraindications, and effects of which should be understood by every physician, but the technique only by those who have had considerable experience in their practical application. To them must be entrusted by the general practitioner the application of these therapeutic agents, just as he allows the physicians who have charge of bathing establishments to determine the special treatment of mineral waters and baths to patients committed to them.[1]

What now can massage accomplish in general and in particular, and what also are its indications and contraindications?

It is generally indicated in local diseases, in which an abundant quantity of nutritive material is necessary, or in which the excessive accumulation of the normal product of the tissue-changes, or pathological products, are to be removed through the centripetal channels, and, through the process of resorption and elimination, rendered innocuous to the system. Thus the effects of massage are explained by the contusion of the muscles and joints and the consequent extravasation of blood. It quickly removes pain and swelling, and acts safer, quicker, and also milder than ice, exemplifying the motto of Paracelsus: *Cito, tuto ac jucunde.*

By massage, the lumen of the veins and lymphatic vessels is not continuously contracted as by the application of ice, but they are momentarily affected only during the periodic stroke of the hand upon the contused portion of the body. Further, the manipulations of massage being made in a centripetal direction, the contents of the vessels are mechanically carried in the normal direction, and a vacuum is formed in their lumen, in which the backward column of blood or lymph, as also the blood extravasated by the injury, is absorbed. In this way, the pressure upon the nerves is diminished, or entirely removed, and the pain is relieved. By the removal of the extravasated blood, the obstruction to the circulation also disappears, while the tissue-change is increased, and, on this account again, the tissue elements, which are destroyed and have undergone fatty degeneration by the contusion, are quickly reabsorbed and regenerated, and healing rapidly follows. *Massage effects wonderfully soon the restoration of the functions of the joints which were entirely lost.* It prevents further the putrid destruction of the infiltrated portions of the tissues, the necessary nutrition of the injured tissues being provided for by the rapid removal of the impediment to the circulation in the blood- and lymph-vessels. Even in those cases of contusion without injury of the integument in which a part of larger dimensions stands in the relation of a foreign body, because every connection of vessels with their surroundings has been separated, massage, which exercises a pressure often repeated upon the necrosed tissues, and at the same time increases the absorbing activity of the vessels nearest the seat of the disease, causes fatty degeneration of the necrosed tissues, prevents suppuration, and is followed by the most favorable results.

For practical purposes, it appears to be especially important now to compare the effect of massage with the ordinary treatment of distortions and contusions of the skin, muscles, joints, and bones with application of ice, and the use of compressive bandages. As is well known, the object of the application of ice is through the irritation of cold upon the nerves, and further upon the skin, muscles, blood, and lymph-vessels, to contract them, to decrease the quantity of blood in the tissues, as well as to prevent inflammation. Actually, the swelling is soon diminished by the application of ice, and the pain is relieved. But the diminution of pain and swelling does not continue. There occurs a contraction of the vessels in the neighborhood of the swelling, a diminution of the afflux of arterial blood, an acceleration of the efflux of the venous blood and the lymph; but the actual blood extravasation is not mechanically forced again into the blood-current; for by the employment of ice the veins and lymph-vessels in the neighboring parts which are not involved are contracted, and exert a pressure upon their own inclosed column of blood and lymph, which does not permit the absorption of the extravasated bood, unless the application of ice is discontinued. While it does not altogether prevent absorption, only a very small quantity of fluid can circulate through the contracted vessels. The extravasation is only slowly removed by the application of ice, it remains, therefore, in the same place, and sometimes induces the formation of fibrin tumors, cysts, and swellings of cell-tissue.

At the same time, the ice contracts the arteries, and also presses the extravasation of blood upon the capillary vessels, so that in severe cases of contusion, gangrene is caused, and demarcation and suppuration take place in the gangrenous tissue, unfavorable results which sometimes follow when the contusions are treated with the application of ice, notwithstanding the integument may be intact. On the contrary, by massage, as we have before seen, the entire circulation is stimulated, and tissue-change is promoted, so that such disturbances in the healing process are not possible.

In regard to the compressive bandage which is so much used in contusions and distortions, in recent cases it causes an increase of the pain and may even favor the development of gangrene. But, if it is applied in a later period, it exercises ordinarily only a moderate pressure upon the diseased part, so that resorption takes place but slowly. Besides, its long-continued use causes an atrophy of the muscles, and the part of the body involved, by being condemned to rest, becomes weak and debilitated. By massage, however, the pressure is not constant, but only momentary. The exudate is broken up, soon changes into a fluid, and is quickly absorbed, especially if active and passive movements are constantly exercised. The compressive bandage should only be applied temporarily; for example, during the time of the removal of the injured person and the ice only when the injured portion can not be treated by the manipulations of massage. Still less than ice and firm bandage are fomentations of a lotion of lead, mercurial and iodine ointments, the so-called resolvent liniments, derivant and absorptive means, equal to the efficacy of massage. In any case the so-called Priessnitz hydropathic cure should be combined with massage, being applied in the intervals of the manipulations and be changed from every quarter to half hour. Such are the *general indications* for the employment of massage. It is *contraindicated* in all suppurative diseases, also in malignant neoplasms, and finally in those diseases in which the formation of thrombi may be suspected. Massage may be followed by dangerous results by favoring the spread of infectious materials, the origin of embolisms and metastases, if it be employed without care and by unskilled persons.

---

[1] D. Graham in the Medical Record, 1879, vol. xvi., No. 2, p. 174.

Especially may massage be used in the following diseases with good results:

1. Contusions and sprains of the soft parts and the bones without breach of continuity.

2. Diseases of the joints of all kinds, both periarticular and intracapsular, bloody or serous exudations and extravasations, false ankylosis, white swelling, rheumatism of joints, gout, especially also the so-called neuroses of the joints.

3. Rheumatic affections of the muscles, tendons, and fasciæ, as well as hyperæsthesiæ and slight circulatory disturbances in the muscles.

4. Connective-tissue indurations, cicatrices, contractures, scleroses, inflammations of the sheaths of the tendons.

5. Paralysis following spinal diseases and after wounds, infantile paralysis, chorea minor, sciatica, commencing tabes, neuralgias, and writer's cramp.

6. Dyspepsia, chronic constipation, and hemorrhoids.

7. Chronic inflammations of the uterus and ovaries.

8. Catarrhal inflammations of the larynx and pharynx, both acute and chronic.

Recently massage has been tried with success by ophthalmologists. It has been used with good results by Pagenstecher in episcleritis and parenchymatous keratitis, and by D. Graham (*Boston*) in muscular asthenopia.[1]

In œdema from heart and kidney diseases, temporarily good results have been observed. In two cases of elephantiasis arabum, a six weeks' employment of massage effected an improvement. The combination of massage with gymnastics, consisting of active, passive, and double active movements, with the overcoming of resistance is very convenient. Further, during treatment patients must be allowed all possible use of their limbs. This is pleasanter to them than forced rest, and improves their general condition through restoration of tissue-changes. The latter is further favored, and the effect of the massage increased, through warm and hot baths with blankets, producing a profuse perspiration, and afterwards followed by a cold douche.

In the Russian and Turkish baths, the attendants are accustomed to knead and rub the whole body and make flexions and extensions of the limbs. Although these procedures produce an agreeable sensation, and in general may be of use, by exciting the activity of the muscles, and at the same time promoting tissue-changes, yet in diseased conditions less may be expected from these manipulations if they are exercised without direction. Especially, these masseurs are accustomed to rub along the periphery, which prevents instead of favoring the resorption of the pathological products. Besides, a steam-bath cannot be taken before every massage manipulation, which should generally be made once or twice a day.

On the contrary, massage exercised according to scientific principles has been followed by very surprising results, a few of which I will quote from recent German medical literature. These are communicated as especially remarkable by Eulenburg, the very distinguished director of a long-established gymnastic and orthopædic institution.

1. A lieutenant, M., had sustained, as a result of a fall from his horse during the French war, a luxation of the right shoulder-joint, with consecutive ankylosis (apparently true). After two years' use of the ordinary means, also treatment by baths in Wiesbaden, he came to Eulenburg for treatment, and was so perfectly restored by massage, with consecutive passive movements, that he was able to discharge his military duties without any inconvenience.

2. Lieutenant von D. received a fracture of both bones of the right leg in the neighborhood of the tibio-tarsal articulation. After union of the fracture, with considerable abnormal callous formation, there remained an ankylosis (apparently true), as a result of which the patient had to quit the service. By the use of massage, accompanied with passive movements, he was restored to a perfect capacity for service.

3. A Swiss confectioner was on the point of quitting his business on account of a white swelling of the right knee. After trying all ordinary means of treatment without success, he was completely cured by massage in the short period of four weeks.

4. Mrs. H. suffered for a year from hydrarthrosis, resulting from a rheumatic affection. After useless employment of all known means, a cure was effected by massage in the comparatively short time of six weeks.

918 North Eleventh Street.

HOSPITAL NOTES.

VIENNA GENERAL HOSPITAL.

Service of Prof. Carl Braun.

LABOR COMPLICATED BY CARCINOMATOUS STENOSIS OF THE CERVIX UTERI; HIGH AMPUTATION OF THE CERVIX, AFTER VERSION BY BRAXTON HICK'S METHOD, AND EXTRACTION OF THE FŒTUS.

(Specially reported for The Medical News.)

The case about to be reported deserves especial attention, as illustrative of a doctrine, growing in favor among modern German obstetricians.

The patient, thirty years old, unmarried, native of Austria, pluripara, in her seventh pregnancy, was admitted into the lying-in-ward of Prof. Carl Braun, at 7 P.M., 4th March, 1883.

---

[1] Medical Record, vol. 16, No. 8, p. 172.

The history of the case, as gathered from the woman's incoherent ramblings, was, that the bag of waters had ruptured four days previous to her arrival in the hospital, and that, since that time, she had felt pain at irregular intervals. Subsequent examination rendered her statements doubtful.

Abdominal palpation revealed a small-sized fœtus, presenting by the vertex. Fœtal heart-sounds were loud, regular, and frequent. By vaginal exploration, it was discovered that both lips of the os uteri were invaded by a neoplasm of globular form. The tumor in each lip was as large as a small-sized chicken's egg. The diseased tissue extended some distance into the cervical canal—two centimetres upon the right side, still higher up upon the left side—constituting a stenosis, which was passable for two fingers. Through the stenosis, the head, covered by the bag of membranes, could be felt.

The general appearance of the woman did not evince any degree of the so-called cancerous cachexia. At the time of admission into the lying-in-ward, the uterus was contracting with force, and pains, of an unusually severe character, were felt.

Prof. Carl Braun was immediately summoned by the clinical assistants, Drs. Felsenreich and Pritzl, in consultation.

Cæsarean section was suggested, but was rejected for the reasons: 1. That the fœtus was immature, although viable, and its chance for life slight. 2. Such an operative procedure would afford the mother the minimal benefit.

Hysterostomatomy, that is, deep incisions into the cervix, right and left, followed by podalic version and extraction of the fœtus, was regarded as impracticable. Prof. Braun proposed, as a last resort, that turning be effected after the method of Braxton Hicks, and that the child be extracted immediately after that operation.

Under Prof. Braun's supervision, Dr. Felsenreich succeeded, by external and internal manipulation, in turning the child. The extraction was effected with some difficulty, after the woman had been thoroughly anæsthetized. The placenta was expelled, after Credè's method, with ease. The parturition was immediately followed by an alarming hemorrhage. It was found, upon vaginal exploration, that the cervix was lacerated upon the right side to the extent of five cm., the rent extending into the parametrium. Both broad ligaments were at once transfixed and ligated with double ligatures. The lower third of the collum uteri was excised, after the arrest of hemorrhage, and the lips of the amputated portions carefully approximated with Hegar's suture. All hemorrhage had by this time ceased, and there remained two holes in the upper portion of the vagina, passable for the half-hand, one leading into the uterine, the other into the peritoneal cavity.

During the operation the patient was placed in Sims' position; the anæsthetic employed was the English mixture of chloroform, absolute alcohol, and sulphuric ether. The operation as thus performed, constituted a high amputation of the cervix uteri, completely removing the carcinomatous mass, after turning and extraction of the fœtus. The child, male, weight 2070 grammes, length 47 centimetres, was immature and was born apparently dead. It was speedily revived by the employment of Gustav Braun's balloon catheter, and is now in a thriving condition in the Foundling Hospital.

The mother experienced little shock from the operation, and, at the time of writing—ten day's after the operation—is in a promising condition. Her temperature during this period has not reached 39.5° C. Pulse and respiration have been nearly normal. Copious irrigation of the cervical portion with 2½ per cent. solution of carbolic acid in the half-sitting posture, was instituted upon the second day after the operation, and is continued at present. The vaginal discharge is considerable in quantity and has a slightly offensive odor.

MEDICAL PROGRESS.

Geographical Distribution of Phthisis in the Eleven Northern Counties of Scotland.—At the late meeting of the Sanitary Institute of Great Britain, Dr. Simpson, the medical officer of health of Aberdeen, read a paper on this subject, in which he summed up as follows: 1. That phthisis has decreased in the North of Scotland during the last eleven years. 2. That phthisis is more prevalent on the north-west coast of Scotland than on the north-east. 3. That the east wind is not productive of phthisis. 4. That the elevated portions of the country do not stand out prominently, even although they are more thinly populated, as being freer from phthisis than the sea-coast on the east, or other low-lying situations. 5. That the Hebrides are not free from phthisis. 6. That local conditions, whether they be social or geological, or both combined, appear to have a greater influence on the prevalence or non-prevalence of phthisis than any general climatic agency. 7. If there is any climatic influence, the north-west wind, combined with excessive rainfall, proves injurious.—*Lancet*, September 29, 1883.

The Germ Theory and Disease.—At the meeting of the British Association for the Advancement of Science held on September 22, Dr. William B. Carpenter read a paper on this subject, which he treated from a natural history point of view. He pointed out the facility which the lower forms of life possess of adapting themselves to changed conditions of existence. He believed, although it has not yet been proved, that the same germs under different conditions give rise to various diseases; and these opinions he supported by various arguments. The decrease of the virulence of the smallpox which ravaged Europe in the fifteenth century, he attributed to the cultivation of the mildest cases which occurred, while a severe dose of any particular disease germ may so affect the system that a disease arises which cannot be recognized as related to that from which it proceeded. Under favorable conditions an ordinary intermittent fever (endemic) may develop into a virulent form, which is highly contagious. There was, in the opinion of the author, very strong ground for the belief that even the innocent hay-bacillus, which, when sown in broth or milk, simply causes its putrescence, and has no power of developing itself, in the human body may undergo such an alteration in its type as to become the germ of severe disease.

Notwithstanding, therefore, the tendency among modern pathologists to regard the various forms of zymotic disease as specifically distinct, and to attribute to inexact observation every recorded fact which ran counter to their preconceptions, the author held that the application of the natural history method to the study of these diseases fully justified the belief that the same germs undergoing development under different conditions might manifest themselves under a variety of forms, and maintained that a larger study of the history of medicine justified the belief that while some of these germs, breeding only in the human body, had acquired a considerable fixity, yet that this fixity did not necessarily hold good over the whole world or through all time; and that there was a large class, including cholera and the various forms of fever originating in germs which breed in the soil as well as in the human body, over which the nature of the breeding-ground, with various atmospheric (possibly electrical) conditions, exerted a most important modifying influence. He held that this inclusive study, taking account of all the facts which science could bring to bear on the inquiry, was much more likely to lead to accurate results than the exclusive method followed by many pathologists.

RELATION BETWEEN THE FLUID ABSORBED AND THE URINE EXCRETED IN SCARLATINA.—According to PROF. GLAX (*Archiv für exp. Path. u. Phar.*, xxxiii. 200), there are three distinct forms of relation between the fluid absorbed and the urine excreted in scarlet fever. The quantity of urine is diminished only while the fever lasts, it then gradually rises to the normal or exceeds it for several days. In this form the course is very favorable, notwithstanding the high temperature at commencement. Secondly, the diuresis increases immediately after the cessation of the fever, but in the next few days sinks greatly, and during the whole course exhibits enormous variations. This course is not favorable when the patients become anæmic; œdema may occur, but the urine remains free from albumen. In the third form, the excretion of urine, which was diminished during the fever, during defervescence rises quickly to the normal or over it, and remains so for several days as in the first form. It then sinks rapidly and remains low until death; or after several days a copious flow of urine takes place, which sinks gradually to the normal. To this class all cases belong in which, after an apparently normal course at first, nephritis and dropsy occur. In these cases a diminution of the urine is frequently the first sign of subsequent complications before any albumen has appeared in the urine, or before any trace of œdema is observable. This is of considerable practical importance, as a careful observation of the body-weight and quantity of urine shows that increase in the weight of the body and coincident decrease in the quantity of urine indicate the approach of complications. These may be averted or greatly diminished by restricting the quantity of fluid absorbed, for generally it is observed that the diuresis increases as soon as the quantity of fluid ingested is reduced. The reason for this appears to be that the weakened heart is unable to cope with any large quantity of blood, and the rapidity of circulation necessary for the secretion of urine is not attained. The author considers also that the convulsions in scarlet fever are chiefly due to œdema of the brain.—*Practitioner*, October, 1883.

SUGAR AS A DRESSING FOR WOUNDS.—DR. F. FISCHER says that in the Strasbourg Hospital, where he is assistant in the surgical department, Professor Lücke has since May used powdered cane-sugar as an antiseptic dressing to wounds. Hitherto, it has been used in combination with naphthalin (equal parts) or with iodoform (1 part to 5 of sugar). In cases of wounds united by suture, the mixture is put up in gauze and applied to the part; where there is loss of skin, the sugar is sprinkled directly over the part. The sugar-dressing is fixed in place by some layers of gauze deprived of fat, over which a layer of gutta-percha is applied, and the whole is secured by a bandage. The sugar-dressing may remain from eight to fourteen days, without the sugar dissolving; the secretion from the wound is equally distributed through the sugar, and it is only when the layer of sugar is too thick (more than about one-fifth of an inch) that lumps are formed. The wounds have a healthy appearance under the sugar, the dressings are not offensive, and bacteria cannot be found in them. Healthy granulations, with no tendency to bleed, are developed; and cicatrization proceeds rapidly. In wounds united by suture, healing by the first intention has always been observed. Dr. Fischer is not able to say whether the sugar is decomposed, or what new products are formed. Writing in the *Allgemeine Medicinische Central-Zeitung* in reference to Dr. Fischer's communication, Dr. Windelschmidt, of Cologne, says that he has used sugar alone as a dressing with good results. He finds that for small wounds and ulcers powdered cane-sugar is not inferior to iodoform as a dressing, while iodoform is necessary in many cases, such as chancres and mammary abscesses. He calls attention to the fact that powdered sugar is a very old popular remedy in cases of fungous granulations, ichorous eczema, and erysipelas of the face. Whether the action of sugar is antiseptic, is not certain; that it is aseptic, is proved by its use in confectionery. In spite of his success, Dr. Windelschmidt has for several months desisted from the use of sugar as a dressing; partly because the patients found out the nature of the powder that was applied and ceased to trust in it, partly because they treated themselves, and so passed from his observation. He thinks, however, that sugar, like iodoform and naphthalin, has its sphere of application; and joins with Dr. Fischer in recommending that it be more extensively tried.—*British Medical Journal*, October 13, 1883.

SALICYLATE TREATMENT OF RHEUMATISM.—DR. ISAMBARD OWEN, in an elaborate statistical inquiry (*The Treatment of Acute Rheumatism*, 1883) into the results obtained in St. George's Hospital in 1877 and 1878 by the use of salicylates in rheumatism, arrives at the following results:

1. The duration of pain and fever after the beginning of treatment would appear to be independent both of the character of the cases (so far as defined by the range of temperature) and of their previous duration.

2. The duration of the primary attack does not appear to be affected by the amount of the initial doses of salicylate (within the limits given, viz., one and a half to three drachms in the twenty-four hours), or by the combination of full doses of alkali with the drug.

3. The duration of the primary attack after the commencement of treatment was only about half as long as under full doses of alkali.

4. In administering the salicylates, an advantage is gained in shortening the total duration of the case (*i. e.*, until convalescence is established) by restricting the initial doses and by combining with them full doses of alkali.

5. In respect of actual suffering, salicylate treatment showed a marked advantage when compared with alkaline treatment; the advantage was least marked where the salicylate was given in large initial doses without alkali, and hardly more so where the salicylate was given only in small doses; the advantage was more marked for the salicylate in moderate initial doses, and most marked of all where the salicylate was given either in large or moderate initial doses combined with full doses of alkali. In the two latter cases the total duration of suffering averaged hardly more than half that shown in the cases treated by alkali alone.

6. Summing up, the greatest aggregate of advantage is derived from a combination of salicylate and alkaline treatment, the salicylate (of sodium) being given in doses equivalent at the outset to two drachms in the twenty-four hours, and reduced as occasion requires. The alkaline treatment referred to consisted in the administration of doses of potassæ bicarbonas, or potassæ citras, of sufficient amount to render the urine alkaline. The salicylate was that prepared from carbolic acid. —*Practitioner*, October, 1883.

Resorcin.—Dr. F. Righi, of Lignago, gives the following summary at the conclusion of a paper on the action of resorcin:

1. Resorcin is well tolerated by the human system. Given in frequent or large doses it causes vertiginous sensations, roaring in the ears, redness of the face, and sometimes a sensation of heat in the stomach, with profuse perspiration in about two hours, and coloration of the urine.
2. In miasmatic affections it is a secure remedy against the febrile attack, and destroys the malarial infection.
3. It is efficacious in reducing recent enlargements of the spleen, but has no effect in chronic enlargements.
4. In typhoid fever, pneumonia, and erysipelas it is a prompt antipyretic, but has no influence on the pyrogenic element.
5. In acute gastro-intestinal catarrh it is of surprisingly rapid and certain effect when combined with bicarbonate of soda.
6. In chronic blenorrhagic urethritis it is to be preferred, for local use, over other more irritating remedies, and quickly restores the epithelium to the mucous membrane.
7. In conjunctival catarrh, whether acute or chronic, and in circumscribed affections of the cornea, it is very beneficial, and Masini recommends it as an efficient collyrium.—*Annali Univ. di Med. e Chirurg.*, July, 1883.

Resorcin may be used as a caustic in the crystallized form or in saturated solution. For vaginal or rectal injection it may be used in the simple form of grs. xv–xxx in f℥iijss of distilled water; for local applications, washes, sprays, inhalations, etc., resorcin grs. xv to f℥iijss of distilled water; for hypodermatic injection, resorcin ℈iv–ʒv to f℥iijss of distilled water. A good form for external medication is resorcin ℈iv–ʒijss to ℥j of glycerine or vaseline; for internal use a good form is resorcin ʒss–j, aromatic water ℥iij, simple syrup f℥j. This may be given in doses of fʒj or fʒij every two hours, or it may be given in emulsion, or in milk. It should be remembered that, during the use of this drug, the urine will be colored green, or brown, or black.—*Gazetta degli Ospitali*, No. 75, 1883.

Paraldehyde—an Antagonist to Strychnia.—Prof. Vincenzo Cervello has made two series of experiments with paraldehyde, the first being on the physiological action of this drug, and the second as to its antagonistic action to strychnia.

Regarding the first point, experiments made on frogs, rabbits, and dogs go to show that paraldehyde has a narcotic action, producing a calm sleep not preceded by excitement or agitation, the respiration becoming calm, and the number of respiratory movements slightly diminished. With very large doses death took place by cessation of respiration, without convulsions or vomiting. The drug seems to be very rapidly absorbed; five minutes after it was given to a dog, by the stomach, its effects were produced. As regards reflex sensibility, it only produced annulment of reflex movements when full doses were given. Though its action is somewhat similar to that of chloral, the diminution of the number of cardiac contractions is not so marked as in the case of chloral, nor are the respiratory phenomena analogous. The drug is easily absorbed when injected subcutaneously or into the rectum. The after-effects are not unpleasant. Cervello recommends that it be given in a 3 to 100 solution of sweetened water or syrup, which has no disagreeable taste, and does not produce the characteristic burning sensation in the mouth.

Antagonistic action to strychnia.—In the second series of experiments three different methods were employed: 1. A non-fatal dose of paraldehyde was given, and then a dose of strychnia; 2. Fatal doses of strychnia were given, and then doses of paraldehyde; 3. The two were given simultaneously. To further assure himself, also, the experimenter gave one or the other of the drugs to the animal after the three methods had been tried. He found that paraldehyde completely antagonized enormous doses of strychnia, but that the administration of the latter did not interfere with the narcotic or other effects of the former, on the other hand, it only seemed to prolong the narcosis produced by paraldehyde.—*Bull. Gén. de Thérap.*, August 30, 1883.

Antimony in certain Skin Diseases.—In a paper read on this subject at the late meeting of the British Medical Association, Mr. Malcolm Morris advocates the use of antimony, in the form of tartar emetic, in doses of gr. $\frac{1}{240}$ to $\frac{1}{32}$, in certain skin diseases.

Eczema.—In the majority of the cases which have come under his care, its beneficial effect has been both marked and rapid. In the acute general eczema of adults, which usually commences somewhat suddenly by heat and burning on the flexor surfaces, and on other characteristic positions, and is soon followed by abundant exudation of clear fluid, and in the form known as eczema rubrum, he generally begins with four or five minims of the vinum antimoniale three times a day, increasing the dose gradually up to seven minims. After a few doses, the exudation ceases, and the local irritation is much relieved; but, in order to prevent a relapse, it is necessary to continue the treatment until all traces of the eruption have disappeared. In acute eczema of children, the dose should be in proportion to the age of the child—half a minim or less up to six months, and one minim or less up to a year. As a rule, he has found that both children and adults bear these quantities well, neither sickness nor diarrhœa being produced. In the case of aged persons, however, the dose should not exceed three or four minims to begin with, as diarrhœa may result from the administration of a greater amount.

In the subacute forms, both of children and adults, similar doses, but continued for a longer period, are necessary. In chronic eczema, especially when localized, the use of antimony is less often successful; but even in this troublesome form, it relieves the acute exacerbations, and is occasionally followed by cure when other methods of treatment have failed.

In eczema impetiginosum of children, he has noticed little benefit from the drug till the scabs have been removed, and formation of pus checked by local treatment. Simple impetigo contagiosa from a local cause is not included in this category.

In the various forms of so-called lichen that occur in children, he has found antimony in the previously mentioned doses of the greatest value in relieving the irritation—a feature in which it resembles arsenic.

Erythema.—The chief feature of this disease is that it is almost certain to relapse. By some authorities this is considered to be idiopathic erysipelas—the public always calls it so; by others, it is looked upon as a peculiar form of eczema, and said to be associated with gout. He has seen several cases, and is inclined to think it may be called relapsing erythema, as it has none of the dangerous qualities of genuine erysipelas. Antimony acts in this disease as in acute eczema, by shortening the attack and diminishing the severity of the symptoms. It should be continued for a considerable time after recovery, to prevent, if possible, a relapse.

Prurigo.—Three or four minims of the vinum, continued over a long period, allay the itching to a large extent, and often prevent the relapses of eczema. In several cases, after arsenic, iron, iodide of iron, cod-liver oil, and numberless other tonics had been tried, antimony was the only drug that produced any benefit whatever. When given in the before-mentioned doses continuously for more than a year, he has never seen sickness, diarrhœa, sweating, or debility; but, on the contrary, the appetite improves and the weight increases. He has not had the opportunity of trying the remedy in a patient older than eighteen and a half years suffering from this disease; but in one particular case of that age, the benefit was most marked while the drug was being taken.

Sycosis.—He has given antimony in five well-marked cases of this disease; in four, it did not seem to produce any effect, either beneficial or otherwise; in the fifth, there was considerable improvement after the vinum had been taken a fortnight in seven-minim doses. It seemed to relieve the pain and burning; but, although the remedy was persevered with for over three months, the improvement was only temporary. The local treatment while the drug was being administered was olive oil or vaseline. In none of these cases was there any bad effect; no depression, diarrhœa, sickness, or sweating.

Urticaria.—In a few cases of chronic urticaria, he has found antimony, like arsenic, of service in checking attacks, so long as the remedy was continued.

Psoriasis.—Though, in the majority of cases of psoriasis, arsenic is to be preferred to antimony, he has elsewhere called attention to the fact that, in certain persons, arsenic not only fails to relieve, but even aggravates the disease. He has, in some of these cases, tried antimony, and has noticed in a few instances that improvement took place, while in others it seemed to have no effect.

The author wishes especially to lay stress on two points: first, that tartar emetic—in doses of $\frac{1}{240}$ to $\frac{1}{32}$ of a grain, according to age—can not only be tolerated, but seems to have a decided tonic action; secondly, that it proves useful in those acute forms of skin disease that are usually aggravated by arsenic.—*British Medical Journal*, September 22, 1883.

KIDNEY IN THE CANAL OF NUCK.—DR. J. D. HUBBARD reports the case of a woman, æt. 36, of previous good health, no fatiguing work, who took a dose of patent pills on Tuesday, July 24, 1883. The pills operated by the next day with considerable violence, causing intense pain and distressing straining. That afternoon she noticed a slight enlargement in the right groin; but, giving her no pain, she thought it was an enlarged gland, and paid no further attention to it, but retired as usual Wednesday night. On arising on Thursday, she discovered the labium majus of the right side greatly enlarged, yet it gave her no pain of consequence; the pain she did have was vague, and mostly referable to the spinal column; intense itching prevailed and caused her to rub the parts, until she found that rubbing did no good; this itching was a most annoying symptom. She then passed water and noticed that it was quite red; her appetite had entirely disappeared, she could not eat anything, not that she could not retain it on the stomach, but for want of inclination. She did not crave water, nor did she pass more or less than usual, though it continued red; bowels moved Thursday, passage looking normal.

The reporter saw the patient on July 28th for the first time. On examining the tumor, he found it to be about four inches long, and about two inches wide; the thickness could not be made out, as the patient was quite fleshy. It occurred to him that it might be a kidney.

On Monday, July 30th, the patient was anæsthetized, taxis applied, and, after a somewhat prolonged manipulation, he succeeded in getting the kidney started in the proper channel, when it went into the abdomen with a decided jump, not stopping until it reached the region of the umbilicus. It made a distinct wave as it passed up. Here he grasped the tumor and examined it. Two other physicians also examined it there, and pronounced it the kidney. It still floats in the abdomen. He has examined it several times since.

Further examination into the history of the case indicates that she has probably had a floating kidney for a year or two.

The next day after the reduction of the hernia, she found that her appetite had returned; she ate very heartily in the morning, also noon and night. She is recovering rapidly, and already going around. She wears a truss, of course.

How did the kidney pass through the canal when the patient was in the prone position and asleep? Certainly no very great pressure could have been exerted from behind. The following is offered as a hypothesis:

It has been already stated that Wednesday evening she noticed a small swelling; now this portion of the kidney had already passed a point of constriction; the arteries being somewhat resistant to pressure, allowed blood to pass into this little protruding mass, while the veins being more susceptible to pressure, prevented the ready return of the blood, and, in consequence thereof, hyperæmia supervened, resulting in œdema or extravasation and swelling: as the little mass grew larger, it either pressed the constriction over a little more kidney, or pulled more kidney through, which in turn filled up and drew down more, and so on, until the entire organ had passed, when, of course, the circulation was reëstablished, the œdema absorbed, and the kidney reduced to its original size.—*St. Louis Courier of Medicine*, October, 1883.

NEW METHOD OF SEWER VENTILATION.—The description and drawings of an ingenious contrivance for ventilating sewers and purifying sewer air have been forwarded to us. The idea seems so good that we regret we have not been able to see it practically applied, though it is stated that successful experiments have been made at Manchester. The apparatus is patented by Mr. T. S. Wilson, F. S. I., and Mr. H. T. Johnson, and is called the Patent Hygienic Furnace. Profiting by the proximity of the gas mains to the sewers, the patentees have constructed a gas furnace to be inserted in the man-holes. The gas is introduced into a little chamber, where it is mixed with a due proportion of air and supplies some Bunsen burners. Immediately above the gas there are some fireclay plates, which soon become heated; while above them are iron divisions. The heat naturally draws the air up from the sewer below; it passes through the Bunsen burners backwards and forwards over the fireclay plates and iron divisions, till at last it finds its exit in the ventilation chamber or man-hole, and hence through the grate into the street. The furnace not only causes a strong current of air from the sewer, but, as it is capable of being heated at from 600° to 700° Fahr., it should destroy all the germ life that travels with the sewer gas. Experiments with sterilized infusions of meat have been made, and whereas ordinary air drawn from the street soon caused the infusions to become turbid with animalcula and fungoid life, no such effect was produced by the sewer air taken after it had passed through this furnace. There is, however, one objection to furnaces when employed to ventilate sewers. They certainly produce a very active suction, but the effect, however energetic, only extends to a short distance. We would therefore suggest, that these ventilating furnaces should be as small and as inexpensive as possible, so that a large number of them might be used, and these at very short intervals.—*Lancet*, September 29, 1883.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

Address, HENRY C. LEA'S SON & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA, PA.

SATURDAY, OCTOBER 27, 1883.

CLINICAL RESULTS OF NERVE-STRETCHING.

In the *Annali Universali di Medicina e Chirurgia*, for March, 1883, will be found an elaborate paper on elongation of the nerves, with a statistical table of 512 cases, from the pen of DR. VINCENZO OMBONI, of Cremona, from which it appears that, of the entire number, 185 were cured, 229 were ameliorated, and 98 were not benefited, the latter including 48 deaths from the affection for which the measure was resorted to, and 12 deaths in consequence of the operation. As the contribution is the most complete of which we have any knowledge, embracing, as it does, over one hundred cases more than were collated by DR. W. J. CHANDLER, in the *Medical Record*, vol. xxii. 1882, we think that we will do our readers a real service by presenting them with an analysis of its contents.

The operation was practised for neuralgia 222 times, with 143 cures, 62 ameliorations, 16 failures, and 1 death, as its direct result. Of the entire number, 62 were examples of neuralgia of the trigeminal and optic nerves, of which 31 were cured, 24 benefited, and 7 failed. 6 cases of neuralgia of the spinal nerves, that is to say, 2 of the intercostals, 2 of the occipitals, 1 of the spermatic, and 1 of the genito-crural, afforded 4 cures, 1 temporary benefit, and 1 failure. Of 37 cases of neuralgia of the nerves of the upper extremity, 23 were cured, 13 were benefited, and 1 failed. Of 117 instances of neuralgia of the lower extremity, in which the sciatic, as a rule, was the nerve stretched, 85 were cured, 24 benefited, 7 failed, and 1 died of pyæmia.

Of 25 contractures with clonic spasms, 11 were cured, 13 benefited, and 1 failed. In 2 of these cases the spinal accessory was elongated, of which 1 was cured and 1 failed. Of the 13 contractures with tonic spasms, 8 were cured, 3 were benefited, and 2 failed. Of 3 contractures without convulsive movements, 2 were cured, and 1 failed. Of 41 cases of contractured muscles, therefore, 21 were cured, 16 benefited, and 4 failed.

For epilepsy, 7 cases show 2 cures, 4 benefits, and 1 failure. The successes were instances of reflex epilepsy. Of 51 operations for tetanus, the author states that 10 were cured and 42 died. The discrepancy appears to be due to the fact that he rates one case as a cure, which died subsequently of erysipelas, so that there were in reality 9 cures and 42 deaths, of which all but one were due to the onward progress of the disease. Eleven of the fatal cases showed a temporary improvement.

Of 40 cases of peripheral paralysis, 2 were cured, 36 benefited, and 2 failed. 6 of these were for motor paralysis, of which 2 were cured, 2 benefited, and 2 failed, the 34 examples of sensory paralysis having been merely ameliorated.

The nerve was stretched for various affections of the central nervous system 149 times, with 5 cures, 100 ameliorations, 27 failures, and 17 deaths, of which 10 were ascribable to the operation. For myelitis, 44 cases afford 1 cure, the success having been one of crural neuralgia following fracture of the vertebræ, 20 ameliorations, 18 failures, and 5 deaths. Of the 4 examples of paralysis agitans, 1 was cured, 1 was benefited, and 2 failed. 2 cases of athetosis gave 1 cure and 1 amelioration. The 99 cases of ataxia resulted in 2 cures, 78 benefits, 7 failures, and 12 deaths.

Finally, the sciatic nerve was stretched successfully once for chronic pemphigus, and once for senile pruritis.

From a careful study of the tables of Dr. Omboni, it appears that elongation of the nerves may be employed with very decided advantage in peripheral neuralgia and in spasmodic muscular contractures which have resisted the ordinary methods of treatment; and there is every reason to believe that it will supplant, in great measure, neurotomy and neurectomy in the former affection. In neuralgia of the cranial nerves, the procedure does not justify the adverse opinion of Nicaise, expressed in the *International Encyclopædia of Surgery*, vol. iii. p. 628, that stretching of the cranial nerves "should be done with reserve and prudence, in the fear of immediately fatal reflex effects, or of trophic disturbances," since none of these ill effects have followed the elongation of the trigeminal branches in fifty-three instances, and of the optic in nine cases. The question of benefit, in consequence of the comparatively few cases hitherto recorded, must remain an open one in epilepsy, peripheral motor paralysis, athetosis, paralysis agitans, senile pruritus, and pemphigus, although the 2 cures and 1 amelioration in the three examples of reflex epilepsy, and the 2 cures and 2 ameliorations in the 6 cases of peripheral motor paralysis, must be regarded as encouraging results. In peripheral sensory paralysis, as, for example, in anæsthetic leprosy, all the cases were benefited, but none cured. For tetanus, if employed early, it is not only justifiable, but worthy of extended trial. In chronic myelitis it holds out little encouragement. The worst results have been obtained in ataxia, and it should not be resorted to in this affection unless the pain is excessive, and there is a fair prospect of primary union of the wound.

As the sciatic is of all the nerves the one which is most frequently subjected to stretching, it is desirable that, in the future, the bloodless method of Trombetta, which consists in forced flexion of the thigh on the pelvis, while the leg is extended upon the thigh, shall be given a fair trial. Of the 117 cases of nerve-stretching for neuralgia of the lower extremity, the sciatic was elongated in the usual manner in 102, 1 proving fatal from pyæmia. Of 2 additional examples, from the practice of Medini, reported in the *Bullet. di Sc. Med.*, No. 3, 1883, 1 died of necrotic phlegmon of the thigh on the fourth day; and this death-rate of two per cent. doubtless represents the actual mortality of the procedure. Of course, it is a desideratum to avoid the dangers and inconveniences of a bloody operation if an efficient substitute can be found for it. Whether this substitute will be forced flexion remains to be seen, since the cases recorded up to the present time are too few upon which to base an opinion as to its therapeutic value. Adding to the 9 cases collated by Omboni the 2 recorded by Medini, the 11 afford 9 cures, 1 palliation, and 1 failure. Of the 104 cases of stretching the sciatic after preliminary incision, 71 were cured, 25 benefited, 6 failed, and 2 died; so that, with these data before us for comparison, the bloodless operation will be seen to yield a greater proportion of cures, while it has not proved fatal in a single instance.

While it has heretofore proved to be safe, the bloodless procedure is now and then attended with subcutaneous rupture of muscles, as indicated by an audible snap and extravasation of blood. In the case of Fiorani, reported in the *Annali Univ. di Med. e Chir.*, for February, 1883, the muscles on the back of the knee gave way, and in one recorded by Medini, the biceps, semimembranosus, and semitendinosus were torn; but in neither example were the ill effects permanent. Fiorani, moreover, points out that the quadratus femoris is contused by forced flexion, and he has even seen it divided in the cadaver by the tremendous pressure exerted upon it by the nerve in its passage across it.

THE ACTION OF BENZINE AND NITROBENZINE.

The free use of benzine in the arts, and the consequent dangers to health and life, render some notice of its action timely. Its physiological effects have been studied by Drs. Neumann and Pabst by experiments on animals, and by the analysis of the toxic symptoms as observed in man. There is a close resemblance in the effects of benzine and alcohol, ether and chloroform. The influence of this substance is exerted especially on the cerebrum. Its first effect is excitant, and this is followed by disorders of voluntary movement, of sensibility (anæsthesia), and of the mental faculties (hallucinations). Amongst the effects observed from its chronic action are antaphrodisia and black discoloration of the teeth and the margin of the gums. Benzine is eliminated almost entirely by the lungs, only a small part of that taken appearing in the urine as phenol and other products.

Nitrobenzine is more powerful. Its effects do not follow immediately, from a half hour to an hour, and sometimes a longer period, elapsing before symptoms are manifest when its vapor is inhaled. The face becomes livid, the integument especially of the face and extremities assumes a bluish hue, and an odor of bitter almonds is exhaled. Convulsions, cramps of certain muscular groups (trismus, opisthotonos) are amongst the nervous symptoms induced by it. Of forty-four recorded cases of its toxic action, fourteen proved fatal, and thirteen of these occurred after the stomachal administration—facts apparently demonstrating that the inhalation of the vapor is less dangerous. There appear to be no characteristic lesions, but in all cases fluidity of the blood has been noted, the red blood-globules are damaged, and hæmoglobin is transformed, to some extent, into hæmatin.

FEMALE PHYSICIANS IN INDIA.

"With regard to the fitness of women for medical practice, in this country opinions differ," says the London *Times*, "but in the case of India there need be no discussion about fitness, for the simple reason that there the question is not one between women and men, but between women and no doctors at all."

Any one familiar with the beneficent results following the labors of the female physicians sent out by the Zenana Missions, both in this country and England, will acknowledge the justice of the statements of the *Times*. The native women, especially those of high caste in the Zenanas, are absolutely shut out from skilled medical aid, since they cannot be attended by men, not even in any ordinary illness or accident, much less in confinements or any female diseases.

The only way to remedy this dreadful state of affairs is to provide for them physicians of their own sex, and this America and England are doing. And the results of the effort are far wider than would seem probable at the first glance. Not only are the physical ailments of the women treated skilfully—for the female physicians sent out are capable, and have been thoroughly trained—but the moral influence exerted towards the destruction of the "caste" system with all its evils, and especially towards the abolition of the systematic seclusion of women will be widespread and powerful, to say nothing of its strictly religious influence, which is at least no less beneficent.

It is not a little significant, that right upon the heels of such an editorial in the *Times*, comes the announcement of the fact that Mrs. Joshee, a young native Indian woman of *high caste*, has left her country and entered upon a course of medical study at the Woman's Medical College of Pennsylvania. From a religious and social point of view it is one of the startling facts of the nineteenth century, the significance of which can only be appreciated by those who are familiar with the rigid rules of the Indian mode of life. She is not a "Christian," but a "heathen" woman who has dared to take this step and yet preserve her "caste" intact, and she will go back to India to minister to her sisters in their sicknesses and accidents, as not even a foreigner, woman though she be, can do.

It is indeed the first step towards filling the need that the *Times* suggests, that not only foreign "Christian" women should be educated as physicians, but also the intelligent native women themselves. The number of the former class can hardly be increased to such an extent by the missionary societies as to afford the requisite relief to the millions of Indian women: the number of the latter can be increased indefinitely.

Queen Victoria has lent her powerful aid to the movement to provide medical aid to her female Indian subjects, by her gracious and conspicuous reception of Mrs. Scharlieb before her departure for Madras; and the sympathies and discreet aid of Mr. Rivers Thompson, the Lieutenant Governor of Bengal, are understood to be heartily in accord with the movement, which will thus feel the impulse of the highest official aid, both in India and in England.

RENAL CIRCULATION DURING FEVER.

Reasoning from the very frequent, if not constant, presence of albuminuria attending high grades of fever, it has generally been supposed that the kidney is at such times hyperæmic and enlarged. But if the observations of Dr. Walter Mendelson, published in *The American Journal of the Medical Sciences* for October, 1883, be correct, it will be necessary for us to modify materially our views upon this subject.

Dr. Mendelson's experiments were made in the Pathological Institute of the University of Leipzig, under the direction of Prof. Cohnheim. The animals experimented upon were dogs, the kidney being carefully drawn out, and placed in an ovoid box known as an oncometer or "bulk measurer." Within this box the kidney is surrounded by some liquid, as oil, which is displaced by any increase of volume which the organ undergoes. The vessels, nerves, and ureter are carefully guarded from injury as they pass out of an opening in the side of the box. A feverish state is induced in the animal by injecting into the blood fresh gastric juice, and its immobility is secured by destroying the optic thalamus of one side. The displaced oil communicates with a graphic instrument known as the oncograph, which produces a tracing on a revolving drum, whence it appears that *during fever a progressive diminution in the volume of the kidney occurs.*

That these changes in the volume of the kidney depend on the amount of blood contained in its bloodvessels is inferred from the fact that the kidney contains no contractile elements outside of the vessels.

Dr. Mendelson's experiments also went to show that this contraction, which is proportionate to the degree of the fever, is the result of a stimulus conveyed to the vessels from the central nervous system, and that this stimulus is the consequence of irritation of the central vaso-motor centres by the abnormally hot blood circulating through them during fever.

Two important phenomena of fever must receive a different interpretation if these views are correct. These are, the decrease in the amount of urine secreted by fever patients, and the albuminuria. The former has heretofore been ascribed to the increased loss of water through the skin and lungs, whereas, according to Mendelson's results, the primary condition is a diminished blood-pressure and a retarded current within the organ, which must be followed by a lessened secretion of urine. The albuminuria so constantly present in high fever is to be ascribed to the anæmia of the kidney, in consequence of which the glomerular epithelium is too insufficiently nourished with arterial blood to enable it to perform its function of retaining within the vessels the albumen of the blood-plasma.

We hope that these experiments may soon be repeated, for, if verified, other important deductions will follow, whence practical advantages may be expected.

THE INITIAL LESION OF SYPHILIS.

In a paper recently read before the British Medical Association, and published in the *British Medical Journal*, of September 22, 1883, Mr. Bernard, Surgeon to the Liverpool Lock Hospital, makes some interesting additions to our knowledge in regard to the situation, period of incubation, and the forms of induration of the primary syphilitic lesion, which should prove to be valuable to those who are especially concerned with these objects of inquiry.

The primary lesion was met with on the inner surface of the prepuce in 118 cases; in the furrow in 71; on the corona in 45; on the skin of the penis in 26; on the outer surface of the prepuce in 23; on the body of the glans in 21; on the frænum in 11; at the meatus in 10; on the free border of the prepuce in 4; and in the urethra in 1 case. It will thus be seen that the prepuce, including the frænum, was the most usual site of the lesion, the furrow behind the corona coming next in order, and that the corona was attacked oftener than the body of the glans.

The period of incubation in sixty-nine cases varied from one to fifty-six days, the average being a little under twenty days, which agrees pretty closely with the generally accepted average of the end of the third week. An interesting point in this connection is the preference given to the multiples of seven as the most usual dates of the outbreak, it having been met with forty-three times out of the sixty-nine. This fact was observed by Fournier in twenty out of forty-five inoculations, and by Lowndes in twenty-five out of forty-seven cases.

Mr. Bernard finds that the induration, in the male, is best marked when the sore is situated on the inner surface of the prepuce and the furrow, where it feels like a piece of cartilage. When the gland is affected, the sensation is rather that of a thickening than of hardness of the part. At the free border of the prepuce, the induration, although characteristic, is not so elastic as when the lesion is seated on its inner surface. Absence of induration is common when the skin covering the body of the penis is involved, but, when present, it feels like parchment. In the female it is best marked on the nymphæ. When seated on the greater labium the sensation is similar to that when the lesion occupies the glans penis. In the fourchette the induration is not characteristic.

THE NEW CODE IN NEW YORK.

In the controversy which has been agitating the profession in New York for nearly two years, many physicians have been led into the advocacy of the New Code by the specious cry of "liberty of action," others by the idea, which has been more ingeniously than ingenuously put forth, that by throwing down all barriers between medicine and "the pathies" we would win over the practitioners of the latter, and, in some mysterious but unexplained way, we would thus advance the cause of scientific medicine.

We have never been able to accept these views. In fact, we have earnestly believed that there is but one way of attaining the eternal truth of science, and that is by quietly, but steadfastly, pursuing it until we reach the goal of demonstration, and that it does not become the true student of medicine, nor the dignity of his profession, for him to impede its progress by stooping to fraternize with what he believes to be a false science, because of any temporary advantage which might possibly accrue to him from this act, which, in this case, must have for its chief result the misleading of suffering humanity.

It is, therefore, with extreme regret that we learn of the approval of the New Code, which has been expressed after mature consideration and careful canvass by the majority of the Academy of Medicine and of the County Society of New York. We are confident that all these gentlemen, imbued with the true scientific spirit, are ready to accept any fact which is demonstrated to be true, from whatever source it may come, yet they have given a formidable stab to rational medicine by declaring that the so-called medicine of unreasoning dogma, in which they do not believe, shall be recognized as its mate. Their action misleads the public, which naturally looks to educated physicians to protect them from medical charlatanry, and deals a heavy blow at the honesty of medical science, the consequences of which we shrink from considering.

COMPARATIVE ACTIONS OF CONINE AND CURARA.

The difficulty experienced in procuring a sufficient supply of curara, and the very great variability in the activity of the commercial specimens, render it very desirable to procure an efficient substitute. This has been found apparently in conine. Until a stable preparation of the lattter had been made available, however, there was little practical utility in the suggestion. The bromhydrate of conine is both stable and readily soluble, and can therefore be employed with ease and certainty. It may be useful to recall to our readers' attention the points of resemblance, as they have been set forth in a series of comparative observations by Schulz and Schroff.

The paralysis caused by curara and by conine is due to an action on the terminals of the motor nerves, and on the nerve-trunks, the muscular contractility remaining unaffected.

Like curara, conine produces slight muscular contractions, especially in the muscles of the face and extremities.

Like conine, curara has a more decided paralyzing action on the pneumogastric than on the motor nerves of the heart. Prevost and Kölliker have noted that the salivary, lachrymal, and urinary secretions are increased by conine, and Luchsinger has observed the same results from curara.

The resemblance of these agents is thus so complete, that there is little doubt conine may be substituted for curara in physiological investigations as in the treatment of morbid states.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, October 18, 1883.

The President, Fordyce Barker, M.D., LL.D., in the Chair.

After the reading and approval of the minutes of the preceding meeting, and the reception of the report of the Chairman of the Library Committee, the Academy went into a Committee of the Whole, for the consideration of the proposed amendments to the

CONSTITUTION AND BY-LAWS,

Dr. Ellsworth Eliot taking the Chair.

Dr. Austin Flint, Jr., said that he had no remarks to make in regard to the amendments, except to say a word or two in explanation similar to the statements which he had made two weeks before. There seemed to him to be no reason for discussing the amendments either in the Academy or the Committee of the Whole, and he was unable to see why a scientific paper had not been presented at the last meeting. It would have been sufficient, simply to give notice that certain changes in the Constitution and By-laws were proposed, and that action would be taken on them at the following meeting; after which the regular scientific work of the Academy could have been proceeded with in the ordinary way. He humbly submitted that the remarks of the gentleman who proposed and seconded the adoption of the amendments had not been in order, for the reason that the latter were not before the Academy for adoption on that occasion, and could not be, according to the Constitution and By-laws. He was here to-night, he continued, as the spokesman of a number of members who believed that the welfare and usefulness of the Academy of Medicine could be best preserved by strict adherence to the National Code of Ethics, and who are uncompromisingly opposed to these amendments—one and all. The amendments, as was well known, had one great object, viz., the elimination from the Constitution and By-laws of everything relating to ethics. They would reduce the Academy to the level of the many smaller medical societies of the city; making it a purely scientific body, with nothing whatever to do with the general welfare of the profession as regards the ethical conduct of its members. Of course, the elimination from the By-laws of the by-law which adopts the Code of Ethics of the American Medical Association, necessitates a certain amount of change in the wording of the Constitution and By-laws in other particulars. That issue is perfectly distinct. Every gentleman here to night who is in favor of maintaining the Code of Ethics that has been adopted by this Academy, will vote against every one of these amendments. He did not believe that any eloquence was sufficient to convert those misguided members of the profession who believed in another Code of Ethics or who believed in making the Academy a no-code organization. If adopted, however, they would leave the Academy without any Code whatever, and this he considered even worse than to accept the new Code. There was one point to which Dr. Flint wished to call the attention of the Fellows of the Academy. Not only do these amendments abolish the Code of Ethics, but in the tinkering (he said he used the word with respect) that has been done to these By-laws, it became necessary to provide that the Council should not appoint delegates to certain bodies, for the simple reason that without a Code of Ethics they could not appoint, or were not entitled to appoint, delegates anywhere. Another point was in regard to a quorum of the Council, which was now constituted by nine members, but by the amendment would be reduced to five. The duties of the Council, he said, were multiform and of great importance, and the proposed amendment put it in the power of three members to adopt measures involving the greatest interests of the Academy, and to take the initiative in disposing of its funds, and in other matters of the greatest importance. He wanted to see the quorum of the Council kept as it was, and he was informed on the best authority that a quorum had hitherto never been lacking, except, perhaps, at some of the meetings in the middle of summer. In conclusion, he stated that at no time in the history of the Academy had any amendments to the Constitution or By-laws ever been adopted which had failed to secure the endorsement of the Council; and, furthermore, that at no time had the Council ever made any recommendation which was not adopted by the Academy. It was simply ridiculous to suppose that a three-quarters vote (which was required by the Constitution and By-laws) could be secured in favor of the adoption of the amendments.

Dr. Flint then moved that the Committee of the Whole should rise.

The motion was seconded and put, and the Chair decided that it was carried.

Dr. Roosa appealed from the decision of the Chair, but the latter was sustained.

Dr. Eliot, Chairman of the Committee of the Whole, made his report, and The President called for the reading of the resolutions adopted by the Committee of the Whole at the last meeting. (These resolutions recommended the adoption of the proposed amendments.)

Dr. Flint, Jr., claimed that this was not in order, and the President maintaining that it was, Dr. Flint appealed, when the Chair was sustained.

The resolutions were then read by Dr. W. M. Carpenter, Secretary of the Committee of the Whole.

Dr. Flint, Jr., moved that the report of the Committee of the Whole be laid on the table.

Dr. Roosa, with four others, called for the yeas and nays.

After some discussion as to whether the register in which the members had recorded their names on entering the hall, or the full roll of the Academy should be used for calling off the names, The President decided that the register was sufficient.

Dr. Flint, Jr., then appealed from the decision of the Chair, but the latter was sustained by a vote of 88 to 84. The yeas and nays having been taken, the motion to lay the report of the Committee of the Whole on the table was found to be lost, the vote standing 114 against to 96 in favor of the motion.

Dr. A. L. Loomis moved that, when the question of the adoption of the amendments was put, the vote should be taken by ballot.

Dr. Austin Flint, Sr., offered, as an amendment to Dr. Loomis' motion, that the question of the adoption of the amendments be indefinitely postponed; and Dr. Loomis not accepting this, the yeas and nays were called for on the amendment. The amendment was found to be lost by a vote of 117 opposed and 95 in favor of it.

On motion, the balloting on the adoption of the amendments was then proceeded with, the Chair having appointed Drs. H. D. Nicoll, Daniel Lewis, and Arthur M. Jacobus, the assistant secretary, tellers. The result showed 121 votes in favor of the adoption, and 92 opposed, and the Chair announced that the amendments were lost.

Dr. Barker now asked the indulgence of the Academy for a few minutes, and said that, in such a body, with its high aims in science, honor and duty demanded of the members that all should acquiesce submissively in the result which he had just announced with great pain and regret. The letter which he had prepared to the Fellows had expressed his views on the present unfortunate state of the Academy, and the importance of the amendments to its organic law which he had proposed. He had, however, failed to convince a sufficient number of the wisdom of the course suggested, and he must acquiesce in the verdict. No one could say that he had endeavored to secure the passage of the amendments by personal solicitation of the members, for he felt that such a matter should be left to the judgment and intelligence of a body of men, such as the Academy is composed of, unbiased by prejudice and free from passion. He begged most earnestly that all past controversies, so far as the Academy was concerned, would be forgotten. He was convinced that very many of these differences had arisen, not so much from differences in principles as from differences in detail. For himself, he could only say that in the future, as in the past, he would give his best effort—and he begged all present to give their best efforts—to keep up the high scientific position of the Academy, and to support and increase their beautiful library for which they were indebted to so many liberal benefactors.

Dr. Loomis then offered a resolution to rescind the resolutions proposed by Dr. Flint, Jr., and adopted at the last meeting of the Academy in the spring, which provided that the Committee on Admissions should propose for election to membership the name of no non-candidate who was not known to be in favor of the Code of Ethics of the American Medical Association as adopted in the By-laws of the Academy.

In moving this, he remarked that the Fellows were not here to decide the code question. The spirit of the meeting was above such a low plane as this, and they were here to decide the welfare of the Academy, whether it should sustain the high position which it had hitherto occupied, or sink into degeneracy and anarchy. The latter alternative was inevitable as long as these objectionable resolutions remained in force. These had been the firebrand which had disturbed the peace of the Academy, and as long as they stood unrescinded, the same unpleasant scenes which had of late been enacted in this hall would occur again and again.

Dr. Flint, Jr., claimed that Dr. Loomis' motion was out of order, for the reason that it involved nothing more or less than a reconsideration of the resolutions proposed by him, and adopted by the Academy; and at the meeting at which they were framed, a reconsideration had been moved and carried, and after this it was voted indefinitely to postpone the reconsideration.

The President having decided that the point of order was not well taken, on the ground that the rescinding of a resolution was of a different nature from its reconsideration.

Dr. Flint appealed from the decision of the Chair, but the appeal was not sustained.

Discussion of Dr. Loomis' resolution now being in order, Dr. D. B. St. John Roosa made some remarks, comparing the action of the State Medical Society, in regard to the Code of Ethics, with that of the Academy; but they were decided out of order by the Chair, as not bearing directly on the question.

Dr. C. R. Agnew then endeavored to prove that the resolutions of Dr. Flint were a violation of the Constitution. In the first place, the Constitution provided only two qualifications for membership, viz., that the candidate should be a graduate or licentiate in medicine, and that he should have resided in this city and county, or in either of the counties of this State adjoining for the term of three years; but these resolutions introduced a third qualification, viz., adherence to the Code of Ethics of the American Medical Association. In the next place, the resolutions were in reality in the nature of an amendment to the Constitution, and the latter provided that no part of it (the Constitution) should be altered, except at a stated meeting subsequent to one at which a proposition to that effect should have been made in writing, and then only by a vote of three-fourths of the resident Fellows present. Instead of giving the required two weeks' notice, however, action had been taken at once on the resolutions, the only notice being a secret circular which was addressed to those known to be in favor of such action. When the resolutions had been passed, a certain movement of conscience seemed to have troubled the leaders of the Old Code party, and they had then resorted to some parliamentary sharp practice in order to render the action taken as permanent as possible.

A motion to adjourn was made at the conclusion of Dr. Agnew's remarks, and lost, and Dr. Loomis' resolution was then put and carried; after which the Academy adjourned.

THE PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, October 17, 1883.

The President, William M. Welch, M.D., in the Chair.

Dr. James C. Wilson presented the following

NOTE ON HYDRARGYRUM FORMAMIDATUM:

Some accounts of this preparation have appeared in recent journals. Towards the close of last year, Prof. Liebreich proposed, in a meeting of the Berlin Medical Society, a new drug for the treatment of syphilis by the hypodermic method. Chemically, this drug belongs to the amide group. Liebreich was led to use it from the fact that the ordinary amides of the body, of which urea is the principal one, are eliminated in an undecomposed state. When, however, the amide is in combination with a metal, decomposition occurs, and the metal is reduced and deposited. Liebreich found, by actual experiment, that this statement is true of mercury. It is supposed that the formamidated mercury, after hypodermic injection, undergoes decomposition, and that the metal mercury is set free in the tissues. The preparation is soluble in water, of neutral reaction, does not coagulate albumen, is not precipitated by caustic soda, and the presence of mercury can be demonstrated by potassium sulphide. It produces its effects very surely and rapidly. Liebreich regards it as the best remedy known for the hypodermic treatment of syphilis by mercury, as it is but little liable to excite local troubles or salivation. Later (*Med. Times and Gazette*, July 7, 1883), we find that Prof. Zeissel, in Vienna, after trial of this remedy in fifteen cases of syphilis, was well satisfied with the results. In three of these cases salivation was produced. Some pain followed its injection, which was not, however, so severe as that following the hypodermic use of mercuric chloride. Twenty injections was the maximum number required to disperse the manifestations, even in severe cases.

Dr. Schacht, of Berlin (*New Remedies*, Sept. 1883), writes at follows:

"Formamide is a colorless liquid, boiling at about 195° C., which can be distilled without decomposition only in vacuo. It is prepared by acting upon formate of ethyl by ammonia. When pure it is neutral, but easily becomes acid

"If a *concentrated* solution of formamide be *boiled* with precipitated mercuric oxide, decomposition ensues, and metallic mercury is separated.

"On the other hand, if a *dilute* solution of formamide be *warmed* on the water-bath with precipitated mercuric oxide, a clear, colorless solution results, in which soda (hydrate of sodium) produces *no* precipitate. Sulphide of ammonium, however, precipitates the mercury as sulphide, both from the formamide of mercury and from mercuric chloride. Solution of albumen is precipitated by the latter salt, but *not* by the formamide.

"Formamide of mercury is prepared in the following manner: 10 to 13 grms. of freshly precipitated, completely washed, and still moist mercuric oxide are gently warmed with a little water in a porcelain capsule, with gradual addition of 10 grms. of formamide. As soon as solution has taken place, the resulting colorless liquid is filtered into a litre-flask, and the latter filled to the litre-mark with distilled water. Each cubic centimetre contains 0.01 grm. of mercury, which is the quantity representing *one* hypodermic dose. Formamide of mercury keeps well in brown-colored bottles, and should also be dispensed in these."

In a note from Vienna (MED. NEWS, October 13, 1883), it is stated that Prof. Neumann is now trying hydrargyrum formamidatum on a large scale as an anti-syphilitic. It is used hypodermically in doses of 1 cc. It acts with far greater efficacy upon the recent efflorescences than upon the later manifestations. Pain of great severity and active local inflammatory troubles have resulted in Neumann's cases.

The preparation which I exhibit, made by Merck, of Darmstadt, is a one per cent. aqueous solution, and the dose of it is from half to one ordinary hypodermic syringeful.

It has not been possible to obtain the drug in this city until the present time. I would be glad to place the specimen which is exhibited in the hands of any member of the Society who may desire to made a trial of it clinically.

NEW YORK COUNTY MEDICAL SOCIETY.

Seventy-eighth Annual Meeting, with Election of Officers and Censors, October 22, 1883.

THE PRESIDENT, DAVID WEBSTER, M.D., IN THE CHAIR.

IN consequence of the very large attendance expected, the meeting was held in the Hall of the Young Men's Christian Association, instead of the usual place, the lower lecture-room of the College of Physicians and Surgeons.

The minutes of the last meeting were read and approved, and the SECRETARY, DR. W. M. CARPENTER, then read the annual report of the Comitia Minora, the By-laws directing that, at the annual meeting, the Comitia should report such of its proceedings during the year as had not already been announced to the Society at large.

THE SECRETARY also read the names of

EIGHTY-ONE CANDIDATES FOR ADMISSION

to the Society who had presented satisfactory documents and testimonials, and whom the Comitia recommended for election.

It was moved and seconded that the recommendation of the Comitia be adopted and the new members duly elected.

DR. AUSTIN FLINT, JR., moved that the motion be laid on the table until after the election of officers. This was defeated, and the motion electing the new members was then put and carried.

Continuing with the report of the Comitia Minora, the Secretary announced that in accordance with the finding of the Committee on Ethics in the case of Dr. H. H. Kane, it recommended that the latter should be expelled from the Society, and the recommendation was then adopted by the unanimous vote of the Society.

DR. O. B. DOUGLAS, read the

ANNUAL REPORT OF THE TREASURER.

At the commencement of the last fiscal year the balance in the treasury was $243.93, and during the year he had received $956 from annual dues, $946 from the assessment authorized at the last annual meeting, $213 from initiation fees, and $55 from the sale of the *Transactions of the State Medical Society*, making in all the sum of $3660.

The principal items of expenditure had been: $1922.52 for legal fees, $502.61 for the Secretary's expenses, $359 90 for the expenses of the State Medical Society, and $200 paid to the Secretary and Treasurer for services rendered; and there was left in the treasury a balance of $235.43.

The report was pronounced correct by the Auditing Committee, consisting of Drs. H. P. Farnham and P. A. Morrow.

THE ANNUAL ELECTION OF OFFICERS

being now in order, the Chair appointed as tellers, Drs. H. G. Piffard, W. T. White, George F. Carey, E. F. Ward, and W. T. Alexander.

The name of Brevet-Lieutenant Colonel Bennett A. Clements, Surgeon, U. S. A., having been duly proposed for honorary membership, Dr. Carpenter moved that Dr. John Milhan, who had presented Dr. Clements' name, should cast an affirmative ballot for the Society, and the motion was unanimously carried.

DR. A. FLINT, JR., having secured the floor, remarked that, as the names of the unusually large number of eighty odd new members had just been announced, he would like to inquire whether these gentlemen were entitled to vote at this election.

THE CHAIR having replied in the affirmative, Dr. Flint moved that the names of those new members who had paid their initiation fees and annual dues, should be read by the Secretary, so as to save the trouble of challenging the new members at the time that they voted; but the motion failed to pass.

DR. OBENDORFER said that he rose to ask for information, and inquired if bribery were a sufficient ground for challenging a vote, for, if it was, he would give notice in advance that he would challenge the vote of every new member.

DR. PIFFARD claimed that the gentleman had used disorderly language, and that his words should be taken down by the Secretary; but Dr. Obendorfer, on rising to make an explanation, was declared out of order by the Chair. This ruling was received with much dissatisfaction throughout the hall, as there was a general desire to hear on what grounds such a charge was made; and Dr. Leo protested that the rights of free speech had been interfered with.

DR. FLINT stated that, in the history of the Society, such a large number of new members had never been known to qualify on the night of an election.

The balloting was then proceeded with, and while it was in progress the reports of the various standing committees were made.

DR. C. S. WARD, Chairman of the

COMMITTEE ON ETHICS,

reported that but three cases had come before the committee during the year. Of these, one had been disposed of by arbitration, and the other two had been referred to the Comitia Minora.

DR. A. E. M. PURDY, Chairman of the

COMMITTEE ON PRIZE ESSAYS,

reported that but one essay had been received by them, the subject of which was "Tubercles of the Breast." The report gave an analysis of the essay, and stated that in the opinion of the committee it was not of sufficient merit to entitle it to receive the prize of the Society.

The report of the

BOARD OF CENSORS

was read by its Secretary, Dr. H. B. Conrad. It stated that the board had actively carried on the work of causing compliance with the medical law of 1880, and, in addition, had accomplished a much more important work in securing the withdrawal of its charter from the irregular institution known as the United States Medical College. It had been clearly proven that the law of 1848, under the provisions of which it claimed its right to exist as a professional school, never contemplated the establishment of medical colleges at all; and the Society had successfully carried its case in two courts, as well as before the Governor of the State.

It was true that an unworthy Legislature had passed a bill granting the institution a charter, but this had been promptly vetoed by the Governor. Consequently, the place was now closed, and could no longer go on issuing diplomas. The history of this case had distinctly demonstrated that in the State of New York medical colleges did not come under the head of benevolent and charitable institutions. In conclusion, the Board recommended that the law should be amended in such a way as to provide that all those who presented diplomas from institutions out of the State should be required to pass a medical examination before being permitted to practice, instead of merely having their diplomas endorsed by a medical college, as was now the rule.

To the report of the Board of Censors was appended that of the legal counsel of the Society, Edward C. Ripley, Esq. It included the narration of prosecutions and legal opinions given in thirteen unfinished and twenty-two new cases. Most of the prosecutions were conducted in the Court of Special Sessions, and the report stated that in no class of criminal cases was so large a proportion of convictions secured as in those brought by the Censors of this Society. A disgraceful state of affairs was shown to exist in the New York Eclectic Medical College, which, during the year, had actually endorsed the diplomas or licenses of five men while they were under prosecution by the Society; which granted them the right to register at the county clerk's office, and thus become legal practitioners of medicine.

DR. S. O. VANDER POEL, Chairman of the

COMMITTEE ON HYGIENE,

begged leave to report progress, and stated that the full report of the Committee would be submitted at the adjourned annual meeting.

The following

AMENDMENTS TO THE BY-LAWS

which were recommended by the Comitia Minora as desirable for carrying on the practical work of the Society, were then unanimously adopted.

Article I., Chapter XII., shall be amended as follows: "When any physician or surgeon applies for admission into this Society, he or she shall place his or her medical diploma, with the blanks herewith appended, properly filled out and signed, in the hands of the Secretary, who shall lay them before the *Comitia Minora*, whose duty it shall be to examine the same, and, if it approve thereof, shall grant him or her a certificate of membership, subject to the approval of the Society.

Chapter XVII. shall read as follows: "No member of this Society shall assume any sectarian designation indicating that his practice is based on any special doctrine or dogma, or specified method of treatment."

Chaper XVII. shall become Chapter XVIII.

APPROPRIATION TO THE COMITIA MINORA.

The treasurer having stated that during the ensuing year the Society would require not less than $3000, and probably more than that amount, Dr. Sturgis moved that $3500 be appropriated for the Comitia Minora in carrying on the work of the Society during the year. Carried.

The Secretary stated that the Comitia Minora had recommended

AN ASSESSMENT OF TWO DOLLARS

from each member in addition to the annual dues of one dollar, as in the last three years, and moved that the recommendation be adopted. Carried.

The Secretary then read the following

COMMUNICATION FROM THE WESTCHESTER MEDICAL SOCIETY:

To the Secretary of the Medical
Society of the County of New York:

At the annual meeting of the Medical Society of the County of Westchester, in June last, the Board of Censors presented the following resolutions, which were adopted:

Resolved, That the Representatives of this county in the State Legislature, be requested to urge the passage of *an act to prohibit all medical colleges from granting diplomas*, and requiring all candidates for the degree of Doctor of Medicine to appear before a State Board of Medical Examiners, who shall recommend successful candidates to the Regents of the State University for a diploma.

Resolved, That the Secretary send a copy of this resolution to the members of the State Legislature from this county, and to every County Medical Society in the State, and urge them to take the same action.

We think this resolution expresses the universal sentiment of a profession crowded with those who have virtually bought their diplomas. Let us earnestly cooperate to obtain the desired legislation. Please inform me of the action of your Society.

N. F. CURTIS, Secretary.

On motion the communication was referred to the Comitia Minora.

SCARLET FEVER IN HORSES.

DR. JOHN C. PETERS, Chairman of a Committee appointed in April last to investigate the subject of scarlet fever in horses, made a verbal report, in which he stated that although the Committee had had but little time as yet to attend to their work, he was firmly convinced that there was no doubt at all that scarlet fever did exist among horses, that it had so existed from time immemorial, and that it was at present in existence in the city of New York. After alluding to the labors of Dr. Stickler on this subject, he remarked that the diagnosis of the affection was often extremely difficult, and that many veterinary surgeons were not as yet willing to acknwledge that it could exist among horses. Among these was Dr. Liautard, who was a member of this committee. As a rule, however, all the best veterinary authorities granted the existence of the disease; and Dr. Peters quoted from a large standard work by Robertson. In modern times, Dr. Percival, a noted veterinary authority, had been the first to call attention to this subject, in the year 1834, and Dr. Copeland, the author of the great medical dictionary, had taken it up with even greater enthusiasm. He stated that scarlatina was a modern disease, which had originated among horses, and which by them had been communicated to men. As a fact, the first record of the disease in the horse was found in the year 1514; while the first record of it in man was not until 1610. This was fully substantiated.

The question naturally arose, Why there were so few cases of the disease? The explanation probably was that, in all large stables, the green horses were put in quarantine for a time after their arrival, as they invariably suffered from distemper caused by their first exposure to the bad air charged with ammoniacal exhalations. While thus suffering, they were also, no doubt, attacked with scarlet fever, but the latter was masked by the more marked symptoms of the other affection. Few cases were noted consequently, because all the other horses had had the disease in their youth. Dr. Peters was of the opinion that the grooms could carry the disease from the stables into their own homes, and, *vice versa*, convey the scarlet fever poison from their homes to the stables.

The next point to determine was, Could the virus from the horse suffering from scarlet fever be used to protect the human subject from the disease? For some time past Dr. Stickler had been engaged in investigating this subject by experimenting with young colts selected with great care, and Dr. Peters said he believed that he was on the eve of establishing this important point. He hoped, therefore, before he died to see inoculation for protection against scarlatina as common as vaccination now was. In conclusion, he trusted that the Society would continue to give the subject some attention, and, as Dr. Stickler would have to encounter much indifference and opposition, that it would endeavor to hold up his hands in prosecuting this good work.

Dr. Peters then spoke of the sanitary condition of the stables of the city, in which were kept one hundred thousand horses. The condition was very bad, he said, in most of the large stables; but he was happy to say that the stables of the Fourth Avenue car line, in which were kept twelve hundred horses, were now a model of cleanliness and salubrity. They presented a marked contrast to what they had been formerly under another superintendent. He concluded his remarks by saying that he trusted that the board of health would soon treat patients suffering from scarlet fever, diphtheria, measles, and typhoid fever in the same way as those affected with smallpox and typhus fever. This would, of course, require an increased appropriation and a larger force of sanitary inspectors, but he believed that if it did not actually stamp out those diseases in the city, it would, at all events, have the effect of greatly diminishing them.

There being now no other business upon the meeting, **Dr. Sturgis** requested that Dr. Obendorfer should be permitted to make

AN EXPLANATION

of what he meant in charging a member or members of the Society with bribing.

Dr. Obendorfer then receiving the permission of the Chair, stated that his object was not to impeach any of the new members, and if he had been thus understood he wished to heartily apologize. The point which he desired to state, however, and which he would have done before if the opportunity had been allowed him, was that positive proofs were in his possession that a member of the Society of long standing had attempted to bribe a member of the profession who did not belong to the Society, but was eligible to membership, to join it and vote a certain ticket in the election to-night. He would mention no names, but was fully prepared to substantiate this statement to the committee before whom the matter would properly come.

Dr. Sturgis remarked that this was a serious charge and moved that it should be referred to the Comitia Minora with full power to investigate.

The Secretary moved that when the Society adjourned it should be to meet at the College of Physicians and Surgeons, on the fourth Monday of November at 8 P.M. Carried.

On motion, the Society then took a recess until the tellers had finished counting the votes. The voting had occupied more than an hour and a half, and the polls were closed at twenty-five minutes to eleven.

THE RESULT OF THE ELECTION

was not announced until a quarter past twelve.

President.			
S. Oakley Vander Poel,	375	T. Gaillard Thomas, . .	220
Vice-President.			
Andrew H. Smith, . .	380	Charles A. Leale, . . .	215
Secretary.			
Wesley M. Carpenter, .	385	E. A. Judson, ...	210
Assistant Secretary.			
Charles H. Amy, . . .	380	P. Brynberg Porter, . .	215
Treasurer.			
Orlando B. Douglas, .	384	Henry D. Nicoll, . . .	208
Censors.			
F. R. Sturgis, ...	385	Charles McBurney, . .	210
David Webster, . . .	383	Richard H. Derby, . .	208
Daniel Lewis, ...	377	Charles S. Wood, . . .	210
F. R. S. Drake, . . .	373	Charles Hitchcock, . .	213
Joseph W. Howe, . .	378	Thomas H. Burchard, .	215

599 ballots were cast in all, but there were some blanks.

The result was the election of the New Code ticket headed by Dr. S. Oakley Vander Poel.

NEWS ITEMS.

PORTLAND, MAINE.

(From our Special Correspondent.)

Litholapaxy.—The information recently stated in The News relative to the progress of litholapaxy by Bigelow's method, suggests that the apparent infrequency of that operation in this country, as shown by statistics therein quoted, is due to the neglect of operators to report their cases.

The number of operations of this nature performed in Maine thus far is small, but may be of some slight statistical value. Professor Bigelow's method was early adopted by the late Wm. Warren Greene, who reported a series of ten cases in the *Boston Medical and Surgical Journal*. One of these cases should be more properly classed as "an attempt to operate," the condition of the patient not warranting a completion of the operation; the other nine were successful. To this report may be added thirteen other cases, all but two successful, reported locally or not at all by other Maine surgeons.

Doubtless our surgeons who have cases affording valuable information have little or no time to write out reports, but it is certain that the profession in Maine are losers thereby, both in information and reputation.

TAIT'S OPERATION FOR REMOVAL OF OVARIES AND TUBES has been successfully performed in this city four times, but no public record of these cases has ever been made.

THE MAINE GENERAL HOSPITAL.—At the annual meeting of the Corporators, held October 9th, plans and estimates were presented with the report of the Superintendent, providing for certain changes in the arrangement of existing rooms, thereby securing new quarters for servants, an amphitheatre, and an increase in the accommodations for patients of sixteen additional beds. These changes are made necessary by increased demands upon the resources of the hospital, at times beyond its ability to meet from lack of room.

The continued prosperity of this institution is most gratifying to its friends and patrons, and its permanent hold upon the interest and good will of the public and profession of this State is now well assured; it is hoped that arrangements may be perfected which will insure the beginning of these much needed additions early next Spring.

THE MEDICAL SCHOOL OF MAINE.—Before long, it is probable that efforts will be made to secure the removal of the Medical School of Maine from Brunswick to this city.

Clinical advantages are now available which ought to be utilized for the benefit of a greater number of students than now enjoy them. This will be accomplished by the proposed amphitheatre at the hospital and a possible out-service, which advantages cannot fail to aid the school in maintaining its deservedly high reputation.

A REGISTRATION LAW AND STATE BOARD OF HEALTH.—Thus far all efforts of the State Medical Association to secure the enactment by the Legislature of a Registration Law and the organization of a State *Board of Health* have failed. A determined attempt was made last winter to secure the former by one of our County Societies, but with no other result than the creation of a favorable public sentiment.

The desired end was nearly secured, the bill having passed a second reading, but "politics" and quackery killed it. Committees were again appointed at the last meeting of the State Association, to labor with the next Legislature to secure these measures of public benefit: they will very likely be delayed, but sooner or later we will have them.

DR. ALEXANDER RAMSAY.—The name of Dr. Alexander Ramsay may be within the recollection of some of your older readers. The *Transactions of the Maine Medical Association*, for 1883, now in press, will contain a biographical sketch of this talented and eccentric man. Visiting this country early in the present century, he lectured in New York and other cities north and south, and in many New England villages; striving to found in the backwoods of Maine "an institute of practical anatomy" to "corroborate faith by facts."

He was at one time an assistant of Dr. Nathan Smith at Dartmouth.

His work on the Anatomy of the Heart and Brain is now a rare book: he not only prepared his own drawings, but engraved the plates with his own hand.

Having been a pupil in London of the Hunterian School, and with the Munroes at Edinburgh, he placed no mean estimate on his own ability; remarking on one occasion that he "recognized only two superiors as an anatomist, GOD ALMIGHTY and JOHN HUNTER."

The record of his observations on the New York yellow fever epidemic of 1803 was published in the *Edinburgh Medical Journal* in 1812.

His therapeutical ideas were far in advance of his time: he never bled, and railed savagely at the prevailing methods of treatment in fevers.

Among his rules for "decorum" in his New York school in 1807 are these:

"Students to remain uncovered in the presence of the teachers. No conversation in the lecture- or dissecting-rooms or museum.

"No tobacco used in any manner in the school. No nauseous appearance of saliva on the floor."

The latter might well claim a modern application in some of our larger schools.

As an anatomist and instructor, he was renowned among the leading men of Europe, combining wonderful talents of eloquence and education with a terrific temper and the most insufferable egotism. His name appears in Knapp's *American Biography;* his death took place in this State in 1824.

The material for the sketch mentioned was gleaned from his collection of papers, books, and specimens formerly in the possession of one of his pupils, recently deceased.

It will be an interesting contribution to medical biography.

YELLOW FEVER AT BREWTON, ALABAMA.—Acting Assistant Surgeon Stone, who was sent to Brewton by Surgeon-General Hamilton, of the Marine-Hospital Service, to make an investigation of the epidemic at that place, in conjunction with a physician from New Orleans, has reported that the disease is yellow fever. Up to the 19th inst., there had been thirty-four cases and eighteen deaths. This is a very high rate of mortality. The population of the town is between 300 and 500, but the disease has not spread to any extent. The adjoining towns have quarantined against Brewton. Three new cases and one death have since been reported.

THE CAPE CHARLES QUARANTINE STATION, established by the Marine Hospital Service, at the mouth of Chesapeake Bay, was closed for the season on the 15th inst. The location of this station is an excellent one, and should Congress deem it advisable to erect permanent quarantine buildings upon Fisherman's Island, the protection from contagious disease of the cities bordering on the bay would be much simplified.

YELLOW FEVER QUARANTINE AT PENSACOLA.—The cordon sanitaire established around the naval reservation near Pensacola, Fla., was ordered to be discontinued on the 25th inst., no yellow fever having developed inside the cordon since the 7th inst., and the last case being convalescent on the 11th.

YELLOW FEVER.—Sanitary Inspector Daniel M. Burgess reports that there were nineteen deaths from yellow fever at Havana for the week ending October 13, and that he had inspected and fumigated twelve vessels bound to United States ports, as follows: Oct. 7—Am. schr. "A. Kingsland," for Key West; Am. bk. "Havana," for New York; Spanish bk. "Sevilla," for New Orleans. Oct. 8—Am. schr. "Nonpareil," for Key West. Oct. 10—Brit. str. "Celtic Monarch," for

New York; Am. schr. "City of Havana," for Key West; Am. ship "Relief," for Key West. Oct. 11—Am. str. "Santiago," for New York; Am. schr. "Dauntless," for Key West. October 12—Spanish bg. "Lola," for Charleston. Oct. 13—Brit. str. "British Empire," for New York; Am. schr. "In Time," for Key West.

Sanitary Inspector R. J. Mainegra reports that there have been eleven deaths from yellow fever in the hospital at Vera Cruz during the week ending October 4th and that he has inspected the following named vessels bound to United States ports: Oct. 2—Schr. "H. Budding," for Pascagoula; schr. "Marian H. Rand," for Galveston; str. "West Indian," for New Orleans; str. "British Empire," for New York. He also states that there has been no yellow fever among the shipping at Vera Cruz for the past month.

The Cholera.—The Consul General at Shanghai, in a report to the State Department, dated September 11, says: Sporadic cases of cholera still continue to occur in Shanghai, but in diminishing numbers. Among foreigners, five deaths from cholera were registered during August, as against ten in July. None have as yet been registered during September. One hundred and twenty were registered among the natives as due to "Tah Shah" in August, and one hundred and twenty-seven in July. The numbers continue to diminish.

The United States Consul at Malta reports to the State Department, under date of September 29, that certain changes have been made in the length of quarantine, imposed by the government, of vessels coming from quarantined ports (other than Egyptian) in which no cholera or other infectious disease exists, as follows:

In the face of the above announcement, a cablegram of the 18th inst. announced that cholera had broken out in a village in the outskirts of Alexandria, which had heretofore escaped the infection. It is believed that the disease was caused by the infiltration into the canal running through the village of water from the adjacent cemetries, in which cholera victims have been interred.

Yellow Fever at Guaymas.—The U. S. Consul at Guaymas, Mexico, in a letter to the State Department under date of October 4, 1883, states that, "While the symptoms are similar to yellow fever, the disease here in the majority of cases has shown that the patient dies either in delirium or a state of coma. That the vomit is alkaline and not acid, nor is it corruptive (destructive?) of textile fabrics, such as bedding, etc. That the urine flows from the body after death of a bright-yellow color; finally, that the vomit lasts from ten to twenty-six hours. These are the main points of difference as noted by the medical profession here and at Hermosillo, but the disease is equally fatal in severe cases as yellow fever. Had this been the genuine type of yellow fever, the deaths would have been quadrupled. Nevertheless, the Board of Health here have pronounced it yellow fever. I am happy to inform you that the disease here is diminishing, only seven deaths in the last three days. In Hermosillo the disease is not so fatal as it was in Guaymas, though there are many sick the ratio of death is less." The Consul adds that he hopes to obtain a complete list of deaths in a few days which he will forward to the Department.

Yellow Fever in Havana.—There were eighteen deaths from yellow fever in Havana last week.

Arrivals from the ports of the Kingdom of Greece, on which twenty-one days quarantine is imposed on arrival from Egypt, will be admitted to free pratique. The "sfralto" against passengers from Egypt is maintained for the present. The quarantine against arrivals from Egypt is maintained at twenty-one days, to commence after the disinfection of the vessel at Malta.

Cholera in Egypt.—The Egyptian Minister of the Interior, a fortnight ago, officially published a statement, denying the existence of epidemic cholera in Egypt, and declaring it to be contrary to the opinion of all competent authorities.

Another announcement appearing in the same *Gazette* is a regrettable instance of stubbornness on the part of the Ministry, who must be presumed to be responsible. The Egyptian Star has been conferred on the members of the Board of Health whose failure and gross incompetency, universally admitted, render it almost an insult to the other wearers of the new decoration.

The German Sanitary Commission sent to Egypt some time ago to study the causes, etc., of cholera, having now exhausted their inquiries in that country, have received permission from the Imperial Government to extend their researches to India, the home and cradle of the terrible disease, and they will accordingly soon embark at Suez for Bombay. The Commission, it seems, discovered a new and peculiar micro-organism which may have something to do with the propagation of cholera, and the further studies of the *savants* in India will enable them to see whether their suppositions are correct.

Yellow Fever in Mexico.—Advices from Altata, Mexico, report that the population of that town has been decimated by yellow fever. The number of deaths for two weeks averaged twenty a day.

Smallpox in New Orleans.—For the week ending October 13 there were three cases of death from smallpox in New Orleans.

Typhoid Fever in Quebec.—In three days of the past week, thirty cases of typhoid fever have been received at the general hospital in Montreal, Quebec. Nearly all have been due to bad sanitary conditions in the patients' homes.

A Gift to a Boston Hospital.—The wife of Lieutenant-Governor Oliver Ames has given $35,000 to the Free Hospital for Women, situated on Springfield Street, Boston.

Surgeon-General Wales' Term.—The question as to when the term of office of the Surgeon-General P. S. Wales, as Chief of the Bureau of Medicine and Surgery will expire has been settled. Surgeon-General Wales was appointed August 16, 1879, but his commission was not issued until January 26, 1880. The appointment was for a term of four years. It has been decided by the Secretary of the Navy that Dr. Wales' term began with the date of his commission and that, therefore, he has still about three months to serve. A press despatch states that it is expected that Surgeon-General Wales will be reappointed, although Medical Director Gunnell is being strongly pushed for the office.

Dr. J. C. Hutchison, of Brooklyn, who sustained an extra-capsular fracture of the femur, on the 31st of August, by being thrown from his carriage at Lake George, his many friends will be gratified to learn, is improving satisfactorily, and will probably recover the use of his limb without limp or deformity. This week, for the first time since his mishap, he has been able to walk about the grounds of his residence.

Important Decision of the Supreme Court on Imitations.—Last year, the Supreme Court of Rhode Island, by final decree, enjoined certain parties from offering for sale "Acid Phosphate," so called, in any package which shall be a substantial or colorable imitation of Horsford's Acid Phosphate. On September 24, 1883, the Court decided that William H. Hughes and Theodore S. Hughes had violated said injunction by selling the "Hughes' Acid Phosphate," so called, and that a writ of attachment must issue against them, whereupon they were fined $300 each.

The New School of Medicine in Paris.—The new School of Medicine, which is being built in Paris, consists of two separate edifices, divided by the street called the École de Médecine, the first of which belonging to the Faculty of Medicine, is to be used for the general purposes of the Faculty, and includes the library, general offices, and museum of normal anatomy; while the second, belonging to the Practical School, will contain the laboratories of the professors and all the services relating to anatomy, such as the dissecting-room, lecture-room, collections, etc., as well as a museum of pathological anatomy. The Dupuytren Museum, which was placed in what was once the refectory of the monks, to whom the monastery, which had been converted into a school of medicine, belonged, is to be rearranged, and will have a façade upon the new street, when it is completed. The total length of the frontage of the new schools upon the principal street is upwards of 400 feet, and they will cost, when finished, about £280,000.—*Lancet*, September 29, 1883.

Professor Chevreul.—*L'Union Médicale*, writing of this distinguished *savant* on Sept. 4th, observes: "M. Chevreul, Member of the Académie des Sciences, and Director of the Muséum d'Histoire Naturelle, enters to-day on his ninety-eighth year. In spite of his great age, he assumes the modest title of *doyen des étudiants*, in which he glories; but we may term him far more justly the *doyen des maîtres*, for sixty years of the exceptional labors and services which he has rendered constitute one of the highest renowns of France. Born at Angers in 1786, he entered the École Centrale of that town in his seventeenth year, having Béclard as a fellow-student. In 1811, after some remarkable investigations, he was nominated *aide-naturaliste* at the Muséum, and in the course of some years he became Examiner at the Ecole Polytechnique, Professor of Mathematics at the Lycée Charlemagne, and the Director of the Dye Works and Professor of Chemistry at the Gobelins. In 1826, he succeeded M. Proust in the Section of Chemistry in the Académie des Sciences, and his great reputation became confirmed by his work on fatty bodies of animal origin. This important work procured for him the Argenteuil Prize of 12,000 fr. He then became the Director of the Muséum, in which post he has rendered great services; and in 1875 he received the Grand Cross of the Legion of Honor. One of the most active members of the Institute and of the Society of Agriculture, M. Chevreul still delivers his lectures at the Jardin des Plantes, and directs a portion of the works at the Gobelins."—*Med. Times and Gazette*, Sept. 22, 1883.

The International Sanitary Congress.—All the governments of Europe, with the exception of the French, which is waiting the completion of Dr. Fauvel's report on the recent epidemic, have accepted the invitation to take part in an International Sanitary Congress which is to meet in Rome next month. One of the objects of the Congress is to organize an international service in Egypt, with the view of protecting Europe against the intrusion of Asiatic cholera.

Health in Michigan.—Reports to the State Board of Health, for the week ending October 13, 1883, indicate that erysipelas, typho-malarial fever, consumption, and pneumonia have increased, and that diphtheria and scarlet fever have decreased in area of prevalence.

Including reports by regular observers and others, diphtheria was reported present during the week ending October 13, and since, at seventeen places.

Seventeen cases of typhoid fever were reported in a school at Adrian, October 12.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM OCTOBER 15 TO OCTOBER 22, 1883.

Bache, Dallas, *Major and Surgeon.*—Assigned to duty at Willet's Point, New York.—*Par. 1, S. O. 238, A. G. O.*, October 18, 1883.

Taylor, Morse K., *Major and Surgeon.*—Assigned to duty at Fort Sill, I. T.—*Par. 4, S. O. 210, Department of the Missouri*, October 13, 1883.

Heizmann, Charles L., *Captain and Assistant Surgeon.*—Granted leave of absence for six months, with permission to go beyond sea.—*Par. 3, S. O. 235, A. G. O.*, October 15, 1883.

The Medical News *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the News *should be addressed to No. 1004 Walnut Street, Philadelphia.*

ORIGINAL LECTURES.

SOME PERSONAL EXPERIENCES OF SURGERY IN TIME OF WAR.

A Lecture delivered, by invitation, at the Bellevue Hospital Medical College, N. Y., October 23, 1883.

By SIR WILLIAM MacCORMAC,
SURGEON TO ST. THOMAS'S HOSPITAL, LONDON.

(Reported by Edward Develin, M.D.)

Gentlemen: When a short time ago your professor, Dr. Dennis, invited me to address a few remarks to his class, I asked him to excuse me, as I was not prepared with any subject-matter which could interest you. He got over that difficulty by choosing a subject for me. The responsibility, therefore, for my being here, and for anything which I may say to you, rests with him and not with me. The subject Dr. Dennis selected is the very large one of Gunshot Wounds. It would take many lectures to discuss so important a topic. He tells me, however, you would like to hear something about these injuries, and more especially my own personal experience.

Now, as a civilian surgeon, my experience of surgery in time of war is, of necessity, limited, and I cannot but think that it is much like "Carrying coals to Newcastle," as we say in England, to talk of gunshot wounds in a country where, perhaps, the largest experience of this kind exists. Your great civil war brought this knowledge to your surgeons, and the teachings of the war are embodied in the splendid volumes issued by the Surgeon-General—a record, which for magnificence, I may say, for completeness of illustration and of detail, possesses no equal in any country in the world. Only the other day I had an opportunity, under the guidance of your distinguished countryman, Dr. Billings, of examining some of the treasures of your Army Medical Museum, in Washington. The number of valuable specimens there contained is enough to stock half-a-dozen museums. Every form of gunshot injury, in every possible variety, is there, and it seems a presumption on my part to venture to talk on this subject at all.

Possibly, however, it may interest you a little if I tell you the story of the experience I have had of surgery in time of war, and I may tell it the more appropriately to an audience such as you are, because it is some account of the doings of the Anglo-American Ambulance during the war between France and Germany, about twelve years ago. I only repeat what others have said over and over again, that the best volunteer aid rendered during that disastrous struggle was rendered by the corps of this ambulance.

That distinguished surgeon, whose reputation is world-wide, and who is loved by all who know him, Dr. Marion Sims, was selected as our chief, and the rest of the staff, some sixteen in number, was composed equally of American and English surgeons. One bright afternoon in the end of August, we left Paris with our wagons and equipment to join the headquarters of Marshal McMahon; and with some trouble and adventure we reached, at last, Sedan, with the intention of pushing on further the next day. Sedan is an old fortified town on the river Meuse, near the Belgian frontier; the fortifications were erected after the fashion of the day, by the great French engineer Vauban; and when we reached the place, which was only a few miles from the scene of the contending armies, the only soldiers, or representatives of soldiers, in or about the town were a few peasants in blouses, keeping guard upon the ramparts and at the gates, armed only with old flint-locks; no regular troops anywhere—not a soldier in uniform. An old army doctor was the only medical man in the whole town, and he besought us to remain, telling us we should find plenty to do. But our orders were to push on, and we determined to try to get further forward, and to reach the front.

Instead of our doing so, the French army rapidly retreated, entered the town, and we found ourselves, without any effort on our part, in the very centre of the scene of the most eventful battle of the war, and assisting at what was to change, at a move, the map of Europe; for next morning, at early dawn, began the battle of Sedan, which was followed by the capture by the German forces of an army of two hundred thousand men, with an Emperor thrown in.

I shall never forget an incident which occurred on the night before, as we lay bivouacked at the railway station, waiting vainly for some train to carry us forward. In the middle of the night an engine, with a cattle truck attached, steamed into the station, and out of it stepped the man who was still Emperor of the French, accompanied only by two or three aides-de-camp. They walked silently to the nearest gate of the town, about three hundred yards away. I followed them. They battered at the gate and called upon the sentry to open. He was afraid, and would not. "Mais ouvrez donc, c'est l'Empereur," cried the aide-de-camp at the top of his voice in the dead silence of the night. The sentinel did not believe the story, and did not open, and at that gate the then ruler of the French was kept waiting for an hour before he could gain admission; it was a scene to awaken many a reflection. There was clearly no reason now for us to go elsewhere, and we also entered the town and installed ourselves in the empty barracks placed at our disposal, a building placed high upon the ramparts and well adapted for the purpose.

Next morning, and all day, the battle was being fought, and very soon the wounded came in to us in large numbers. For several days and nights we had operations going on continuously; all the first day we were under the direct fire of the German artillery. The shells were whizzing past us, and occasionally the splinters struck the building, but it was clear we were not being fired at, else we should have been "knocked into a cocked hat" in no time. Indeed, I met, a few years after, in Berlin, the German officer who commanded the batteries facing the hospital, and he told me he could see our red-cross flag flying, and tried to avoid injuring the building, supposing it to be a hospital. This officer is a son of the distinguished Surgeon von Langenbeck, who lost his other son in the charge of the Prussian Guards, at Gravelotte, where such heavy slaughter took place. We had four hundred beds, and these were soon filled; the corridors were filled with poor fellows badly injured, and they were also sitting on the staircases. In the town, every house was filled; the churches were filled; in all the country houses round about, the wretched wounded soldiers were to be found. There was ten times more, a hundred times more to be done, than our united efforts could accomplish. All that it was possible to accomplish under such circumstances, we endeavored, to the best of our ability, to realize. Amputations, of course, we had to perform in large numbers; some few ligaturing of vessels, chiefly for secondary hemorrhage, and later on a considerable number of resections of the larger joints. It was in the days before the antiseptic method had revolutionized surgical treatment, and a most disheartening number of our operative cases and of more simple wounds, died from blood-poisoning. In the cases of ligature for hemorrhage, the bleeding too often recurred, and the resections in many instances, either ended in amputation or death.

Most of the resections of joints were in the so-termed secondary period. I agree with Langenbeck in thinking primary resections, though performed immediately after the injury, are unsatisfactory. The power of regeneration, the probability of procuring a useful limb or joint, are much less. In the secondary stage, the periosteum has become thick and vascular; it can be more readily detached from the bone, and its powers of ossific reproduction are enormously increased. Immediately after any injury, it is very difficult to detach and preserve it to any extent; it possesses very little power of forming new bone. Besides, there is in the secondary period a better delimitation of the injury; its extent is better known; some of the fragments have necrosed, others show vitality. Cases only fit for amputation have already been disposed of. In resections for gunshot injury of joints, we may lay down for certain the necessity for preserving the periosteum as a condition of success, and we may also affirm that these operations should not follow the formal rules for excision of joints, for in most instances we can save portions of the joint, and, whenever it is practicable, partial excisions are to be performed; they are less dangerous to life, and the functional results are better. I know of several cases in which very complete reproduction of the lost parts has followed, even where large portions of bone were removed.

The ankle-joint and the elbow-joint are the articulations most suitable for surgery of this kind, and after them the shoulder and the wrist. The hip and knee have been seldom successfully excised for gunshot wound. For these, conservative treatment is the only applicable method, viewing the great mortality after operative interference in these two articulations. Indeed, for the cases of penetrating wound of the knee-joint, Bergmann and Reyher have demonstrated, by their experience during the Turco-Russian War, that the method of antiseptic occlusion, healing under an antiseptic scab, with complete immobilization in plaster of Paris, is by far the most successful method of dealing with gunshot wound perforating this articulation. These results, published in Volkmann's Vorträge, are most surprising. If I remember rightly, nineteen out of twenty-one cases recovered not only with preservation of life and limb, but actually with free, and in some cases perfect, movement of the joint.

One case I should like to relate to you of recovery after severe injury, with a useful limb, from my own experience, a case which is, I think, almost unique.

Louis H. Aubin, a chasseur d'Afrique, was wounded by a shell explosion, which laid open both his shoulder- and elbow-joints. The veteran Hanoverian surgeon, Stromeyer, who probably saw more war surgery than any man of his time, told me he is prouder of the invention of his cushion than of any thing else he had done. The risk of any tight constriction in arm is very great. This cushion gives support without constriction, and permits a certain amount of mobility which is so desirable.

In this case, the advantages of the Stromeyer cushion were apparent, and it possesses equal advantages for all fractures of the arm; indeed, in forearm as well as after excision of shoulder- or elbow-joints. In the ankle not less surprising results have been obtained after excision. I may mention one I remember, a case of Langenbeck. A German officer of noble rank was shot through the ankle, and his tibia shattered and ankle-joint laid open. Langenbeck removed the bones forming the ankle-joint, the upper surfaces of the astragalus, three inches of the tibia, and a considerable part of the fibula; yet the reproduction of bone was so complete that the shape of the ankle was not in any degree lost, the malleoli were perfectly reformed, and the power of walking so good that some time afterwards this officer ascended the Monte Rosa, one of the highest peaks in the Swiss Alps, a feat which most persons who never received any injury to the ankle would find themselves unable to perform.

The after-treatment of injury to the ankle is of great importance. The foot must be supported in such a way that it shall remain at right angles to the leg, and neither become abducted nor adducted, everted nor inverted. A case otherwise successful may terminate in the patient possessing a useless foot if these points be not carefully seen after, and to realize this result the closest attention is required.

One thing I hope I have learned from my experience of gunshot injuries, and I should like to teach it to you. It is to do as little probing as possible; the first instinct of the patient is to inquire what has become of the ball, and surgical enthusiasm too often induces the surgeon to hunt after it. He probes the wound, introducing his finger into it, seeks with one forcep after another to pull out the missile, very often tugging at some piece of the unfortunate man's skeleton instead, and most certainly introducing much septic matter into his body, thus laying the true foundation of a dangerous septic suppuration. A joint that might otherwise have been preserved has, indeed, been often sacrificed. A gunshot fracture thus may be robbed of all chance of recovery, and loss of limb, or loss of life, has been the frequent result. A bullet in the body is, as a rule, I feel convinced, a harmless object when we contrast the mere fact of its presence with the incalculable damage which may be done by over-zealous attempts at seeking for it.

In the Army Medical Museum are many specimens which illustrate what I would like to enforce. A soldier was wounded in the knee and elbow; he thought a bullet was in the knee, but the surgeon who attended him, I cannot but think most fortunately, was of the contrary opinion. The man recovered, and was able to use the limb as before. On his death, years after, a ball was found imbedded immediately beneath the articular surface of the condyle, which it had entered after ripping up the front of the tibia, and, therefore, of course, penetrating the joint. In this position it had been imbedded without causing any irritation whatsoever. It may be said that this is a rare event, and so it is, but it teaches a lesson of wide application, and the application of this lesson has been subsequently made with most brilliant results in the case of this very joint, as I have already mentioned, by Professors Bergmann and Reyher.

The veteran surgeon Stromeyer, whose friendship I had the honor to enjoy, pointed another illustration of this fact in his method of treatment of gunshot fracture of the femur. He got better results than anyone else by avoiding all meddlesome interference, and especially by treating the fracture where the man fell or as near to it as might be. Cases recovered and did well in his hands, while similar ones were amputated and died in those of others. *Nur nicht schaden* is the text from which Esmarch preaches when speaking of gunshot injuries, and I think there can be little doubt of its importance.

Gunshot Fractures in General.—I would like for a moment to advert to those most interesting papers recently published by my distinguished friend Dr. Marion Sims. He urges that we should not any longer permit persons with gunshot injury of the abdomen to be simply allowed to die, as has hitherto been the case, without making some effort to save them. He advises that the abdomen should be opened, the injured portion of intestine sought for, the wounded part cut out, the cavity then disinfected, and the external wound closed.

I hope that in some future case this may be attempted —why should it not? The abdominal cavity can be opened with comparatively little risk. Exploratory operations of this kind are done every day. Portions both of the small and the large intestine, large portions even, have been successfully excised, and the cut ends of the bowel sutured together. The pyloric end of the stomach has been excised, almost every abdominal viscus except the liver has been successfully removed. Tumors of the intestine and in the intestine have been successfully dealt with. Dr. Sims' proposal will doubtless one day be also successfully carried out. There are great difficulties certainly, the two principal being extravasation of blood and of fecal contents into the peritoneal cavity, and the possible perforation of several coils of intestine; but extravasation is by no means certain to occur in the comparatively small wound which a rifle-bullet causes. I remember I once sutured a ruptured bladder successfully after escape of urine into the abdomen had taken place, and I cannot help thinking cases of intestinal wound may arise which can also be successfully dealt with.

I have adverted to the fact that the military surgery of the Franco-German war was not practised with the advantages which antiseptic surgery affords. The mortality was very great. In my own hospital, pyæmia and erysipelas were scourges which blasted our best efforts. Since then, the greatest and most unceasing attention has been devoted to perfecting antiseptic methods for use in time of war. They were employed to a considerable extent in the Turco-Russian war, in which I had a vicarious interest in the person of many of my pupils who were present at the great battles of that war; and lately, during the short campaign in Egypt, our own military surgeons treated the wounded with complete antiseptic precautions. The expedition sent out to Egypt was supplied with the fullest and most complete equipment procurable of this kind. What were the results? I speak from memory as to number of wounded: they were, I think, 426, and amongst them many serious injuries and cases needing amputation. Yet this I know, on the most indisputable authority, that throughout this campaign not one single case of pyæmia, of erysipelas, or of any other infectious disease occurred. Not a single instance, in short, of blood-poisoning of any description took place after any gunshot wound during this war. Such a result is quite unprecedented in the history of military surgery in any part of the world.

I need not weary you with any account of the many varieties of antiseptic material recommended for use in time of war.

I believe there is an important future for iodoform. It is efficient, easy of application, and very portable. In cases where the occlusive method of treatment is desirable, in cases of wound of the thoracic cavity, in penetrating wounds of joints, iodoform may prove of especial value.

Gentlemen: What is Surgery? The work of a master hand. The surgeon of olden days was a mere *χειρουργός*. He was a tool which others used. But the surgeon of to-day is something far different, and the work he does is not only of his hand, but of his head, and of his heart, too. Surgery is a fight with death, in which the surgeon is often worsted; but never before in the history of surgery have greater advances been made, or greater victories been won. Never have the arms of the surgeon, literally as well as metaphorically, been so well appointed as they are now. People are apt to speak of conservative surgery as if it were something apart. All surgery is conservative in the truest and best sense. A surgeon who is not conservative is no surgeon at all. He who cuts off a mangled limb, or removes a malignant tumor, does so to save the patient's life. The term is misleading, and should be abandoned. Surgery is a vast field, and our best and most cultured intelligence is not too great to devote to the noble object of alleviating suffering, and directing to safe issue the casualties that may beset us in so many and various forms.

The surgical student should receive the best preliminary training the schools and colleges are able to impart. The future progress of surgery will best be promoted by increased breadth of culture, and increased general knowledge.

The field is vast, but the human mind seems capable of ever-increasing development. New triumphs of skill, a deeper insight into the causes of premature human destruction, yet more effective means of dealing with the many forms of suffering which it is our task to abate, await, without a question, the surgeon of the future, as they have more or less attended the surgeon of the present, and of his brother of former days. Presently, this duty will fall upon you. You can have none nobler or more worthy. May you all endeavor, to the best of your ability, to prove yourselves competent for the task.

One word more and I have done. I wish to say how much I appreciate the compliment of being asked to address you, however imperfectly I may have fulfilled my part of the undertaking, and to say also my best thanks for the patience with which you have listened to me. I am now on the point of returning to my own country, and I return, carrying with me the happiest recollections. I am not vain enough to suppose that the many compliments which have been paid to me, the lavish hospitality and great kindnesses I have received, are attributable to any personal merit of my own. I regard them as expressions on the part of a highly cultured portion of the American people of their love for the old country—for home, as in very many places I have heard it called. During eight weeks of almost constant travel I have heard but one feeling expressed, and I should like on this occasion, the most public opportunity I have had, to say how much this friendly feeling is reciprocated by those at home. I hope and believe that this sentiment will constantly grow stronger. There may be, there are, doubtless, disturbing elements. The growth of such a young giant as is America cannot be quite so even as that of an ordinary child, yet my firm conviction remains that the people of America and of England are in true and cordial sympathy with each other.

LOCOMOTOR ATAXIA.

A Course of Three Lectures delivered before the Cincinnati Medical Society.

By PHILIP ZENNER, A.M., M.D.,
OF CINCINNATI, OHIO.

LECTURE III.

TREATMENT.

Gentlemen: Last year the subject of nerve-stretching in locomotor ataxia was very fully discussed before the Berlin Medical Society. That discussion, which, apparently, forever settled the question of the value of nerve-stretching in this disease, brought prominently forward another important fact, that improvement of the symptoms in locomotor ataxia for a shorter or longer time is no infrequent occurrence. This fact, which had been long known, had not hitherto been sufficiently recognized by the profession. It should never be overlooked when trying to judge of the value of therapeutic measures in the individual case. Of equal importance, lest one be misled by apparent therapeutic results, is the establishing of a correct diagnosis. I can scarcely illustrate this statement better than by the mentioning of a case. A few months ago I was requested by a physician to examine a case of so-called cured locomotor ataxia, where a special value had been attributed to a given remedy. A careful examination revealed that the patient had had an attack of acute ataxia, such as occurs sometimes after infective diseases, diphtheria, etc., or without apparent cause, whose pathology is unknown, and which usually runs its course within a short time, generally terminating in recovery. How easily in such cases one might be deceived as to the value of remedial agents!

There has always been much scepticism as to the value of treatment in this disease. Leyden, in the latest systematic article on this subject, published in Eulenburg's *Real-Encyklopädie*, has unhesitatingly declared that locomotor ataxia cannot be cured; that it cannot even be held definitely in check. This sweeping statement I believe to be too strong, to be disproved by ascertained facts. Nevertheless, we learn from what was above stated that we can be very easily deceived as to the effects of remedial agents, and it is doubtless true that, as yet, the value of none of them has been positively determined.

Before speaking of the various therapeutic measures, of which I will only mention those having the greatest claims to the confidence of the profession, let us inquire, from a purely pathological standpoint, in how far we may speak of the curability of the disease, and of the manner of improvement. If we knew something of its proximate cause, why it originally attacks Burdach's columns, why the primary degeneration later occurs in the same columns in higher portions of the cord, we would be better able to state the probability of checking the disease in its beginning, or in its later stages. But, as it is, some clinical observations and pathological studies will at least enable us to say something of the possibility of a cure and the manner of improvement. Not very infrequently cases have been reported where all the symptoms of locomotor ataxia have been manifested and have later disappeared. Are we to believe that degenerated portions of the cord have been reproduced? I believe not, for experimental researches appear to show that destroyed portions of the cord are not, or at least very rarely, restored. Doubtless symptoms are often produced or increased by transient causes, local congestion, hyperæmia, or the like, and with the disappearance of the latter the symptoms improve or disappear. It is a common occurrence that patients entering a hospital, after lying in bed for a few weeks, improve very markedly, an improvement which can only be attributed to the cause just mentioned. But how is it if the symptoms are caused by destruction of nervous elements in the cord? Erb, in his work on diseases of the spinal cord, reported two cases of locomotor ataxia as about cured. One of these, in whom the usual symptoms, anæsthesia, ataxia, etc., had been manifested, and later disappeared, excepting a slight bladder trouble, after an apparent recovery of about eight years suddenly died of acute poisoning. An examination of the cord made at this time revealed the degenerative changes in Burdach's columns characteristic of this disease. So, in this case, the symptoms had disappeared, while the pathological changes, which probably produced them, remained. Here we must attribute the improvement to vicarious functions, certain nerve-fibres in the cord assuming the functions of those which had been destroyed.

In this sense, then, we may speak of the curability of the disease; that at times transient conditions, hyperæmia, etc., are removed, and the symptoms caused by them disappear; at other times the functions of destroyed portions of the cord are assumed by other nerve-fibres, and, therefore, again the symptoms disappear.

With these ideas of cure or improvement, let us proceed to the consideration of the various methods of treatment. First, a few words as regards general treatment. As exposure to cold may cause or aggravate the disease, the patient should be guarded against deleterious influences of this kind. If he be poorly nourished, cod-liver oil, good diet, etc., are indicated. As the disease often occurs in those of a nervous temperament, rest of body and mind is often called for. We should attempt to relieve him from mental worry or anxiety, forbid mental overwork, and often rest of body will be very beneficial. We have already mentioned that complete rest in bed is often followed by great improvement; but this cannot be always demanded. Exercise is often beneficial. But great muscular exertion should always be discouraged, and, at times, perhaps when the changes in the cord are more active than usual, complete rest will prove very serviceable.

The various symptoms may each demand special treatment, but we will here only refer to one of them, the severe pains. External applications, electricity, etc., may act beneficially; but, after all, our main reliance is opium. And we must here be especially guarded lest our patient contract the opium habit. Remembering that the pains are often not of very long duration, that they sometimes get milder, and even disappear in the later stages of the disease, we must use this powerful remedy as cautiously as possible during the periods of severest pains, and may thereby guard the patient from contracting a habit which would be even a greater calamity than the disease itself.

Of the therapeutic measures intended directly for their curative influence, I will first mention nitrate of silver. This remedy, first recommended by Wunderlich, has since been favorably spoken of by many physicians. A few cures have been reported, but far more frequently merely improvement. The medicine is usually administered in small doses, so that a grain or more is taken daily, and is continued for a number of weeks or months. Eulenburg has recently given this whole subject a careful examination, and asks why it is that, in a few cases, this remedy has acted so admirably, while in the great majority of cases it is entirely useless. He believes the answer to be found in the fact that the nitrate of silver is generally decomposed by the organic constituents with which it is administered, or with which it comes in contact in the alimentary tract or in the walls of the intestines. To overcome this difficulty, he has resorted to hypodermic injections. He uses a solution of albuminate of silver, or a solution of chloride of silver and sulphide of sodium. He states that these solutions are locally non-irritant; and that they are absorbed is proved by their later appearance in the urine. Whether this contribution will add to our success in treating this disease is yet to be determined.

A much-favored therapeutic measure is hydrotherapy, chiefly in the form of hot or cold baths. Baths of a temperature between 70° and 90° are usually given. The cold baths appear to have more frequently proved beneficial; the hot are supposed to be indicated where there are very severe pains, but if not very cautiously used may do harm, as happened to a patient of my own this summer, who tried baths of a higher temperature and more frequently than I had counselled him to use.

We do not know exactly in what way baths prove of benefit. They increase tissue-metamorphosis, and thereby improve the general health. They also appear to harden the system, so that it can better resist deleterious influences, exposure to cold, etc. We can perhaps thus account partly for their beneficial influence. But they also cause an increase of the arterial tension, and perhaps cause local changes of circulation in internal organs, and, it may be, in this way exert their principal curative influence in this disease.

The use of baths is largely experimental. We cannot tell before trying them whether they will prove of value, or what temperature will be best. Generally, baths are taken every day, or every second day, and are of ten or fifteen minutes' duration. If beneficial, they may be continued for a number of weeks or months.

Baths are not the only form in which we can apply hydrotherapy. Hot or cold applications may be made directly to the spine in coils of rubber tubing made for the purpose, or sponge baths may be taken with much benefit.

The method of treatment which has gained the greatest confidence of the profession is the application of electricity. The constant current is most commonly applied. Meyer speaks very highly of applying the positive pole to painful points along the spine. But painful points are not often found, and the most common method is the application of both poles to the spine—one above, the other below—and either leaving them stationary, or moving one slowly up and down. The current may also be applied to the peripheral nerves. The duration of a sitting should usually be short, about five minutes, and only a moderate strength of current used. The current should be applied daily, and for a number of weeks or months. Like hydrotherapy, this treatment is experimental; we cannot tell before trying it whether it will prove beneficial or not.

Rumpf has recently spoken very highly of the value of the electric brush. Influenced by the knowledge that the application of the same had restored lost tactile sensation in hysteria and other conditions, and had even improved motor symptoms, he tried it in this disease, and obtained results even exceeding his expectations. Several cases, with the usual symptoms of locomotor ataxia, appear to have been almost cured, though the lapse of time is too short to say whether this improvement is more than temporary. He applies one electrode to an indifferent part of the body, as the sternum, while the brush is applied over the spine and limbs. The duration of a sitting is ten minutes; the strength of current moderate.

He believes this will prove most serviceable where the sensory symptoms, pain, anæsthesia, etc., predominate. Yet, inasmuch as experiments of his own and others have demonstrated that applications to the surface may cause local changes of circulation in internal organs, it may be that this measure exerts a direct curative influence on this disease.

I have tried this method of treatment in two cases. One, living in a distant city, passed from under my observation too early to observe any effect. In the other there was at least some improvement.

These various methods of treatment may be tried at the same or at different periods of time. A course of hydrotherapy in summer, and of electrical applications in winter, and nitrate of silver or other internal remedies administered at the same time, might be advisable. As the disease is a chronic one, so must the treatment be long continued. The same plan, if apparently beneficial, may be tried for several years. But in old cases, where treatment has proved unavailable, the conscientious physician will advise the patient to abstain from further therapeutical measures, and thereby, at least, spare him useless expense.

Before closing with the subject of treatment, we must approach a question which has been largely discussed in the medical world, that is, whether locomotor ataxia is usually of syphilitic origin. This idea, first brought prominently forward by Vulpian and Fournier, has since found adherents in most parts of the world. It is based upon the observation that in many of those suffering with locomotor ataxia a previous syphilitic history could be obtained. Fournier, in his latest publication, states that he has succeeded in obtaining a history of syphilis in more than ninety-one per cent. of his cases. Erb, in his most recent publication, announces that he has succeeded in obtaining a previous specific history in 91 of 100 cases of locomotor ataxia. To prove the direct relationship of the two diseases, he contrasts the above table with another of 1200 consecutive cases, adults, who did not have locomotor ataxia, and did not come to him directly for syphilis. Of these 1200, only 22.75 per cent. gave a previous specific history. Erb concludes from his observations that not only is there a direct relationship of these two diseases, but also that one, not previously infected with syphilis, scarcely has a chance of becoming afflicted with locomotor ataxia.

It is a further question whether the specific disease directly attacks the cord, or whether, through the constitutional taint, the cord merely becomes more susceptible to disease. The former opinion is generally held, and, in partial confirmation of it, it is mentioned that other diseases, as diphtheria, may cause diseases of the posterior columns, and even some poisons, as ergot, directly attack the same limited parts.

I do not wish to enter into a discussion of the question of the syphilitic origin of this disease, nor to give all the arguments, the various statistical tables, and other considerations on the one side, the contradictory statistics, the pathological changes, the non-success of anti-syphilitic treatment, the occurrence of locomotor ataxia chiefly in men, etc., on the other. For I believe a conscientious study of all that has been brought to bear on the subject can lead us but to this conclusion, that the statement, locomotor ataxia is usually of syphilitic origin, has not yet been proven; that this statement cannot be positively denied. I make this statement thus broadly, because I believe this state of doubt should be fully recognized, as it imposes certain duties upon us.

According to observations hitherto the spinal disease generally begins from five to ten years after the primary syphilitic infection. The syphilitic manifestations appear generally to have been mild, and to have been very slightly treated. The duties apparently imposed on us by these observations are, first, that every case of syphilis should be carefully treated, and for a long duration of time, however mild its manifestations. This is doubtless true whether or not the above relationship of disease exist; secondly, whenever one, formerly infected with syphilis, presents the earlier manifestations of locomotor ataxia, lightning pains, ocular paralyses, etc., he should be put upon a careful and persistent anti-syphilitic treatment.

There is even some encouragement to hope that in the fully developed disease the same treatment may prove beneficial. A number of such cases have been reported, and Rumpf, in the article already mentioned, states that in some cases where there was a previous history of syphilis, he has succeeded, by the combined action of the electric brush and anti-syphilitic remedies, in obtaining flattering results.

But it will probably always appear that far less is to be obtained from such treatment after the disease is once developed than at earlier periods. The future will doubtless prove that in this disease, as in many others, prophylaxis rather than treatment is the highest duty of the physician.

ORIGINAL ARTICLES.

THE TREATMENT OF PSORIASIS.

BY ARTHUR VAN HARLINGEN, M.D.

(*Read before the Philadelphia County Medical Society, October 17, 1883.*)

PSORIASIS is one of the commoner skin diseases met with in this country. The statistics of the American Dermatological Association show that it occurs in the proportion of about six per cent. in all diseases of the skin encountered. Daily experience would seem to indicate a still more frequent occurrence, because the affection is a disfiguring and annoying one, and therefore patients are more inclined to seek relief, and also because it is a stubborn disease and greatly prone to relapse. The history of a single case will often extend over many years, and bring it under the observation of a number of different physicians.

It is because of the comparative frequency with which psoriasis is met and its stubbornness to treatment that I have selected it as the subject of my remarks this evening. Having had a good deal of experience in the treatment of the commoner forms of the disease, it is my intention to confine myself chiefly to the consideration of such remedies as have come under my own observation and use, only touching incidentally on others.

The object of treatment in psoriasis is the removal of the eruption as it exists upon the skin. We cannot hope with any degree of certainty in any given case to prevent a recurrence of the disease, or, if you please, a relapse. For the drug has not yet been discovered which will surely take away all tendency to the recurrence of psoriasis, and whoever promises a cure, in the wider sense of the word, to his patient, will, in a very great number of cases, find that he has been too sanguine. Fortunately, however, a certain number of patients do seem to recover. I do not know what has been the experience of others in this respect, but I have patients who have been under observation three, five, even eight and ten years without relapse. Such cases are, unfortunately, few.

Preëminent among the internal remedies which are useful in the treatment of psoriasis, is arsenic, which may justly be called a specific in this disease. I think I am not asserting too much when I say that eight out of ten cases of psoriasis of average character and severity will do better under the use of arsenic than with any other remedy. I prefer Fowler's solution, given in the average dose of four minims thrice daily. I think this solution is often prescribed in too large doses, and I am sure the dose of five to ten minims, as given in the books, is too large for ordinary use. Most patients bear a four-minim dose very well, but there are idiosyncrasies. I have sometimes been obliged to limit the dose at the beginning to one minim in cases where subsequently such toleration has been established that twelve minims have been taken with impunity. However, four minims is a good dose to begin with, and if the effect does not begin to show itself within ten days or two weeks, the amount may be gradually increased. Fowler's solution should never be given to the patient in a vial with directions to drop out the requisite number of drops. The patient is apt to make a mistake, vials of different sizes may pour out more or less in each drop, and there is always danger in leaving a half empty vial of poison about the house. The solution is better given mixed with water, or with wine of iron or other convenient vehicle.

The effect produced by arsenic upon the eruption of psoriasis is, first, a diminution of the quantity of epidermic scales thrown off, and then in preventing the appearance of new lesions. The patches gradually lose their scaliness, begin to heal in the middle, and disappear little by little. It must be remembered, however, that arsenic is a slowly acting remedy, and its use should be continued through many months to get the best security against relapse.

The other liquid preparations of arsenic used in psoriasis are Pearson's solution of the arseniate of sodium, and Donovan's solution of the iodide of mercury and arsenic. I have used the former in a few cases without noticing any perceptible difference as regards efficiency between it and Fowler's solution. The solution of mercury and arsenic (Donovan's) I have employed, with good effect, in certain stubborn cases where Fowler's solution has seemed to fail. The existence of syphilis as the cause of the eruption in these cases having been excluded, I am at a loss to account for the apparently greater efficacy of the mixed treatment. The dose given was as much as ten drops, and although this solution is weaker in arsenic than Fowler's, yet I am inclined to the opinion that the conjoint administration of the two drugs, mercury and arsenic, was the cause of the good result, rather than the increased dose. I should be inclined to use Donovan's solution in cases where Fowler's solution had failed.

The mixture of arsenious acid, black pepper, and sugar of milk, known as Asiatic powder, and recently placed in the Pharmacopœia, with the pepper left out, among the triturations, is of no particular value above the other preparations, and is not so convenient of administration.

Hypodermic injections of solutions of arsenic have been employed in the treatment of psoriasis, but I have had no experience in their use.

Next in value to arsenic in the treatment of psoriasis is iron. I commonly employ the tincture of iron in cases where arsenic does not seem indicated. There is one type of psoriasis which includes robust, rosy, well-nourished individuals, "the very picture of health." Such people have never been sick a day in their lives, or perhaps may have had slight attacks of articular rheumatism. Such patients do well under arsenic.

But there is another type in which the individual is thin, poorly nourished, and perhaps somewhat anæmic. These are the cases which do well under iron, which is best administered in the form of the tincture of the chloride. With these two remedies, arsenic and iron, I usually succeed in curing ordinary cases of psoriasis, adding in rare cases cod-liver oil to the use of the tincture of iron when debility is present. Of course, local applications are employed at the same time. Of these I shall speak presently.

In addition to the internal remedies mentioned, quite a host of others have been employed from time to time. Such are tar, carbolic acid, copaiba, phosphorus, tincture of cantharides, tincture of maize, carbonate of ammonia, acetate of potassium and other diuretics; the alkalies, as liquor potassæ and the alkaline mineral waters. Of these I have found alkalies and diuretics useful in cases when a markedly inflammatory condition of the skin has existed. The other remedies I have not employed, nor do I think the reports of their usefulness based on a sufficient number of facts, except in the case of tar possibly, to make it worth while to try them.

Equally important with the internal treatment of psoriasis is the external management of the disease. It is, of course, desirable to remove the eruption as soon as possible wherever it may be situated; but when it is found upon the face, there is every reason to endeavor its cure by all means and in the shortest time. External and internal treatment should therefore be combined when practicable. The first thing to do is to remove the scales. This may be done by means of local or general baths, wet dressings, etc., or by inunctions with fats and oils, by the use of soap, or by the action of impermeable dressings of India-rubber or oil silk. When only a few lesions are to be acted upon, a solution of salicylic acid in alcohol, 1 part to 16, well rubbed in with a sponge, will remove the scales very nicely.

The scales having been removed, the next thing is to apply such substances to the diseased patches as may most quickly modify the abnormal condition of the skin, and bring it back again to a healthy condition.

An innumerable number of applications have been recommended for this purpose, the most of which I shall pass over with only a mention. Such have been soaps and alkalies, citric and hydrochloric acids, sulphur, iodine and mercury, alone and in combination, together with the various forms and preparations of tar, creasote and carbolic acid.

All of these remedies have their uses, and most of them, especially the tarry preparations, I have employed time and again in years gone by, and with moderate satisfaction. The introduction, however, of chrysarobin or chrysophanic acid, some six or seven years ago, put quite a new face on the local treatment of psoriasis; and since then, with the aid of this and other later discoveries, we are able to work a much more rapid change in the appearance and condition of the skin in this disease.

As chrysarobin is perfectly well known to all here present, both as to its advantages and defects, I shall say but little about it in the ordinary form of its application—namely, as an ointment. When it first came out, I tried it quite extensively, but its disadvantages seemed so great that I had already begun to restrict its use greatly in my practice, when a new agent appeared, which, for every-day use, has in my hands, until very recently, almost entirely superseded all other local applications. I refer to pyrogallic acid.

I do not think pyrogallic acid is by any means so well known as an application for the relief of psoriasis as is chrysarobin. If I may judge by the infrequency with which its virtues are mentioned in the journals (although I believe all recent text-books speak of it), it is not in general use. But it is, in my opinion, one of the very best remedies we have for the cure of cases of psoriasis of average severity. Employed in the form of ointment, of the strength of one-half to one drachm of the pyrogallic acid to one ounce of simple ointment, the effect produced by it is almost as rapid and decided as that brought about by chrysarobin, without the accompanying discoloration. A slight blackish staining is all that is produced, and the ointment can even be employed in the scalp without markedly discoloring the hair, if applied cautiously. It is desirable, however, not to apply soap or alkalies at the same time, because this causes a more permanent and deeper stain.

Pyrogallic acid cannot be used in extensively generalized psoriasis, when large surfaces are affected by the disease, without a certain amount of danger from absorption, as indicated by strangury and olive-green or tar-colored urinary secretions. With care, however, and the occasional suspension of the remedy for short periods, I believe this remedy could be employed even in universal psoriasis with good effect.

One more external application in psoriasis remains to be spoken of—namely, naphthol. This drug, a derivative of coal-tar, was introduced into use several years ago by Kaposi, of Vienna, as a sort of substitute for carbolic acid. He recommends it very highly in psoriasis, in the form of ointment, about eighty grains to the ounce, and I have used it in this and other strengths, and also in solutions in alcohol and oil, with fairly good effect.[1]

Naphthol is not so active in its effect as chrysarobin or pyrogallic acid, but it is much more agreeable, and is, I think, peculiarly well adapted for employment upon such parts as are exposed to the view, as the face and hands. Like pyrogallic acid, it must be used with caution over large surfaces, as absorption, with toxic effects, may be produced.

It remains to mention briefly two or three methods of application of those remedies which have recently been brought forward. The first of these is the treatment by medicated gelatine which was introduced by Prof. Pick, the well-known dermatologist of Prague. My attention was first drawn to this by a pamphlet which Prof. Pick kindly sent me, in which he gave an account of his earlier experiments with medicated gelatines, but I have not as yet had an opportunity of testing this method of medication as I should desire. I may say, however, that the method does not seem to me calculated to prove convenient and popular in private practice. I had for some time been making some experiments in my service at the Polyclinic in the preparation of gelatines impregnated with chrysarobin and pyrogallic acid, but without much satisfaction, when Dr. Chas. L. Mitchell, the well-known pharmaceutist of this city, sent me some excellent preparations of his own, which seem to be perfectly adapted to the purpose for which they are intended. A bit of one of these gelatine sticks is cut off and placed in a water-bath, where it soon melts into a clear homogeneous fluid, which may then be applied to the lesions of the skin by means of a paint-brush. The advantages claimed are cleanliness and transparency. The coating of gelatine does not rub off on the clothes, and is therefore not so dirty as an unctuous application. A fresh coating can be painted on every day or two as the old layer wears off. The chief disadvantage of this method of treatment is that it requires apparatus which is not convenient to carry about, nor can the patient be trusted to employ it at his discretion. My own experience is that, in psoriasis at least, the gelatine applications are not active enough. I have not, however, used them with sufficient frequency to pronounce a positive opinion.

---

[1] In a communication read before the American Dermatological Association, last month, and published in the AMERICAN JOURNAL OF THE MEDICAL SCIENCES for October, I have given the results of my experience in the use of naphthol in various diseases of the skin, psoriasis among the number. I may refer to that paper for further details as to the action of the drug in this disease.

Recently a solution of chrysarobin in collodion has been recommended in the treatment of psoriasis by Dr. George H. Fox, of New York, and several dermatologists have confirmed his statements with regard to its efficacy. I have employed this preparation in one or two instances, but it has seemed to me so much less active than the chrysarobin ointment that I have not been encouraged to continue its use. It has one great advantage over the gelatine applications, however, and that is that it can be applied extemporaneously and without the paraphernalia which must accompany the use of the gelatine.

A few weeks since, a pamphlet by Prof. Auspitz, of Vienna, reached me, in which that distinguished dermatologist recommended liquor gutta-perchæ as a vehicle for the application of chrysarobin. I at once obtained a ten per cent. solution, or rather emulsion, of chrysarobin in liquor gutta-perchæ, and happening to have a case of psoriasis of the face and scalp under treatment, I gave some to the patient to apply once daily. The effect was so happy as to encourage me very much to hope that we have in this preparation the most convenient method of applying chrysarobin yet devised; and as chrysarobin is, after all, the most efficient local agent in the treatment of psoriasis as yet brought forward, I have no hesitation in urging the trial of this preparation on any one who may have a case of psoriasis under treatment. It is to be noted, however, that the same watch must be kept upon the skin for fear of exciting dermatitis as when the ointment is used. When the liquor gutta-perchæ dries, which it does very quickly, there is little or no danger of rubbing the chrysarobin over the good skin, nor is there much danger, if any, of staining the clothing.

RAILROAD INJURY.

RUPTURE OF THE ABDOMEN, WITH LACERATION OF THE NECK OF THE BLADDER AND PROSTATIC PORTION OF THE URETHRA; FRACTURE OF THE PELVIS; OCCLUSION OF THE EXTERNAL ILIAC ARTERY; AMPUTATION OF THIGH ON TENTH DAY; DEATH IN THIRTY-FIVE DAYS.

By I. S. STONE, M.D.,
OF LINCOLN, VA.

F. N., male, æt. 21, was caught between the couplers (drawheads) of freight cars on August 9. The writer witnessed the accident. The patient was saved from instantly being cut in twain by the cars not entirely closing together. Patient at once became pallid and nearly pulseless. Large quantities of ammonia and brandy were administered, and by enforcement of the prone position the patient was probably saved from speedy death. Examination revealed a wound extending from the median line, at the root of the penis, over the pubic bone, horizontally to the left five inches, opening the abdominal cavity, by pressure of Poupart's ligament with muscular attachments, backward toward the sacrum. The intestines were fully examined through the wound, and as no rupture was discovered, the wound was dressed and closed temporarily. The patient was treated for shock in the usual manner.

As three hours had elapsed since the patient had passed urine, the catheter was introduced for diagnostic purposes, but no urine was found. A small quantity of blood was discharged. It was then discovered that urine was discharging from the wound, which continued for twenty-seven hours, when a half pint was found in the bladder. After this time, a flexible catheter was retained in the bladder until the fifth day. The abdominal wound was thoroughly cleansed of urine, and solution of carbolic acid in glycerine and water used as an injection down to the base of the bladder. The wound was then closed permanently, and soon healed.

Large quantities of morphia were required for the first forty-eight hours, to control the pain in the nerves of both legs. Sensation was entirely absent in left leg from knee to toes. The external iliac artery was occluded, the circulation having entirely ceased throughout. Traumatic fever set in after recovery from shock.

On the 14th, the fifth day, the catheter was removed, and during the day a half pint of urine was passed normally. After this time, the patient continued to pass urine without the help of the catheter. The bowels were moved naturally on the sixth day.

Eight days after the accident, the left leg gave signs of gangrene below the knee. The temperature in the mean time was 100° to 104° F. On the ninth day, a severe rigor, lasting an hour, occurred. Temperature 106.3°; pulse 120. Amputation was decided upon as the only resort.

On the tenth day, the thigh was amputated in middle third, using carbolic spray and the usual antiseptic care. The collateral circulation had become established, and the stump healed rapidly. The abdominal wound also improved. Peritonitis was only slightly developed. Two weeks after the accident, a pus cavity was discovered at the base of the bladder, which was thoroughly drained with the catheter by aspiration, and washed out with a solution of potash permanganate. This treatment was continued every twelve hours. The prostate gland was very nearly absorbed.

Three weeks after the injury, the patient continued to suffer from high temperature and pulse; the former 101° to 105° F., the latter 110 to 120. Slight rigors.

For four weeks the patient was in constant stupor, except when aroused. A large abscess opened on the back, at the junction of the posterior-superior spinous process of the ilium with the sacrum, extending to and around the acetabulum, and through the sacro-sciatic foramen.

After five weeks of persistent sustaining and stimulating treatment, the patient finally succumbed to septicæmia.

An average of one gill of strong beef-tea was taken every three hours during the five weeks. Large quantities of milk, with "Mellin's food," were also given. Beef peptonoids and pepsin and dilute muriatic acid were given with domestic beef-tea when the stomach gave signs of weakening. It has never been my experience to see such large quantities of food given and assimilated under such circumstances. Quinine was freely given, and after the first rigor, the patient did not suffer from them severely.

Autopsy.—The symphysis pubis was disarticulated; the peritoneum was free from inflammation, save over the right kidney. Both kidneys were congested. Liver, stomach, and intestines were healthy. An abscess was found in front of and to the left side of the bladder and rectum, capable of holding nearly a pint of fluid, and connecting with the abscess outside of the pelvis. The prostate gland was absent. The rupture extended through the prostate and the neck of the bladder. The left external iliac artery and vein were closed. A large quantity of pus was found along the course of the vein (femoral), extending down into the stump about seven inches. The stump was nearly healed in spite of the adynamic condition of the patient.

The noteworthy features of the case may be summarized as follows:

1. That the patient rallied from shock.
2. That peritonitis did not follow and cause death during the first week.
3. That the amputation was successful (mixture of ether and chloroform, 2 to 1, was used).
4. That large suppurating surfaces did not cause death at an earlier period.
5. That the digestive organs continued in such healthy condition.

In conclusion, I must acknowledge the invaluable services of my friend, Dr. Townsend Heaton, of Hamilton, Va., who kindly assisted me in the case, and to whom I shall always remain indebted for his hearty coöperation and sympathy.

NOTES ON FISHBERRIES (COCCULI INDICI), AND A UNIQUE CASE OF FATAL POISONING THEREFROM.

By THOS. S. SOZINSKEY, M.D.,
OF PHILADELPHIA.

The *Anamirta cocculus*, a climbing shrub, indigenous to India and Ceylon, is the source of the *cocculus Indicus*, or *Indian scarlet berry*, or *bacca Orientalis*, or *Eastern berry*, or *fishberry*—the last the vulgar name of it. The names given to this fruit are deserving of a little study. *Cocculus Indicus*, *bacca Orientalis*, and *fishberry* are each open to criticism, because it is not a berry at all. The German name, *fischkorn*, plural *fischkörner* (spelled *fischkkörner* in *The National Dispensatory*—a typographical error)—or *fish-grains*, is too indefinite; and although not open to this objection, the French name, *coque du Levant* or *Levant shell*, mistranslated *Levant nut* by some, is also wrong. It is not a *berry*, nor is it a *nut;* and it is certainly more than a *shell*. This fruit is really, like the *butternut*, what botanists call a *tryma*, which is a dryish form of *drupe*, of which the *plum* and *peach* are examples. I may further say that *cocculus Indicus*, the singular, is generally used when the plural is proper, and that the name *fishberry*, so called from its use to destroy fish, the one by which it is known by the public, is not given in most of the books, so that the medical graduate may be utterly at a loss to know what the old woman around the corner is talking about when dilating on its value, if it be properly applied to Johnny's head or to the bedstead.

It is beyond my purpose to give a description of the cocculus Indicus and its properties and uses; but a few words thereon may be in place. Each is somewhat kidney-shaped, rough, blackish, and about a third of an inch in diameter. When split in two, in the line of its greatest diameter, the kernel is seen to be markedly crescentic in form: hence the name of the order of plants *Menispermaceæ* (from the Gr. *mene*, moon, and *sperma*, seed), to which the *anamirta* belongs. The active principle *picrotoxine* (from the Gr. *pikros*, bitter, and the L. *toxicum*, poison, literally *bitter poison*) was obtained from it as early as 1819. Another principle, named *menispermine*, has been obtained from the epicarp. Both are extremely powerful in their effects. A twentieth of a grain of picrotoxine is sufficient to kill a rabbit weighing three pounds. The dose is about one-eightieth of a grain. Of a tincture made from the fruit, in the proportion of one to eight, the dose would be about five minims, but no such preparation is in use, picrotoxine being preferable.

Cocculus Indicus is a good deal used as a parasiticide. Some medical men, and among them Prof. Gross, have a partiality for it as a remedy for pediculi. It is one of the best of the cures for ringworm in all its forms. As four hundred pounds or so are imported yearly, it must have many patrons; but some of it may be used in beer, which, it is said, is sometimes done by the unscrupulous, it having the property of imparting the desired fulness and apparent richness as well as bitterness to that beverage when malt and hops have been sparingly used in its production. The remedial properties of picrotoxine have not yet been sufficiently investigated and popularized. Admirable effects attend its use against night-sweating in phthisical and other cases.[1]

Cocculus Indicus, or rather the active principle, picrotoxine, is possessed of properties somewhat similar to those of strychina. As said recently by a learned authority—Prof. Stillé[2]—when it is administered to animals, it causes "dulness, muscular tremors, and convulsions and tonic spasms by turns, the body being strongly bent in opisthotonos." Unlike strychnia, it produces gastro-intestinal disturbance, and the spasms are apt to be clonic. Its power is exerted chiefly on the motor-spinal centres. Recent experiments have been made by Professors Chirone and Testa, of the University of Padua. These investigators found that picrotoxine may determine true epileptic attacks, even to the cry. There is loss of consciousness; the animal falls; there are abundant salivation, tonic and clonic convulsions, loss of urine, convulsive rolling of the eyeballs, and the action of the lungs and heart is arrested. The convulsions are of spinal and bulbar origin, and are more intense after the removal of the higher centres.[3]

In regard to its effects on the human subject, Prof. Stillé says: "There is no case on record in which cocculus Indicus, or picrotoxine, has produced in man such spasmodic phenomena as have just been described. Its chief effects in excessive doses appear to be slight giddiness and lightness of the head, and partial loss of power in the lower limbs. In one case only have symptoms of active poisoning by cocculus been described. Among them were gastro-intestinal irritation, congestion of the brain, strabismus, sweating, exhaustion, and death. The absence of any spasmodic phenomena throws doubt upon the alleged nature of the attack."

The rather remarkable fact that no case of fatal poisoning from cocculus Indicus or its active principle, picrotoxine, is recorded renders of interest the report which follows of what I observed in a case of the kind which recently fell into my hands:

B. McV., aged thirty-nine years, a man of medium strength, drank by mistake several ounces of whiskey in which a handful of fishberries had long been steeping, the preparation being intended for the destruction of bedbugs. I saw him a little less than an hour afterwards. He had vomited once before I reached him, but there was no recurrence of it, although mustard and salt and alum were given to cause it. I found him totally unconscious, a condition in which he remained to the end, and powerful general convulsions were following one another every five minutes or so, each lasting about two minutes. Between the convulsions there was perfect relaxation; hence they were very pronouncedly clonic. There was considerable opisthotonos. Each convulsion began with twitching of the muscles about the left corner of the mouth. As each attack came on, there was more or less of an outcry, as in epilepsy, and, as in that disease, some frothing was observable at the mouth. The pupils were markedly contracted. Respiration was extremely slow, and grew more so to the last. The action of the heart was not very noticeably disturbed. There was profuse perspiration. Decided diarrhœa came on within two hours. Death occurred just three hours after the fatal dose was taken, and was apparently due to failure of respiration and exhaustion. By way of counteracting the symptoms, half a grain in all of sulphate of morphia was used, and was given hypodermically. After using it, the convulsions did not occur so frequently, but their power was not lessened in the least. No chloral or anything besides the morphia was used.

2210 FAIRMOUNT AVE., PHILADELPHIA.

MEDICAL PROGRESS.

TRISMUS AND TETANUS UTERINUS DURING LABOR.—From a number of cases observed, **ROPER** draws the following conclusions:

Trismus comes on at the beginning of labor; it comes on in premature labor when the cervix and the lower part of the uterus is not completely dilated.

It is generally associated with a vicious presentation. In some cases this vicious presentation is not rectified by uterine action, as the uterine body remains inert while the spasm of the cervix continues. Also, when trismus of the cervix is accompanied by uterine tetanus there is no tendency toward expulsion of the fœtus.

Although cervical trismus is not accompanied by uterine contraction, it is associated with a systemic weakness which tends to a fatal termination. It is not infrequently associated with placenta prævia. Roper has not found any efficacy in the proposed methods of treatment.—*L'Indipendente*, June 25, 1883.

TREATMENT OF EXTRA-UTERINE PREGNANCY.—The indications for treatment are: 1. To kill the fœtus. 2. To open the sac and remove the fœtus by ovariotomy. The fœtus may be destroyed by puncturing the sac by means of a trocar introduced through the abdominal wall or through the vagina, and the amniotic fluid removed; by puncturing the fœtus itself and killing it; by injecting morphine into the fœtus; or by electropuncture. For opening the sac, laparotomy should be performed with antiseptic precautions.—*L'Indipendente*, June 25, 1883.

PORRO-CÆSAREAN OPERATION.—PROF. **MARTINO** recently performed this operation on a rachitic woman. Strict antisepsis was employed, the operation resulting favorably for both mother and child.—*Revist. Clin. dell' Univ. di Napoli*, August, 1883.

---

[1] Vide The Medical and Surgical Reporter, Jan. 14, 1882, for some very enthusiastic remarks on the subject by Dr. F. P. Henry, who had used it in a hundred cases.

PAINLESS TREATMENT OF CONDYLOMATA.—NUSSBAUM (*Münch. ärztl. Intell'bl.*, 1882) recommends the treatment of small condylomatous patches on the penis by daily washings with salt solution followed by the sprinkling over them of calomel powder. Chemical change takes place and corrosive sublimate is produced; the condylomata disappear, and no pain is felt. Solution of corrosive sublimate in collodion, which acts more quickly, gives rise to much pain, and requires the patient to rest in bed. The proposed method is not new, but has fallen into unmerited disuse.—*Practitioner*, October, 1883.

GASTROSTOMY IN CUBA.—On September 7th, DR. DON RAIMUNDO MENOCAL performed, at the Hospital San Felipe y Santiago, in Havana, gastrostomy on a man, æt. 60 years, for carcinomatous stricture of the œsophagus. The *Cronica Medico-Quirurgica*, Sept. 1883, in reporting the case, fails to say whether or not the patient recovered.

PRIAPISM IN LEUKÆMIA.—In a Hungarian medical journal, PROF. KÉTLI, of Buda-Pesth, has described a case of leukæmia, accompanied with priapism. A man, aged 35, was seized last October with a severe attack of paludal fever, followed by bronchitis; since that time, priapism had been present. At first, the erections occurred daily, lasting for several hours, and totally unaccompanied by subjective phenomena of any kind; but, for the last two weeks that the patient was under observation, priapism had been continuous, and very painful. The morbid condition was confined to the corpora cavernosa, the glans being perfectly unaffected; the urethra became so compressed by the swelling of the cavernous part of the organ, that the catheter had occasionally to be used. The spleen was enormously enlarged, and the proportion of colorless corpuscles in the blood was greatly increased. No enlargement of the lymphatic glands could be detected. Lupulin and bromide of potassium had been given as remedies for the priapism, but without effect, as might be supposed, since the symptom was related, more or less directly, to a constitutional affection that needed other treatment than the administration of sedatives. Prof. Kétli observes that Longuet describes a case of leukæmia, where priapism came on, and lasted for six weeks. Salzer found the same condition in five out of eight cases of leukæmia under his care. The true relation of the symptom and the constitutional disorder remains as yet unknown.—*Brit. Med. Journ.*, October 13, 1883.

TREATMENT OF THE PLACENTA AFTER BIRTH OF THE CHILD.—PROF. DOHRN sums up the comparative results to the woman, in cases in which the placenta was left to nature, spontaneously expelled, or treated by Credé's method.

1. In one thousand lying-in-women, in whom the expulsion of the placenta was left to nature, the results were far better than in one thousand others in whom Credé's method of expulsion was used.

2. The one thousand lying-in-women in whom the placenta was spontaneously expelled, had considerably less hemorrhage and fever after delivery. In those cases treated by Credé's method, portions of the membranes were frequently retained, and there were more fatal cases than in the others.

3. The disadvantages which are conditional to the method of Credé, are especially seen in the cases in which the placenta is expressed during the first five minutes. After a longer time the expression was more complete, but never as safe as by the spontaneous method.—*Deutsche med. Wochensch.*, Sept. 26, 1883.

MIDWIFERY FORCEPS LEVER.—DR. WILLIAM HENRY TAYLER describes a new instrument recently invented by him to aid in forceps delivery. It consists of a square block of wood, scalloped out on its under surface to make it fit well into the bed or mattress. In the centre of the block is a perpendicular lever, working in a ball-and-socket joint. To this lever is attached a leather strap with a ring, which works up and down the lever in circular grooves about one inch apart, according to the height required. To the other end of the leather strap is fixed a hook for attachment to the forceps On one side of the block, that placed towards the foot of the bedstead, is attached another leather strap, with holes at intervals and a hook at the end. This strap is passed round the rail of the bedstead, and the hook inserted into one of the holes according to the length required, and keeping the block in the desired position.

Each handle of the forceps terminates in a flat ring, the two, when placed together, forming one ring, in which is inserted the hook on the strap attached to the lever; the forceps are also fitted with an improved catch, which easily and securely fastens them when locked.

In using this machine, the woman having been placed in the proper position, and the lever-block placed on the bed and fastened according to the distance required, and which can be readily shortened or lengthened, the forceps are introduced, locked, and fastened by the improved catch: then the hook of the strap attached to the lever being inserted within the ring on the handles of the forceps, the instrument is ready for use.

The accoucheur, sitting by the side of the bed, places one hand on the lever, and manipulates with the other to feel the gradual descent of the head, and so regulates the force of the lever, that the traction can be increased or lessened with the greatest nicety and precision, while the leather strap allows the head and forceps to rotate at will. The lever being fixed with a ball-and-socket joint, the extension can be made in any direction. As soon as the head has been brought sufficiently low down, the lever can be unhooked from the forceps, and the head brought through the vulva in the ordinary manner.

The advantages claimed for the midwifery forceps lever are—1, increase of power with less exertion; 2, it allows of the proper rotatory movements of the head; 3, it works on a level plane; 4, there is an easy graduation of the force employed; 5, it enables the accoucheur to work in a sitting comfortable position; 6, it can also be used for reducing dislocations.—*Brit. Med. Journ.*, Oct. 13, 1883.

TREATMENT OF PERINEAL RUPTURE BY IODOFORM.—BEHM, after nicely cleaning the perineal wound, dusts it over with iodoform powder, and then brings the edges together. A very small quantity of iodoform is used, in order that union may, if possible, take place by first intention, as has been the case in some of Behm's operations. After the edges of the wound are brought together, he uses a dressing containing iodoform, and covered by cere-cloth. By this means, the wound is protected from the vaginal discharges.—*Bull. Gén. de Thérap.*, Sept. 30, 1883.

MUSCULAR ATROPHY IN RHEUMATISM OF JOINTS.—DR. LUIGI PETRONE (*Lo Sperimentale*, May, 1883) has collected a few cases in which muscular atrophy accompanied or followed immediately upon rheumatic inflammation of the larger joints, especially of the shoulder and knee. The deltoid and triceps suffered especially. The atrophy showed itself about the beginning of the second week after the articular pain;

sometimes there seemed to him more loss of power than atrophy, sometimes the reverse. Similar muscular atrophy was noticed by M. Valtat after traumatic injury of the joints (*Archives générales*, 1879, p. 159); in some cases occurring more rapidly, even within twenty-four hours of the injury. This led Dr. Petrone to a series of experiments consisting in the artificial induction of acute synovitis in animals. He found, on post-mortem examination within ten or twelve days of the experiments, that the muscles in the neighborhood of the inflamed joint had lost ten to thirty per cent. of their weight. The nerves showed nothing abnormal. He does not pretend to determine the method of the influence of the joint affection on the surrounding muscles, but urges that the effects are too rapid to be explained either by the atrophy of disuse, or by Vulpian's hypothesis (*Leçons sur l'Appareil vasomoteur*, vol. ii.) that the irritation of the articular nerve produces an effect on the gray matter of the spinal cord which leads to the muscular atrophy.—*Practitioner*, October, 1883.

FISTULÆ OF THE URACHUS.—DR. S. HERMANN has observed two cases of fistula of the urachus at the polyclinic service of Prof. Baginsky at Berlin. In one case there was a fistulous opening one and a half inches wide leading into a suppurating tract. There was no communication with the bladder or the intestine. In the second case a small catheter could be passed into the bladder through an opening in the umbilicus, urine mixed with pus flowing out. Both cases recovered; the first spontaneously, the second after syringing with solution of thymol, cauterization with nitrate of silver, and lead-water cataplasms.—*Centralb. f. d. med. Wissensch.*, June 16, 1883.

INFLUENCE OF MALARIA ON PREGNANCY AND THE PUERPERAL STATE.—GOTH, of Klaussembourg, a very malarial place, has had very favorable opportunities for studying this subject. From his observations it seems that: 1. Pregnancy gives no immunity from malarial infection. 2. Malaria predisposes to abortion, and especially to premature labor: it causes premature labor (*a*) by the death of the fœtus, produced either by the high temperature of the mother, or by the direct action of the infecting principle on the fœtal organism; (*b*) by bringing on uterine contractions, MacRunge having demonstrated experimentally that an elevation of the temperature to 40° C. causes uterine contraction. As in all paludal affections and symptoms, quinine is the remedy to be relied on.—*L'Indipendente*, June 25, 1883.

HEREDITARY SHORT-SIGHTEDNESS.—Considerable attention has lately been paid in Germany and Switzerland to the question of the increase of myopia amongst school children and students generally. Dr. Cohn has, in a recent number of the *Gesundheit*, summarized various statistics on the question of hereditary short-sightedness, which have from time to time been collected by Erisman, Scheiding, Pflüger, and other authorities on the subject. The researches of the last-named writer resulted in the following facts being elucidated as to the percentage of short-sighted pupils: Public schools: Without predisposition, 8 per cent.; with predisposition, 19 per cent. Higher schools: Without predisposition, 17 per cent.; with predisposition, 26 per cent. The difference of about 10 per cent. in favor of those children without a hereditary predisposition to short-sightedness is, according to Pflüger's opinion, a reliable basis of argument. At the same time, he asserts that this relatively low figure is arrived at after the necessary elimination of those cases where the predisposition has remained latent, and where it is of such a nature as only to become the source of ocular affection under circumstances of an unfavorable character. The quoted opinions of oculists, such as Von Arlt, Kotelmann, Loring, Nicati, and Javal, vary from each other in the manner of regarding the question at issue. Those who acknowledge the existence of such a predisposition consider that its importance should not be over-estimated. The statistics published on the matter are regarded as hardly sufficiently conclusive to allow of a definite solution of the question at the present moment.—*Lancet*, October 13, 1883.

NUCLEATED RED CORPUSCLES IN ANÆMIA.—HAYEM (*Archives de Physiol.*, No. 3, 1883), like Cohnheim, Litten, Erb, and others, has found nucleated red corpuscles in the blood of six anæmic patients, two suffering from gastric cancer, one from pernicious anæmia, one from post-puerperal anæmia, and three from leukæmia. The nucleated corpuscles were always few (two or three in several thousand), and were not detected in fresh blood, but only after various methods of preparation. Some of them resembled fœtal blood-corpuscles, others were like the cellular elements of the fœtal bone-marrow or spleen-pulp.—*Practitioner*, October, 1883.

SPECULUM FOR UTERINE ELECTRIZATION.—M. Dujardin-Beaumetz has presented to the Académie de Médecine, for DR. DRISLER, the inventor, a speculum for uterine electrization. It is an ordinary cylindrical speculum, made of some non-conducting material, and furnished at the end with a metallic ring, which connects with a conducting stem, the latter passing out along a groove in the speculum. This stem terminates at the external end in a convenient handle, so as to render it easy of introduction, and a slot for the battery wire of one pole, the other pole being applied to the abdominal wall. Dr. Drisler has obtained good results with this instrument in various uterine neuroses, due either to abnormal nutrition or to irregularities of innervation. One of its chief advantages is that it is not necessary to withdraw the instrument in order to make applications, etc.—*Annales de Gynecol.*, July, 1883.

TREATMENT OF FRACTURE OF THE LARYNX.—DR. W. WAGNER, of Königshütte, points out (*Centralbl. f. Chir.*, No. 23, 1883) that fracture of the larynx is very rarely met with, and that not even the most experienced surgeons are in a position to derive from personal experience fixed rules for treating this injury. Most observers, however, agree that in such cases the first indication is the performing of tracheotomy in order to prevent suffocation. Occasionally, where there is much displacement of the fragments, it is advisable to perform thyrotomy.

A case is reported of multiple fracture of the larynx, which led the author to consider the subject of the treatment of this injury, and convinced him that further therapeutic measures were necessary beyond opening the trachea. The subject of this case was a robust and very powerful man, whose neck had been forcibly squeezed in a fight. He remained unconscious for about half an hour, and on recovering himself found that his breathing was very bad. On the following day, when the patient first came under the notice of Dr. Wagner, there was extreme dyspnœa; and, with coughing, much blood, partly fluid, partly coagulated, was brought up. The face, neck, and surface of the thorax were distended through emphysema. There was found to be free abnormal mobility of the left wing of the thyroid cartilage; and during the prompt performance of superior tracheotomy, the cricoid was found to be also fractured, and partly torn away from the upper ring of the trachea. The patient did well up to the third day after the date of operation, when signs were presented of hypostatic pneumonia on the left side, and there was a complaint of acute pain beneath the sternum. On the evening of the fourth day, there was free bleeding from the wound in the trachea, and on the following day the patient died. On post-mortem examination, there was found to have been mediastinal emphysema and suppurative mediastinitis. The lungs, with the exception of the lower lobe on the right side, appeared quite healthy.

Dr. Wagner thinks now that in any similar case of laryngeal injury, thyrotomy would be indicated, not so much for the purpose of replacing any fragments of cartilage, as for rendering the seat of fracture antiseptic, and for maintaining for a time this antiseptic condition. In a recent case of this kind, he would, after having plugged the trachea, incise the larynx in the middle line, and then separate the two wings of the thyroid cartilage so as to be able to see the whole of the interior of the larynx, and to apply some antiseptic fluid. He would then plug the interior of the larynx with small pieces of iodoform gauze. The wound would thus be rendered antiseptic, the fragments of broken cartilage be kept at rest, and the risk of hemorrhage be diminished. If there be no longer any danger of infection, a late thyrotomy, it is held, is still justifiable if performed with the view of putting displaced fragments of cartilage in a better position, and, if the thyroid cartilage be fractured, of uniting the alæ by silver suture. If the fragments of the thyroid cartilage cannot be thus united, or if stenosis cannot be prevented, Dr. Wagner would advocate extirpation of the partially detached portion of thyroid cartilage, and even removal of half the larynx. In a case reported by Billroth in which this partial operation had been performed, a good voice was retained, and, at all events, the patient is thus placed in a better position than that of having to go through life with a completely useless and much obstructed larynx.—*London Med. Record*, October 15, 1883.

TREATMENT OF PUERPERAL ECLAMPSIA.—DR. CAMILLO FUERST, assistant to Prof. Braun, communicates to the *Wien. med. Blätter* for July 26 some therapeutical notes from his obstetric clinic in Vienna. In the treatment of eclampsia, the following rules are observed: 1. For the prevention of fresh attacks, chloral-hydrate is given in the dose of 2 grammes (30 grains) by the rectum immediately after each fit, and if the greater part be returned, it may be repeated to the extent of 10 to 12 grammes (150 to 180 grains) in twenty-four hours. 2. If fits occur during the birth, it must be terminated artificially. 3. If the birth be over or not yet begun, diaphoresis is induced by hot baths, beginning at 38° to 40° C. (100.4° to 104° F.), and gradually raised by the addition of hot water to 42° or 45° C. (107.6° to 113° F.). After half an hour of this bath, or sooner, if much sweating of the face be induced, the patient is packed in warm flannels for two or three hours, from which she is freed gradually. This is repeated daily until the œdema disappears; and the treatment has been specially useful in eclampsia occurring during pregnancy.—*London Med. Record*, October 15, 1883.

PHOSPHATE OF CODEIN.—The *Wien. med. Blätter* of August 16th, contains the mention of a new drug, the phosphate of codein, which has been prepared by Merck, of Darmstadt, under the directions of Professor Hegar, of Freiburg. It is intended for hypodermic injection, for which neither the sulphate nor the chlorate are suitable, being nearly insoluble in water. The new salt is soluble in four parts of water, and contains seventy per cent. of codein. It crystallizes in four-sided columns, and is similar to morphia in action, with the advantage of having less tendency to excite toxic symptoms. It is peculiarly suitable for sensitive patients.—*London Med. Record*, October 15, 1883.

TREATMENT OF SYPHILIS IN INFANTS AT THE BREAST.—DR. FERDINAND LINK (*Prager Med. Wochensch.*, Aug. 8, 1883) reports four pretty severe syphilitic cases, in children aged, respectively, ten weeks, four months, eight days, and nine weeks. All were out-door patients, whose parents belonged to the working-classes.

Their symptoms were of the usual kind—eruptions on different parts, ulcers and rhagades of the nose and lips, troublesome coryza, etc. Two of the cases, moreover, presented serious complications, in the shape of intestinal catarrh and stomatitis.

The only internal remedy employed was iodide of potassium, two grains of which were given to each of the mothers daily, without interruption, during periods varying respectively from fourteen days to eight weeks.

In every instance a complete cure was indisputably effected—either by the time the medicine was discontinued, or very shortly afterwards—no traces of the disease being left beyond a more or less pronounced discoloration of the affected integument.

The apprehended effect of the iodide in lessening the secretion of milk was not perceptible in either of the four cases. If any slight diminution actually took place, it certainly did not interfere with the success of the treatment.—*Journal of Cutan. and Ven. Diseases*, November, 1883.

ERGOT IN ENTERIC FEVER.—DR. DUBOUÉ, of Pau, in a recently published essay (Paris, G. Masson, 1883), points out that the prominent symptom in enteric fever is enfeeblement of the muscular tissues. This enfeeblement is present in greater or less degree from the very commencement of the fever, and increases with the progress of the disease. It affects the muscles of the limbs, giving rise to the lassitude which is so marked a feature of this fever. It affects also the muscular fibres of the cardio-vascular system, and in this fact lies its great importance. The heart becomes enfeebled, and the blood current becomes retarded; and hence arises congestion of the various vital organs with its more or less serious consequences—imperfect oxygenation of the blood, defective nutritive power, and the like. This being so, the main indication in the treatment of enteric fever consists, according to the author, in combating the muscular enfeeblement and the consequent retardation of the blood current. The other important indication, viz., the prevention of nutritive disorders, can only be attained by giving attention primarily to the cardio-vascular debility.

For the fulfilment of this primary indication various therapeutic agents are useful, viz., the external or internal application of cold water, quinine, creasote, carbolic acid, the preparations of salicylic acid, ergot, etc., all of which act either directly or indirectly as excito-motors. While all of the agents enumerated are valuable for the end in view, the most valuable of all is ergot. Dr. Duboué has given this drug an extended trial, and the results he has attained have satisfied him of its extreme value. He has administered it with the happiest results in cases of enteric fever of the greatest gravity—in some even where the patient seemed *in extremis.* He believes that this remedy may cut short the fever even in its prodromal stage. Dr. Duboué insists on the necessity of the ergot being of good quality. If the drug be bad, as it too often is, it may give rise to sickness and other untoward symptoms; but if it be good no such symptoms occur, and the author has found that patients suffering from enteric fever, as a rule, show a remarkable tolerance of the pure drug. The mean dose used has been from one gramme and fifty centigrammes to three grammes (about twenty-three grains to forty-six grains) daily for an adult, and from forty centigrammes to one gramme (about six grains to fifteen and a half grains) for children between six and twelve. The dose must, however, be varied according to the circumstances of each case. The administration of the drug should, according to the advice of the author, be continued until convalescence has been well established.—*London Med. Record*, October 15, 1883.

Hydriodate of Hyoscin in Phthisis. — Dr. Fraentzel recommends (*Wein. med. Blätter*, July 5) hydriodate of hyoscin in the treatment of the night-sweating of phthisis, in subcutaneous doses of half a milligramme ($\frac{1}{110}$ gr.), or in pill, beginning with the same dose. He does not find it so universally beneficial as atropine, and it sooner exhibits a narcotic action; but he has seen good results from it in cases where atropine has proved useless, or has failed to act after being in use for some time.—*London Med. Record*, October 15, 1883.

Tetany.—At the meeting of the Medical Society of Vienna on May 25, Dr. N. Weiss communicated some interesting facts bearing on the nature of tetany. He had collected from German literature thirteen cases of tetany which had followed the operation for extirpation of a bronchocele. From the table which had been drawn up, it appeared that tetany had only been met with in cases of young women on whom total extirpation of the enlarged thyroid had been practised; that the nervous affection came on not later than ten days after the operation; that only eight of the cases showed signs of damage to the recurrent laryngeal nerve; and, finally, that five cases got well, seven died (two as a certain result of the tetany), and the remaining one still suffered from tetany three years after the operation. In three cases in which Dr. Weiss had the opportunity of performing a post-mortem examination, changes were detected in the gray matter of the anterior cornua of the cervical enlargement of the cord, and chiefly at the level of the fifth and sixth cervical nerves. The alterations observed were, briefly, swelling of the ganglion-cells, with lateral displacement of the nuclei, vacuolation of the cells, atrophy and shrinking of the protoplasm and cell processes. In the discussion which followed, Prof. Billroth contrasted and compared the characters of tetanus with those of tetany: he regarded the anatomical changes found microscopically in the gray matter of the cervical region of the spinal cord in tetany as probably of the nature of a direct continuation of the nutritional disturbance from the site of the operation. The proximity of the brain and spinal cord was an important factor, and it was not improbable that the neural changes occurred in all cases of removal of goitre, but it was suggested that they had to reach a certain degree of intensity before they could give rise to tetany. Prof. Rosenthal remarked that vacuolation could be by no means characteristic of tetany, seeing that vacuoles were described in connection with many nervous diseases.—*Wiener med. Woch.*, 22.—*Practitioner*, September, 1883.

The Mental State in Certain Diabetics.—There exist, in certain diabetics, moral troubles and intellectual peculiarities which enable the physician to diagnosticate the affection before there are other symptoms, and before the urine is examined. A young man becomes impotent, and tells it without shame, nor does he seem to regret it, but accepts the loss of his genital functions with resignation. This is significant, for hypochondriacal impotence is profoundly humiliating, and the person consults the physician several times a week; the diabetic on the contrary manifests, under these circumstances, a sort of indifference and relative optimism. At a more advanced period of the disease, when there is a greater quantity of sugar, the mental state of the diabetic undergoes modifications. He becomes melancholy, reserved, dejected, and speaks but little; he has parsimonious tendencies which become more developed day by day.

A man of the age of forty years, who, without appreciable cause and presenting no other mental trouble, becomes avaricious and thinks himself ruined, is very likely a diabetic. At a still more advanced stage of the disease when the pathological process has gone on for a considerable time, the diagnosis may still be made from the mental symptoms. The patient is lazy, continually wishes to rest, and is profoundly apathetic. Finally he falls into a state bordering on marasmus, and dies as frequently from some complication as from the disease itself.—*L'Abeille Médicale*, September 10, 1883.

Absorption of Fat in the Small Intestine.—M. Zawarykin has recently been making experiments with a view to determining the question as to the digestion and absorption of fatty substances by the villi of the small intestine. From these experiments he concludes that there are lymphatic cellules of the solitary follicular glands of the intestine, which, traversing the epithelial cells, seize upon the globules of fat and, passing them into the blood or chyle vessels, return charged with fat, bringing back also the fat from the intestine into the general circulation. These changes may be seen by examining the intestinal villosities at different periods of digestion. If the examiner causes osmic acid to act on the preparation, he will see that certain lymphatic cells, placed between the epithelial cells of the villus, contain fat. Some of them contain fat only in one part of their protoplasmic substance. Then, in other preparations one may see the fatty lymphatic cells accumulated between the subvillous connective tissue and the villus itself. M. Zawarykin also states that the lymphatic cells, by their amœboid movement, cause the fat to pass into the intestine, thence to be carried into the general circulation. This hypothesis is very seducing, but needs supplementary proof in order to be adopted. — *Revue Scientifique*, Oct. 13, 1883.

Labferment—Rennet-ferment. — Baginsky has been recently studying the subject of ferments, and particularly one which he calls Labferment (rennet-ferment). He finds this ferment in the juice of certain vegetables, as has been stated by Würtz, in artichoke flowers, in fig-juice, and in the aqueous extract of the Carica papaya. This last is the most active.

The small intestine of the calf seems to contain a ferment. If a small quantity of the intestinal mucous membrane be digested in the presence of hydrochloric acid, and the liquor then filtered and neutralized, a few drops of it will almost instantly coagulate milk. The hydrochloric extract seems to be more active than the alkaline extract. The best temperature for the action of this ferment seems to be between 35° and 50° C.

Putrefaction does not seem to alter the ferment so as to cause it to become ammoniacal or strongly alkaline. Trypsin appears to destroy the ferment rapidly; but, contrary to the opinion of Roberts, there is none of this ferment in pancreatic juice.—*Revue Scientifique*, October 13, 1883.

THE MEDICAL NEWS.
A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

Communications are invited from all parts of the world. Original articles contributed exclusively to The Medical News will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

Subscription Price, including Postage,

Per Annum, in Advance,	$5.00.
Single Copies,	10 cents.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

Address, HENRY C. LEA'S SON & CO.,
Nos. 706 & 708 Sansom Street,
Philadelphia, Pa.

SATURDAY, NOVEMBER 3, 1883.

THE TOXIC EFFECTS OF JEQUIRITY.

Now that so much is said on all sides in regard to the effects of jequirity in the treatment of trachoma, as demonstrated first by Wecker, it is desirable to know something of its action when introduced into the system. This important investigation has been made by MM. Cornil and Berlioz, and their paper, giving an account of their studies, was presented to the Académie des Sciences in September last.

The effects of jequirity depend on the presence of an organism—a microbe or bacterium. This organism excites a local inflammation of considerable violence, due, doubtless, to its growth and development in the tissue to which it is applied. Jequirity also contains a crystallizable principle, but this appears to be devoid of toxic activity, since it produced no appreciable result when administered to animals. That the bacteria constitute the active agent, was proved by filtration of the infusion by the method of Gautier, for then it is found no longer to excite the active inflammation and the systemic disturbance produced by the unfiltered preparation.

For the purpose of the inquiry undertaken by them, MM. Cornil and Berlioz operated with an infusion of jequirity so prepared and preserved in flasks as to prevent the admission of germs from the air in the usual mode of preparing infusions for such purposes. It preserved its activity for several weeks. In the first series of experiments, they injected the infusion into the subcutaneous connective tissue of rabbits and guinea pigs. All died within thirty-six to sixty hours, having œdema of the skin, bacteria in the peritoneal cavity with slight peritonitis, ecchymoses of the stomachal mucous membrane, and very considerable tumefaction of Peyer's patches. In these animals, however, such a state of these glands, similar to that of human typhoid, occurs in many infectious diseases.

In another series of experiments, the same infusion injected into the peritoneal and pleural cavities caused death in from twenty-four to forty-eight hours. Intense inflammation of the serous membranes was produced, and the fluid in these cavities was cloudy, filled with pus globules, with bacteria in the form of rods and spores, and shreds of false membrane, free and attached. The lymphatic glands and Peyer's patches were usually tumefied, and the lungs on the side corresponding to that in which the injection was made presented points of congestion and broncho-pneumonia. Besides these lesions, in many of the autopsies made, the liver presented on the surface yellowish-gray patches, and, on section, the same color with a certain amount of opacity. This appearance was found to be due to the presence of the rod-shaped organisms of jequirity.

Sections of these made after hardening in alcohol, and colored with methyl-violet, and examined with Verick's immersion No. 10, exhibited the following characters:

At the periphery of some of the hepatic lobules, an interlobular branch of the vena porta is filled by a fibrinous clot containing in its meshes numerous bacilli characteristic of jequirity. A similar thrombus may stop the circulation in a part of a hepatic lobule, and in some of the patches a portion of the interlobular capillaries contains either the bacilli in small numbers, with red and white blood corpuscles, or aggregations of bacilli, either as rods or as spores. The white corpuscles may be more or less altered—atrophied—and their protoplasm no longer visible. The hepatic cells in the yellowish-gray patches are pale; their nuclei altered in color or absent, and without actual fatty degeneration there exist, in the atrophied cells, pigment granules.

Frogs injected with an infusion of jequirity, either in the dorsal lymph-sac or in the peritoneum, die in twenty-four to forty-eight hours, presenting in the blood, connective tissue, and peritoneum notable quantities of bacteria.

These researches, as well as the clinical observations made by various ophthalmologists, indicate the remarkable powers of jequirity. In trachoma, as in the other chronic ophthalmic disorders for which this agent has been used, the therapeutical results are due to the predominating action of the remedy, and the substitution of the morbid process caused by it for the original affection.

The question of safety must not be overlooked.

Is there danger, under some circumstances, that the bacteria of jequirity enter the organism, and multiply in sufficient numbers to cause a septic state?

OVARIOTOMY AND HYSTERECTOMY IN THE ROYAL INFIRMARY OF EDINBURGH.

DURING the three years ending on the last day of May, 1883, as we learn from the *Edinburgh Medical Journal*, for September and October, sixty-eight ordinary ovariotomies, ten hysterectomies for fibrous tumors, and one hysterectomy and double ovariotomy have been performed in the new Infirmary of Edinburgh, with a degree of success which, when the magnitude of some of the operations is considered, is simply marvellous. Of the 68 ordinary ovarian cases, 15, or 22 per cent., were free from adhesions, while 53, or 78 per cent., were more or less freely attached. 30 of the cases had been tapped from one to nine times before operation. Both ovaries were removed 8 times. In all the cases of hysterectomy, the ovaries were taken away, and they were enlarged or diseased in every instance.

In the simple ovariotomies, the pedicle was invariably dropped into the pelvis. The cautery was used fifty-five times for dividing the pedicle, the time required for that object having varied from five to eight minutes. The ligature was used only when the pedicle was very thin, or in those cases in which the tumor had to be enucleated from one or both broad ligaments. The extraperitoneal method was employed in all of the hysterectomies, with one exception. In the case of combined hysterectomy and double ovariotomy, the adhesions were universal, and ligatures and the clamp were resorted to.

Of the 79 cases, only 5 died. Of the 68 ordinary ovarian cases, 4 perished, one of rapid septicæmia and two of supposed carbolic acid intoxication, the cause being obscure in the fourth. All of the 8 double ovariotomies recovered. The 10 cases of hysterectomy for very large or bleeding fibroids, despite the fact that the operations were of the most severe kind, and that the weight of the tumors averaged over twenty pounds, were successful. The double hysterectomy and ovariotomy proved fatal.

The mortality appeared to be influenced by the use of the spray, which, as is well known, Mr. Keith has now abandoned. Thus, of 25 ovariotomies and hysterectomies, including the combined extirpation of the uterus and the ovaries, conducted under the spray, 4, or 16 per cent., died, while of 54 ovariotomies and hysterectomies without the spray, only 1, or 1.8 per cent., perished.

Of the 68 ovarian tumors, 2 were dermoid, 2 suppurating cysts, 1 was sarcomatous, 1 malignant, 1 solid, and 1 a gangrenous cyst, the remainder having been ordinary cysts.

In addition to the foregoing laparotomies, the uterus was twice successfully removed by the vagina, once for epithelioma, and once for inversion with a fibrous tumor embedded in its walls. The ovaries and tubes were removed twice, with one death, the operation having been performed under the carbolic spray; and a tubo-interstitial pregnancy was prevented from doing harm by abdominal section.

While the results of the ovariotomies were most brilliant, those of the more serious and more formidable operation of removal of the uterus are unequalled. The truth of this statement will become the more apparent upon comparing the successes here recorded with the results obtained by another accomplished surgeon. In a paper on the operative treatment of uterine fibromyomata, read at the recent meeting of the British Medical Association, and published in the *British Medical Journal*, for October 13th, Mr. KNOWSLEY THORNTON states that he has performed supravaginal hysterectomy 12 times with 5 deaths; and he attributes the large mortality to the fact that in the majority of these operations it is impossible to carry out strict antiseptic or aseptic surgery. We believe, however, that this opinion is erroneous. The hysterectomies of Keith were done without Listerism; those of Thornton with antiseptic precautions. The former saved all of his ten cases; the latter lost 41.66 per cent. of his patients. In nine of Keith's cases, the stump was treated extraperitoneally, and all of Thornton's managed in the same way recovered. Hence, we have a perfect right to assume that the extraperitoneal method of treating the stump, through which sepsis and hemorrhage are prevented, and not Listerism, is the true cause of Keith's successes; and we doubt not that if dropping of the pedicle be abandoned, future experience will show a much smaller death-rate than has hitherto attended the procedure.

THE PHYSIOLOGICAL ACTIONS OF IODOFORM.

As iodoform is now so largely employed in surgical practice, our readers will, doubtless, be interested in the elaborate study of its physiological effects conducted by DR. RUMMO, of Naples, in Vulpian's laboratory. The experiments were made on frogs, rabbits, Guinea pigs, and dogs, and the observations included the functions of circulation, of calorification, of respiration, of nutrition, and of the nervous system. It would be quite impracticable, in the space at our disposal, to do more than analyze the conclusions with which the paper ends.

Iodoform depresses the cardiac functions and slows the movements by lengthening the systolic contraction, and by prolonging the diastole, so that the sphygmographic tracing bears some resemblance to that made under veratrine. Atropine does not affect the slowing of the heart caused by iodoform, but destruction of the medulla oblongata in the frog prevents this effect. Dilatation of the capillaries of the interdigital membrane first ensues, but a progressive contraction succeeds.

The respiratory movements are correspondingly affected. With large doses the respiration is at first accelerated, but afterwards slowed. The blood pressure falls with the diminution in the number of cardiac pulsations. In the dog, small doses of iodoform do not affect the temperature; medium doses raise the body-heat, but large doses cause a considerable decline.

Iodoform acts especially on the nervous centres, depressing the functions of the anatomical elements, but as the action continues, the peripheral nerves are at length affected, and finally the muscles. Motility is first impaired, then lost; sensibility declines somewhat, and the reflexes become less active.

Iodoform in the beginning of its action increases the secretions in general, and notably the salivary, the biliary, and gastro-intestinal. It is in part eliminated by the secretory organs, probably in part as an alkaline iodide (iodide of sodium?) and a small quantity passes out unchanged by the respiratory organs. Some small portion escapes by the urine, not enough, however, to explain the albuminuria and hæmaturia which result from the administration of large doses. The elimination begins in an hour after its ingestion, but it may be recognized in the urine, three days afterward.

Various morbid changes are found, the most important being a fatty degeneration of the organs, especially of the liver, a glomerulo-nephritis, and an acute anterior poliomyelitis. In these anatomical alterations, we recognize the community of effects produced by the mineral remedies. The most important practical point, however, is the action of iodoform on the bacteria of disease. It has a more decided germicide action than on the multiplication of spores. Iodoform dissolved in turpentine kills microbes in active reproduction—a practical fact which might be advantageously applied in surgical practice.

FAT CRYSTALS IN STOOLS IN CANCER OF THE PANCREAS.

It is well known that more or less fatty stools frequently attend serious disease of the pancreas, and are often of diagnostic value. Dr. Franz Ziehl has, however, recently reported a case in the *Deutsche medizinische Wochenschrift* for Sept. 12th, in which the microscope showed that three-fourths of the stool-mass, which was of a silver-gray color, was composed of fat crystals. These were needle-shaped, partly isolated and partly in bundles. They were soluble in ether, and there remained after evaporating the ethereal solution an abundant fatty residue, out of which again crystallized a moderate number of spherical crystals, which reacted in the usual manner with osmic acid. The autopsy revealed primary cancer of the pancreas, with secondary cancer of the duodenum and stomach; ulceration of the latter with compression of the ductus choledochus and ductus hepaticus. There was general icterus.

Friedreich has described in Ziemssen's *Cyclopedia* two cases in which were the same silver-gray stools, and in which the microscope discovered crystalline fat. The important practical deduction to be made from these observations, is that we should not be satisfied with a simple ocular inspection of the stools in suspected pancreatic disease, since this crystalline fat may be present in large quantities, and give no distinctive features to the stools, while the microscope will readily discover the crystals.

It will be remembered that the ordinary macroscopic characters of fatty stools are at times a simple milkiness, at others the presence of greasy or butter-like, pale-yellow, and whitish masses of the size of a pea or larger, mixed with fecal matter. Or there may be, upon cooling, a pellicle of stiffened fat at the edge of the chamber vessel or surrounding the masses of fecal matter. In other cases still, there may be a fluid more closely resembling oil.

It is important to observe, also, that in all three of the cases referred to, there was jaundice due to obstruction of the hepatic duct. Alongside of this fact should be placed an announcement by Gerhardt, that in the pale, uncolored stools of a case of icterus were found large numbers of fat crystals. So soon as the stools again resumed their natural color by the admixture of bile, the crystals disappeared. From these facts the inference is legitimate, that it is the coincident absence of bile which causes the fat to assume the crystalline rather than the amorphous shape.

THE INDEX CATALOGUE

We are receiving, from physicians who have purchased from the Public Printer the first three volumes of the Index Catalogue of the Library of the Surgeon-General's Office, complaints that they cannot obtain Vol. IV. in like manner, and therefore find it impossible to complete their sets.

It appears that of the first three volumes the Public Printer struck off a sufficient number of copies to supply the demand, selling them at two dollars per volume. When Volume IV. was ready for the press, he decided that he had no authority to strike off extra copies for sale unless such copies were ordered *before* he began to print. This decision is in accordance with the letter of the law, which is as follows:

"If any person desiring extra copies of any document printed at the Government Printing Office by authority of law shall, previous to its being put to press, notify the Congressional Printer of the number of copies wanted, and shall pay to him, in advance, the estimated cost thereof, and ten per centum thereon, the Congressional Printer may, under the direction of the Joint Committee on Public Printing, furnish the same." (*Revised Statutes*, 1875. Sec. 3809.)

We should certainly have supposed that there could be no objection, in regard to a series of volumes like those of the Catalogue, to considering an order for the first volume as equivalent to an order for the whole work, but the Public Printer has decided otherwise. Under these circumstances, what is to be done? The very limited number of copies (1500) printed for distribution by the Surgeon-General is quite insufficient to supply the demand, and of course no copies of Vol. IV. can be spared, since they are all required to complete the sets of those institutions which have received the previous volumes from this source. Fortunately, Vol. IV. has been stereotyped, so that extra copies can be printed at comparatively small cost, if Congress so directs. It appears to us, therefore, that the members of the profession in this country should request of Congress the passage of a joint resolution authorizing and directing the Public Printer to print a sufficient number of Vol. IV. and of all succeeding volumes of the Index Catalogue to meet all probable demands for purchase. This request should be urged both upon individual members and Senators by personal interviews or letters from their medical friends, and also by formal memorials from societies, addressed to Congress as a body.

Meanwhile, we understand that the first part of the manuscript for Vol. V. is about to be sent to the Public Printer, and it will probably be judicious for those who wish to purchase copies of it to send in their orders within the next month or two.

AEROTHERAPY.

Amongst the novelties in therapeutics recently brought forward, is the application of compressed air in the form of a douche directed against some part of the body. The inhalation of compressed air is by no means a new expedient, but in the method proposed by Dr. Dupont (*Bulletin Général de Thérapeutique*, Sept. 30, 1883) a novel application is made of a well-known remedial measure.

For the air-douche, the compression of the air is carried to three atmospheres. A flexible tube connected with the gasometer and having attached, at its free extremity, a canula with an orifice of 8 to 10 millimetres in size, is the simple apparatus required. The jet of compressed air is directed against the surface, wholly bared, the patient lying recumbent. The effects are partly mechanical; partly dynamical. By the attrition of compressed air, percussion is made, the superficial tissues are forced to glide over those beneath, and the blood is displaced and turned in from the more superficial to the deeper vessels. Considerable cooling of the surface, followed by reaction which quickly reddens the skin, are the chief dynamical local effects. The sensations experienced by the patient are of an agreeable character—there is a general sense of well-being, combined with a warm glow of the whole surface.

The air-douche is recommended for the following conditions: For consumption, chlorosis, anæmia, obesity, and allied affections, with a view to increase the activity of the nutritive functions. In œdema, hydrarthrosis, ankylosis, and analagous diseases, to increase the circulation and promote absorption of effused fluids. In hysterical contractures, hyperæsthesia, and painful local muscular spasm.

With compressed air may be mixed carbonic acid gas to obtain the local anodyne effects of the latter, or anæsthetic or anodyne liquids to effect at the same time the results of pulverization of fluids. Apart from such adjuvant effects, the application of the compressed air-douche must be regarded as an efficient mode of massage.

THE RESULTS OF THE GERMAN CHOLERA COMMISSION.

No official report of the results of the investigations made in Egypt by the German Cholera Commission, under the direction of Dr. Koch, has, as yet, been made. But it is announced, that in addition to numerous micro-organisms found in the cholera dejecta, which seem to have no relation to the disease, a special form of bacillus has been found in the walls of the intestine which corresponds in size and shape more closely with the bacillus of glanders than with any other bacillus.

Further investigation and experimentation in Egypt having been rendered impossible by the disappearance of the disease, Koch asked permission to extend the labors of the Commission into India. The request has been granted, and we may expect soon to learn more concerning this special bacillus.

The report of Acting Assistant Surgeon Main, published in another column, shows what might be an alarming condition of affairs in Mexico, were it earlier in the season, but, as cold weather will soon be upon us, no apprehension of further spread of yellow fever into the United States need now be felt.

REVIEWS.

The Roller-bandage. By William Barton Hopkins, Assistant Demonstrator of Surgery in the University of Pennsylvania, etc. 12mo. pp. 95. Philadelphia: J. B. Lippincott & Co., 1883.

This little work begins with a description of the roller-bandage, and gives some concise and definite information respecting its material and manufacture, and also the general methods of its application. The different bandages in general use are then described, and illustrated by drawings taken from photographs, the same bandage, in many cases, being shown at different stages of its application. By this means, a very original set of drawings has been produced, which, if carefully studied, will give the reader the essential points in the application of the various bandages. The drawings are certainly more accurate than the stereotyped plates generally seen in works of this nature; but their execution is so bad that they do much to mar the general appearance of the work, which in other respects is very satisfactory. The author's modification of the third roller of Desault (Fig. 33) presents, so far as we can see, no advantages over the original.

The directions for the application of the bandages are clearly and carefully given, and we do not doubt that the work will be of great service to students who desire to make themselves familiar with this most important class of surgical dressings.

SOCIETY PROCEEDINGS.

CINCINNATI ACADEMY OF MEDICINE.

Stated Meeting, October 22, 1883.

The President, W. W. Seely, M.D., in the Chair.

THE TREATMENT OF EMPYEMA BY PLEURAL INCISION; OPERATION ON THE SEVENTEENTH DAY; REPORT OF CASES.

The discussion on this subject was opened by Dr. Joseph Ransohoff, who reported three cases, in two of which he had operated successfully.

The first case was a youth aged twenty years, the son of healthy parents, in whom, after five days' illness with symptoms indicative of acute lobar pneumonia, including bronchial breathing, increased vocal fremitus, an acute onset, and a percussion note not absolutely flat, a pleuritic effusion developed. During the two weeks that followed, the condition was unchanged. Then, however, symptoms of a graver character set in. The purulent character of the exudation was demonstrated by the hypodermic syringe, and on the seventeenth day of the disease an incision three inches in length was made in the seventh intercostal space, midway between the external margin of the scapula and the axillary line. Nearly two pints of creamy pus flowed from the wound. Permanent irrigation with borated water was at once established by means of a double siphon, and continued for six hours. Then the tubes were cut three inches from the wound, and iodoform dressing applied. During several succeeding days, the patient suffered from severe pain and a most persistent cough, unaffected by morphia, and alleviated only by the irrigation. The tubes were removed, and all pain and cough ceased, showing that these symptoms had been due to pleural irritation by the tubes. The cavity was now irrigated daily until the water came away at each time free from pus, and the iodoform dressing was reapplied. Two complications, however, arose: On the fourth day erysipelas developed and travelled down the back to the nates. Incisions had to be made to evacuate accumulations of pus, and these were followed by fistulous openings or gangrenous sloughs. The second complication was iodoform poisoning, in the form of nocturnal maniacal attacks. These subsided promptly upon the substitution of boracic acid for the iodoform dressing. Notwithstanding all this the recovery was rapid and complete, the opening into the pleural cavity being entirely closed at the fourth week.

The second case was that of W. B., æt. 26, whose father died of heart disease, and his mother of pulmonary hemorrhage. On the 19th of March he was prostrated by a chill, followed by symptoms recognized by his physicians as those of pleurisy with effusion into the right side. Two weeks before admission to the Good Samaritan Hospital he had another rigor followed by sharp fever. When admitted early in May, owing to the urgency of the case, Dr. Whittaker, whose patient he was, removed about a pint of purulent fluid, when the needle became blocked up. The case was operated upon and treated in the same manner as the previous one, and in one month there remained only a small fistulous opening, which in another month had entirely closed.

The third case was less fortunate. The patient was suffering from phthisis, and had an enormous effusion on the left side, displacing the heart to the right of the sternum. Aspiration, removing fifty ounces of serous fluid, the last of which was turbid, gave but slight temporary relief, and was followed on the third day by pneumothorax; ascites developed. Tapping had to be resorted to every two or three weeks during the next five months. During this time, however, the fistulous opening in the lung closed. The pleural cavity was opened and the case was conducted as the two previous; but little effect was produced. The heart remained fixed in its abnormal position; the cough and dyspnœa persisted and the patient died on the fifth day of exhaustion.

From these and other cases within his experience, the speaker drew the following conclusions: Leaving out of consideration the empyemata of children, in whom the immunity from firm adhesions and the elasticity of the chest-walls are accountable for the good results, aspiration of purulent accumulations is rarely followed by permanent benefit. Aspiration is sometimes attended by danger, and deaths have followed it, even where the effusion was serous.

The presence of a tubercular basis for the empyema should not deter one from incising the pleura, unless both lungs are seriously implicated.

The principles on which pleural incision is performed and drainage obtained are analogous to those which guide us in dealing with a diseased joint. König, Bull, and the most recent French authority, M. Hache, do not consider the presence of phthisis a contraindication to the operation.

The speaker had been unable to find a case reported in which the operation was performed so early as the seventeenth day, as in the first of his cases. But the speedy recovery which followed this operation he believed was sufficient evidence of the propriety of early operative procedure.

The objects to be sought in all the operations that have been proposed are:

1. The free evacuation of the pus that is present, and a ready exit for that which is to be formed.

2. An opportunity for the expansion of the lung, and a total agglutination of pulmonary and parietal layers of the pleura. In recent empyema, a simple incision of the pleura is all that is required to insure the first object. The incision must be made on the dorsal side

of the axillary line, and not lower than the sixth or seventh intercostal space.

With regard to the after-treatment, if provision is made for the ready exit of the pus as quickly as it is formed, it is unimportant whether the pleural cavity be irrigated more than once, and that immediately after the operation, as König advises. One of the most successful operators, Dr. John G. Blake, of Boston, believes that injections are not at all required when the pus is perfectly pure. It is better, however, to irrigate often, in order to remove all pus and shreds of adventitious membrane. Carbolic acid solutions should not be employed, because of their toxic effects.

The second requisite is best secured by the early operation. If patients are not benefited by the incision, and if fistulous tracts remain, it is because the operation was too long delayed. When such fistulous openings remain, they are to be considered as indications of a permanently retracted condition of the lung, and nothing remains to be done but to assist Nature in adapting the chest-wall to the form of the retracted viscus by an extensive resection of several ribs.

DR. JONES reported a case in which pleuritic effusion supervened upon pneumonia in a youth of seventeen years. Three pints of serous fluid were removed by the aspirator, and relief was afforded for a few weeks. Three months later, however, the symptoms became so alarming that an incision was made in a manner similar to that reported by Dr. Ransohoff. Several relapses occurred, but the patient has improved greatly, and is now (five months after) apparently almost well.

DR. J. S. KROUSE reported the case of a man who had a pleuritic effusion into the right pleural sac, resulting from a fracture of the seventh rib. A quart of straw-colored fluid was drawn off by aspiration, and a speedy recovery ensued.

DR. J. T. WHITTAKER reported two additional cases similar to those of Dr. Ransohoff, which were operated upon by Dr. P. S. Conner, not present. In one of them the speaker had used the aspirator one night when the dyspnœa was so great as to demand immediate relief. The other had been previously operated upon. Both recovered. This operation, he said, really marks an epoch in the treatment of this disease. A few years ago it was customary to attempt relief only by aspiration. Cases were allowed to die from want of surgical treatment. He himself had had cases die, years ago, from amyloid disease, the result of an empyema. This is, however, by no means a new operation, as we have evidence that Hippocrates opened the pleural cavity and evacuated pus. It is strange that an operation attended by such remarkable results could have fallen later into such disrepute that some of the great surgeons of the time discountenanced it. Dupuytren discarded it, saying of it that he had rather die by the hand of God than by the hand of man. In our day the result is entirely different. Fatal cases uncomplicated by phthisis are exceedingly rare. The cases of idiopathic empyema, so called, form the great minority of cases. It is stated that ninety out of one hundred and twenty-one cases were phthisical; many of them afterwards died of phthisis. It is questionable whether a serous effusion into the pleural cavity ever goes on to the formation of pus without a background of pneumonia or tuberculosis. In still more advanced cases of tuberculosis, the individual has an effusion, not of serum or of pus, but of blood. The operation in one case of Dr. Ransohoff was notable for having been performed so early, but the belief now is in favor of early operation. "*Ubi pus, ibi incisio*," should prevail here as elsewhere.

The speaker was decidedly in favor of frequent irrigation of the pleural cavity after incision, and believed that the great cause for the operation having ever fallen into disrepute was the failure on the part of operators to carry out with sufficient zeal this after-treatment.

The speaker referred also to the value of examining the pleural or abscess sac with the finger to ascertain the condition of its walls. In old cases, with stiff walls, irrigation is an absolute necessity to remove the disintegrating fragments of tissue from the sac, and in very old cases it is advisable to use a sharp spoon or curette to secure their detachment. Experience has shown that this procedure is entirely unattended by danger, as from hemorrhage or otherwise. To secure easy adaptation of the pulmonary and parietal pleuræ, it may be necessary in very chronic cases to cut the ribs in two places, as recommended by Roser, or even to exsect the anterior thoracic wall, including the parietal pleura, and adapt the skin to the pulmonary pleura, as practised by Scheder. Early operations remove the necessity of such radical procedures, and are attended with much speedier obliteration of the pleural sac. In the speaker's opinion, the case should be put not only "where there is pus, there should be incision," but, also, "when there is pus, there should be incision."

DR. E. W. MITCHELL reported a case in which he had performed the operation, but without good result, the patient dying within a month afterwards. He attributed the result, however, to the impoverished condition of the patient, owing to intemperate habits, bad hygienic surroundings, and the impossibility of having the after-treatment well carried out.

DR. A. RAVOGLI spoke of the favorable results following aspiration as he had seen it performed in the hospitals of Rome. He also placed considerable importance on the method of Barelli for differentiating between serous and purulent effusions, by means of changes in the vocal resonance.

DR. S. NICKLES objected to the view that aspiration could be relied upon for cure, even in simple cases with serous effusion. He had seen fatal cases where the exudation was serous from first to last. Again, the diagnostic signs referred to by Dr. Ravogli are not to be relied upon. Where the symptoms are severe from the start, and especially when following an acute disease like scarlet fever, the probabilities are that the exudation will be purulent.

In a case of empyema following scarlatina, the speaker made a very free incision, introduced a tube and in a few weeks recovery was complete. In another case, a number of years ago, he was undecided as to the character of the fluid until hectic fever appeared, it not being the custom to make an exploratory puncture in those days. Then he made an incision, and the case recovered without washing out the cavity. He does not think irrigation essential, but it may hasten the recovery. It is questionable whether serous fluid should be removed early, unless it is so great in quantity as to cause alarming dyspnœa.

DR. J. S. CLEVELAND spoke of the cases he had seen in hospital practice, in which the incision was made by means of the trocar. The results were very fatal. In one case where a permanent fistula followed the puncture, recovery occurred, but no lesson was drawn from it.

DR. W. H. WENNING reported the case of a young man (æt. 23) belonging to a tuberculous family, in whom aspiration relieved a serous effusion for six months. Then the procedure had to be repeated, and the fluid was decidedly purulent. During the six months that have elapsed since the second aspiration there has been no return of the trouble.

DR. RANSOHOFF, in closing the discussion, agreed with the speakers who opposed the view that single aspiration is sufficient for a cure in cases of serous exudation. In his own experience it almost never proved successful. Again, it is not without danger, for pneumothorax not infrequently follows it. He does not consider Barelli's sign of any value. It is very strange that Billroth should say that no benefit has been derived from this operation. The character of the operation should be determined by the length of time that the case has existed and the degree of thickening that has occurred in the pleura. In old cases with very thick pleura, it is useless to trust to simple incision. It is then sometimes necessary to remove a rib or two, as König has recommended; but it is better not to trephine, as Langenbeck advises. The large opening made by the removal of several ribs becomes necessary in severe cases, in order that a portion of the thickened pleura may be removed with the sharp spoon.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

Stated Meeting, Thursday Evening, Sept. 27, 1883.

THE PRESIDENT, JAMES TYSON, M.D., IN THE CHAIR.

DR. SEILER presented a specimen of

POSTERIOR NASAL HYPERTROPHY IN SITU, TOGETHER WITH AN EXOSTOSIS FROM THE VOMER.

The anatomical relation of the parts on the right side of the nasal cavity was perfectly normal.

When, however, this partition was removed, a very marked enlargement of the posterior end of the lower turbinated bone on the left side was noticed, which proved to be a posterior hypertrophy.

On the left surface of the vomer a projection was also seen, which proved to be an exostosis, the existence of which, in nasal disease, is denied by some authors. The tumor-like projection into the nasal cavity consists of a hypertrophy of the erectile tissue underlying the nasal mucous membrane.

Its presence is due to a long-continued catarrhal inflammation which, by the infiltration of its inflammatory products into this cavernous tissue has distended the venous sinuses, and has increased the thickness of the connective-tissue walls of the caverns, so that when they are empty of blood a perceptible swelling or tumor still remains, as is seen in the specimen.

The reason why these hypertrophies occur more frequently at the anterior or posterior ends of the lower turbinated bones, must be looked for in the fact that the blood, favored by gravitation, distends the caverns of the erectile tissue more easily under the excitement of local irritation in these localities, and that the anterior as well as the posterior ends of the lower turbinated bones, forming the entrance to the in- or outgoing air current, are more liable to irritation by irritants contained in the respired air than any other portion of the nasal cavity.

DR. O'HARA asked what was the pathological condition generally found in hay fever, and was it due to a local nasal condition or to some constitutional influence.

DR. SEILER said that, of late, great interest had been taken in the pathology of hay fever, particularly in its relation to the pathological condition of the nasal cavities, and that great success had attended certain methods of treatment. In hay fever there is general hypertrophy of the mucous membrane of all the turbinated bones and septum nasi. The membrane is thickened and puffed up, thus occluding the nasal cavities. The inhalation of impure air, dust, etc., will produce irritation and cause asthmatic attacks. The pressure exerted by foreign growths or hypertrophied normal tissue in the nares also causes asthmatic symptoms.

As regards the possibility of cure, we may say that all sufferers from hay fever invariably have hypertrophic nasal catarrh, and if you, during the winter, remove the hypertrophied tissue the hay fever will not return during the summer. This removal is done either with a dentaldrill or the cautery knife.

He did not believe it to be due to rotten grains, as the worst cases occur in travelling, from coal-dust, etc. The disease is due chiefly to the hypertrophies. Sometimes the attack comes on frequently, and lasts only a very short time, the patient in the mean time being well. He had seen a number of such cases. In one case a young lady was attacked at every menstrual period, the disease lasting a half-hour. There was every symptom present: sneezing, watering of the eyes, running and clogging up of nose, difficulty in breathing, etc. In another instance, a gentleman had the same kind of seizures, but they were accompanied with intense pain in the nose. By surgical means, he succeeded in relieving him very much. Instead of one attack in three or four days, he has had but one in four months. These cases show how localized hypertrophies can produce spasmodic attacks.

DR. MUSSER asked if obstruction of anterior nares would give rise to as marked symptoms as if the disease was localized further back. He has a case of exostosis of one side which has given rise to no special spasmodic symptoms as yet.

DR. SEILER said that the anterior end of the nares is not at all sensitive, and the septum of the nose may be deflected at this point without producing symptoms other than those caused by the occlusion of the cavity. The middle and posterior parts are very sensitive. This can readily be demonstrated by the passage of a probe. Where there are marked spasmodic symptoms the middle and posterior tracts will usually be found to be affected.

DR. J. T. ESKRIDGE presented specimens of

MALIGNANT GROWTHS OF THE STOMACH AND OVARIES,

with the following history:

Mrs. A., æt. 32 years, married, born in Germany, had done hard service-work all her life. She had had two children, both living and healthy, three and two years old respectively. Her husband was a drunken, dissipated fellow. Her children were born at term. Neither she nor they presented any evidence of syphilis. She had had no abortions. Her confinements had been normal. After the first she remained in bed ten days, but after the last only five, as she was compelled to go out washing to earn bread for herself and children. Until her last confinement she had always felt well, and weighed, two years ago, one hundred and forty pounds; but soon after the birth of the child she began to lose flesh and strength. So far as she knew, none of her relatives had suffered from cancer or tuberculosis. In the latter part of the year 1882, she fell on her stomach and hurt herself considerably. Soon after the accident her abdomen became painful and began to swell. In March, 1883, she was admitted to the Episcopal Hospital. She remained in that hospital several weeks, and during her stay there her abdomen was twice tapped, a large quantity of a straw-colored serous fluid having been drawn off each time. She entered the Hospital of the Jefferson Medical College, very much emaciated, July 1, 1883. Dr. Getchell twice drew off large quantities of fluid similar in appearance to that obtained from her while she was in the Episcopal Hospital. She came under my care July 17th. She was very weak, and her appetite was poor, but her stomach was tolerant, and had been so during her entire illness. Her abdomen was greatly distended, and slightly painful to palpation. No nodules could be felt in any portion of the abdominal cavity. No heart or lung trouble was detected. The urine was normal in appearance and quantity. The temperature over the abdomen was a little higher than in the axillæ, in each of which it was 99.4°. A few days later, about three gallons of a yellowish serous fluid were drawn from the abdominal cavity. After the operation the abdomen was flaccid and tolerant of manipulation. A tumor just below the ensiform cartilage of the sternum was felt. It was thought to be connected with the stomach. A tumor, much larger on the right side than on the left, was observed in each ovarian region. The liver and spleen presented, so far as I was able to detect, no evidence of disease in these organs. Occasionally she was troubled by diarrhœa. She grew weaker, and her abdomen more tender. She died from asthenia, August 1, 1883. Her stomach remained tolerant to the last. From July 27th to August 1st, her temperature ranged from 100.4° to 102°. She was treated mainly with anodyne and supportive measures. Anti-syphilitic treatment was at one time employed, but without any improvement.

Sectio Cadaveris (twenty-one hours after death).—Body greatly emaciated, the adipose tissue being almost completely absorbed. Parietal layer of peritoneum thickened, opaque, and quite firmly attached to abdominal muscles. Its internal surface is very rough, and presents a rugose appearance almost as well-marked as the mucous membrane of a healthy stomach. The rugosed surface is made up of layers of firmly adherent lymph, and is studded throughout with deposits of pigment. The peritoneal cavity contains about one and a half gallons of a straw-colored serous fluid. Bowels are distended with gas, and variegated externally by deposits of old lymph. Stomach is distended with fluid. It is very small, capacity not more than a pint. It is firmly bound to all adjacent structures by bands of old and recent adhesions. Externally it presents the appearance and feel of an old cystic kidney. Its length is about eight inches; greatest breadth three inches. The walls of the pyloric two-thirds of the stomach vary from three-fourths of an inch to one-quarter in thickness, the calibre of this portion not being more than one and a half inches in diameter. The mucous surface is smoother than normal, and anæmic in appearance. While the growth encircles the stomach at its pyloric end (two-thirds), its thickest portion is along the lesser curvature. The walls at the cardiac end of the stomach are thinner than normal, easily torn, and present several ecchymotic spots. The pyloric orifice is greatly dilated, and admits of all the fingers of one hand being passed up to their second joint.

The calibre of the upper portion of the duodenum is two or three times larger than normal. The walls of the bowel at this point are thickened, but the thickening does not extend more than two or three inches, when the bowel resumes its normal appearance. General adhesions are found, binding together the greater and lesser bowels, but at no point are their calibres materially lessened. The caput coli is much enlarged, and its appendix is curled upon itself, presenting a snail-like appearance. Bladder healthy. Kidneys nearly normal in appearance. Spleen small, soft and pulpy. Liver slightly enlarged. The edges of incisions made in it are slightly prominent. The capsule is easily detached without tearing the hepatic substance. The interior of the organ is dark, pulpy, and very soft, being almost as easily torn with the finger as a healthy spleen. Gall-bladder is distended with a fluid similar in appearance to that found in the general peritoneal cavity. It also contains three angular stones about the size of a hickory nut.

A spherical growth, about five inches in diameter, is connected with the right ovary. About two-thirds of the tumor is formed by a cyst whose walls are about an eighth of an inch thick. The inner surface presents a cheesy appearance from broken-down exudated lymph. The contents of the cyst are a dark, muddy liquid. The remainder of the tumor is made up of a caseous-like substance, in which a cyst about the size of a walnut is found. Connected with the left ovary is an ovoidal growth, about three inches in length and two in breadth. The tumor is made up of a fibro-fatty substance. The womb is quite small, and apparently is not the seat of any disease.

The stomach seems to be the point of chief interest in the above case. The absence of nausea, vomiting, eructations, and other symptoms of gastric indigestion in a contracted stomach, the pyloric two-thirds of whose walls are infiltrated by a neoplastic growth, can be explained only, I think, by the presence of the enormous dilatation at the pyloric orifice. This condition of affairs permitted indigested food to pass from the stomach into the bowel readily. Gastric digestion was apparently almost *nil*, the fluids in the intestine performing their own function and that of the gastric juice.

It is probable that the growth in the stomach is secondary to those of the ovaries, and that the peritonitis followed by ascites was occasioned by the fall received eight months before the death of the patient.

The President said that he had never seen a case of disease of the stomach with so much thickening of walls and contraction of the cavity combined with so much dilatation of the pyloric orifice.

Dr. Formad said that, judging from the specimen, without a microscopic examination, he did not think there was any trace of cancer either in the ovaries or stomach. It looked more like a case of chronic fibroid gastritis. He has seen several cases of that kind. They are described and figured by Thierfelden in his *Pathological Atlas*. He also has in his possession a specimen of the affection. The ovaries also look fibrous, and malignant disease of the ovaries is usually sarcomatous. It would be interesting to know if there were any metastases, but it is not likely. In fibroid disease of the stomach the muscular coat is affected by fibroid changes, as is also the mucous coat.

Dr. Musser thought that it would not be possible to say positively what the growth was, unless a microscopic examination was made. It resembled very much a case which he had reported to the Society some time ago. The disease in that instance was confined to the stomach.

Dr. Eskridge, in reply, said that after examining the specimen carefully he felt that he would not be justified in calling it either sarcoma or carcinoma, and so called it a "malignant growth." In reply to Dr. Formad's query as to whether there were any metastases, he said that there were none. He would like to ask Dr. Formad if, in the cases he referred to, there was intolerance of food. In this case there was an absence of vomiting, notwithstanding the extent of the disease.

Dr. Formad said that he did not have the cases under his care clinically.

The President said that in one of his cases, with all the symptoms of cancer of the stomach, post-mortem examination showed what was called fibroid thickening by one pathologist, but which Dr. Formad and himself regarded as cylindrical epithelioma.

The specimen was referred to the Committee on Morbid Growths for examination.

Dr. de Schweinitz exhibited, for Dr. J. Ashhurst, Jr., specimens of

CYSTO-SARCOMA OF THE FEMALE BREAST,

with the following history: Bridget C., æt. 38, single, was admitted to the University Hospital during August of this year. She is a blonde, moderately anæmic from menorrhagia, with a sallow complexion, and in poor general health. Suffered with constant flatulent dyspepsia and headaches. Father died of phthisis; mother, living and healthy; two brothers alive and in good health; and of three sisters, two are healthy and one, younger than the patient, suffers with chronic gastric disturbance, probably some form of dyspepsia. No family history of carcinoma or tumor of any kind could be obtained.

In February, 1883, she first noticed a commencing lump in her left breast. This gradually increased in size, the growth being painless until the following March, when she began to suffer intermittent pain of lancinating character, and the tumor's growth became more rapid. She applied for treatment, and on August 9th Dr. Ashhurst removed the breast; the patient making a good recovery. No history of previous inflammation in or injury to the breast was obtained. Microscopically the nipple is seen to be healthy, though small, and the skin is freely movable over the surface of the tumor. Upon section it will be noted that the growth is filled with cysts varying in size from a pigeon's egg to some as small as split peas. The cut surface shows clefts of a more or less parallel or concentric arrangement, sometimes intercommunicating and giving the mass a characteristic appearance which Virchow has compared to the divided head of a cabbage. These cysts, at the time of the operation, contained a dark-colored, viscid, mucus-like fluid, while some of the smaller cavities were filled with a cheesy material, composed of degenerated epithelial cells. The interior of the cyst-cavities are smooth but irregular, being pushed up here and there by papillary excrescences of their walls. Macroscopically the tumor is one of the forms of *cysto-sarcoma* of the breast. Microscopic examination of the growth shows it to be composed of several forms of tissue. In the main, it is made up of fibrous tissue, sometimes loose and wavy, but more often well felted together or even so densely packed as almost to approach homogeneity. The acini are enlarged. The excretory ducts are dilated, lined with cuboidal or cylindrical epithelium which is frequently luxuriantly hyperplastic. Scattered through the fibrous matrix are round and some small spindle-cells, which, in the neighborhood of the lactic ducts, are more numerous, and simulate sarcomatous tissue. The cyst-walls are composed of fibrous tissue and lined with epithelium. The origin of these cysts is of course to be found in the altered excretory ducts. The rather rapid growth of the tumor, and the papillary excrescences into the lactiferous ducts would seem to indicate that this tumor belongs to the class cysto-sarcoma mucosum; but minute examination fails to show the presence of mucoid tissue. Its considerable hardness and dense fibrous structure, however, classify it more properly as a *cysto-sarcoma fibrosum* or a fibroma intracanaliculare papillare mammæ of Virchow's classification.

Dr. de Schweinitz also exhibited specimens of

RECURRENT SCIRRHUS OF THE MALE BREAST,

taken from the person of Moses W., æt. 60, a native of Ireland, and at the time of operation an in-patient in the University Hospital. He was of dark complexion, had a somewhat cachectic look, of bilious constitution, and rather melancholic temperament. His family consisted of ten members. Father and mother died in old age; of his brothers and sisters he had little knowledge, but, as far as he knew, none of them ever suffered with carcinoma in any form. Four and a half years ago, a small kernel appeared beneath his left nipple. Gradually the nipple retracted, and the tumor slowly increased in size, until, at the end of a year and ten months, its dimensions were those of an orange. He then applied for treatment and a Belfast surgeon removed the growth. Eight months later the growth began to recur in loco, the first nodule appearing in the scar at the point where a stitch was passed in the approximation of the wound. During August of this year, he came to the University Hospital, and Prof. Ashhurst removed the secondary growth and also some enlarged axillary glands, which the patient claims were present at the time of the original operation. The patient denied any injury or inflammatory trouble in his breast previous to the appearance of the original tumor. He also denied that this breast had been larger than its fellow, or that it had ever secreted milk. Macroscopically the growth is seen to be composed of two portions, the one, larger, is a fibrous mass, rising above the level of the epidermis, brownish-red in color on the surface, and yellowish-white within, and of moderate consistence. The skin in the immediate neighborhood at the time of operation was of a dusky hue. The other and smaller portion, is a nodule situated beneath the skin in the subcutaneous connective tissue, and is of similar color and consistence. A section under the microscope shows a connective-tissue framework, composed of round and oval alveoli, and scattered through it some spindle and round cells. These alveoli are quite closely packed with polymorphous epithelium, but chiefly of a spheroidal type. Much yellow elastic tissue is present in all sections. The skin in the neighborhood of the larger mass is involved in the carcinomatous process. The tumor is an ordinary scirrhus or spheroidal-celled carcinoma.

It is needless to speak of the interest which attaches to carcinomata of the male breast and of their infrequency of occurrence when compared with similar growths in the female mammary gland. I need only refer to Prof. S. W. Gross' interesting exhibit and remarks upon this subject in this Society's *Transactions*, vol. vi. I have mentioned that the tumor recurred at the point where a stitch was passed. It is permissible to speculate whether, if the surgeon's knife had removed a larger area of skin, this local recurrence would have been prevented or at least delayed. It would not be an uninteresting study to make sections of the edges of flaps that are about to be approximated after the removal of malignant growths, and note whether any morbid manifestations would present themselves, ready to be lighted up in active growth by any irritation, as in this instance by the passage of a suture. At all events this may serve the purpose of another warning that all incisions for such purpose should be carried as far into healthy tissue as is possible.

Dr. W. E. Hughes presented some specimens from a case of

PHTHISIS WITH ABSENCE OF PARIETAL PERICARDIUM AND MALPOSITION OF LIVER,

with the following clinical history: C. L., white, æt. 33, was admitted to the University Hospital, July 21, 1882. He had been previously in the Philadelphia Hospital, under the care of Dr. E. T. Bruen. By occupation a carpet weaver, he had done of late years general laboring work, often much exposed to weather. He had been a moderate drinker and user of tobacco. There was a distinct history of asthma in the family both mother and maternal grandfather having been affected, but no phthisis. When eleven years old, he had pneumonia, and since then winter cough. Till three years before being seen he was well and strong, then the cough became continuous, and flesh and strength began to fail; a year afterwards dyspnœa developed; at first produced only by exertion, it soon became constant, and a most urgent symptom in the case. In the fifteenth month preceding admission to the hospital, he had had two or three attacks of excruciating pain about the fifth interspace to the right of the sternum. The attacks would begin suddenly, last a few minutes, and disappear as suddenly as they came, leaving him completely exhausted. On admission to the hospital he was weak, somewhat emaciated, breathless, face sallow with a circumscribed flush on left cheek. Expression cheerful. Left pupil larger than right, both responded well to light. Cough constant, rather dry, some muco-purulent expectoration in the mornings, dyspnœa constant, with marked exacerbation on exertion. Appetite and digestion poor, bowels irregular. On the right side of the chest a distinct prominence reaching its greatest elevation at the fifth interspace, midway between the sternum and nipple. Over right chest poor movement with flattening at the apex. At the apex there were evidences of a cavity, while from the third rib to the base and from the sternum to the anterior axillary line (over the area of prominence just spoken of) there was flatness, with absence of vocal resonance and fremitus; posteriorly, dulness with mucous râles and scattered friction sounds.

On the left, resonance was impaired at the apex, and respiration blowing, elsewhere normal. The apex beat of the heart was in the fourth interspace, one half inch outside of the left nipple. With the systole could be noticed a slight localized retraction of chest wall immediately inside the apex beat. Cardiac dulness extended from the right border of sternum two inches to the left of the sternum in the second interspace, two and a half inches in the third, and three and a half inches in the fourth. First sound weak and valvular. Second pulmonary sound accentuated and reduplicated. Liver dulness extended to the margin of the ribs anteriorly, continuous above with the flatness in the chest, posteriorly it was normal. A diagnosis of chronic plastic pleurisy, with consequent phthisis, was made, and the needle of an aspirator introduced about the middle of the area of flatness with negative results. The needle, as was shown after his death, must have punctured the liver. While in the hospital his condition remained much as it was on admission. A most interesting symptom was one connected with the pupils. They were usually unequal, sometimes the right, sometimes the left being the largest. When first seen the flush was limited to the cheek corresponding with the largest pupil.

March 15, 1883.—After a fall, he had a slight pulmonary hemorrhage and died in fifteen minutes, of apnœa, the heart continuing to beat after the respirations had ceased.

Autopsy (twelve hours after death).—The upper right lobe of the lung had been converted into a cavity with contracting walls. The upper part of the middle lobe had undergone marked fibroid change. The rest of the middle lobe and all of the lower were collapsed, congested, pushed back by the liver, which lay in front of them. The lung was universally adherent to the chest wall and diaphragm. The left lung had small masses of cheesy deposit at its apex, with the remaining substance healthy. It was less adherent than right. The heart was normal in size and position. The valves and great arteries were normal. What lends the case its chief interest was a complete absence of pericardial sac, the heart lying free in the left pleural cavity, its surface in contact with the left visceral pleura. Toward the apex there were a few fibrous bands connecting the heart with the lung and diaphragm (evidently the results of old pleurisy), while toward the base it was impossible to separate the heart and lung on account of the density of the adhesions. The serous covering of the heart was directly continuous with the visceral pleura. From the diaphragmatic pleura immediately beneath the heart was a fold of serous membrane one inch broad, three inches long, apparently an abortive attempt at the formation of a pericardial sac. No such formation could be demonstrated at the base, on account of adhesions between the heart and lung. The liver presented a curious departure from the normal position. The right lobe about its middle turned sharply upon itself, and, carrying the diaphragm with it, extended upward to the third rib. This accounted for the prominence and dulness in the chest before noted. The gall bladder was carried with the liver, its fundus pointing upward. The left lobe was very small and was not carried up with the right. On section the liver showed a nutmeg appearance. The other organs were normal.

DR. EDWARDS said that the misplaced liver had been punctured several times by the attending physician, while he was his resident. The idea was to see if there was any accumulation of fluid at the place on the chest where resonance was absent.

DR. ESKRIDGE said that he had a case in which he thought the pericardium was incomplete, but he came to the conclusion that it was normal; the anterior layer of the pericardium having been removed along with the sternum, to which it was afterwards found attached.

DR. FORMAD said that he helped to make the autopsy, and was perfectly sure that the parietal layer was absent. On removal of sternum, the heart was visible. The parts were very carefully investigated. The heart was seen lying in the left pleural cavity. On looking up the literature, he found in Virchow's *Archives* three or four such cases recorded. In this case there was some anomaly of the diaphragm and displacement of the liver. There was a healed phthisical cavity at the top of the right lung, and it is possible that in healing the scar may have caused the retraction of the diaphragm and ascent of the liver.

DR. HUGHES.—There are cases on record of this anomaly. There was no adhesion of the two layers of the pericardium, or of the pericardium and pleuræ. The cicatricial contraction of the lung would hardly have been sufficient to draw the liver so far out of position.

DR. MUSSER had had two cases in which marked retraction of the chest-wall occurred at each heart-beat. In these cases there were no pericardial adhesions. Clinically, he regarded retraction of the chest-walls as of no value in the diagnosis of pericardial adhesions.

DR. SEILER asked if Dr. Formad considered that the lung disease was tuberculous.

DR. FORMAD replied that he considered it a case of fibroid phthisis.

DR. HUGHES said that there was some cheesy material in the left lung, but not in the right.

DR. WOODBURY said that he saw in the Pennsylvania Hospital, two cases of absence of a part of the pericardium. One was congenital and the other was due to inflammatory action. In the specimens presented this evening, there may have been inflammatory adhesions early in life, and later on rupture of these and of the pericardium.

DR. WM. G. MACCONNELL exhibited microscopic specimens from a case of

SPINDLE-CELLED SARCOMA OF THE RECTUM,

operated upon by Dr. Levis.

J. M., æt. 43 years, machinist, three years ago noticed pain, uneasiness, and tenesmus of the rectum; was very constipated, and was compelled to resort to purgatives aided by enemata to secure an evacuation. Bleeding rarely occurred and was then due to the passage of hardened feces. Two years ago he was laid up with an inflammatory attack, as he said, in the neighborhood of the rectum, accompanied with attacks of retention of urine lasting for two to three days, which have recurred from time to time until the operation. At the end of the second year he first noticed a tumor, about the size of a walnut, which was detected by the patient's finger within the rectum. He habitually passed his finger through the anus to relieve the tenesmus, etc. The tumor was hard and steadily increased, until at the time of operation it was of the size of a fœtal head. It was globular, nodulated, and sessile. By bearing down he could protrude the tumor, when the parts presented the appearances of the fœtal head when distending the vulva. The tumor was soft and elastic, weighing nearly one and one-half pounds, and on microscopic examination proved to be a small spindle-celled sarcoma.

NEWS ITEMS.

CINCINNATI.

(*From our Special Correspondent.*)

The Relation of Physicians and Druggists.—The committees appointed by the Academy of Medicine, the Cincinnati Medical Society, and the Pharmaceutical Society, held a joint meeting on the 26th of September, to consider and, if possible, rectify the charges made against the druggists. The charges were: illegal prescribing, the advertising of patent medicines, the repetition of prescriptions without the physicians' order, and the substitution of other drugs for those prescribed. Others might have been added. The druggists based their defence upon the flimsy counter-charge that the physicians too often prescribe proprietary articles and sugar-coated pills. This was a feeble charge, because the profits on these proprietary goods and sugar-coated pills are so fair that the druggists aid the manufacturers in advertising, and it is but a few days since prescription blanks specifying a certain make of pills were distributed to the physicians by the retail druggists. A committee was appointed to draft rules to govern (?) both physicians and druggists.

The Health of Cincinnati still remains remarkably good. There were but sixty-eight deaths during the week ending October 27th, a rate of 12.29 per thousand of the population per annum. The report further states that twenty-one were "*infants* under five years of age."

Yellow Fever in Mexico.—Acting Assistant Surgeon Main, stationed at Brownsville, Texas, in a report to Surgeon-General Hamilton, under date of October 16, states that "Matamoras, Mexico, still continues a twenty day quarantine against Havana, but has reduced it to eight days against Vera Cruz. Tampico and Tuxham have adopted the same regulation." He says: "there is no yellow fever north of Vera Cruz on the gulf coast, and that it has disappeared as an epidemic at Vera Cruz; though a few sporadic cases of a non-malignant type occur in the city. Tabasco, Campeche, and Progresso continue to be nests for its propagation, and that Vera Cruz and latitudes south are the zones of its hibernation." He learns "that the fever has been much more fatal at Culiacan than previously reported on the 8th of October, the average mortality being three daily up to the 1st of October, and nine daily since that date. Less care seems to have been taken to prevent its propagation than was observed at other points of invasion, and the consequence is that the fever has spread through some twenty villages which lie between that city and the mountains. In like manner it has spread with rapidity northward, dealing death to the Indians. There is constant travel and traffic from these points to the frontier of Arizona and Upper California by land, and steamship navigation on the Gulf of California to the Colorado River (which empties its waters into the Gulf of California), thence to Fort Yuma on the Gila River, carries the disease northward. Some cases of fever of an unknown type (?) have already been reported in Arizona as having occurred among some travellers from the affected districts further south.

"At Mazatlan the fever still exists. Great complaint is made by the press against the doctors, and the nurses are said to be incompetent. At La Paz no provision whatever was made for the fever, notwithstanding a timely warning of the approaching danger was given, and the consequence is that the fever is spreading to the interior towns of Lower California on both east and west coasts (the State being a peninsula), and thus the fever may make its way by both coasts to San Diego, in upper California. At Mazatlan, where the same indifference was manifested, there had been, up to the 8th of October, 521 deaths from yellow fever; at that date the disease was rapidly diminishing, doubtless for lack of material. The fever still exists at Presidio and Concordia in the State of Linaloa, with an average mortality of three deaths daily for the past ninety days. In the State of Jalisco, the towns of Coraco and Gualian have suffered greatly, and it is reported that three thousand had fallen victims to the disease, with a mortality of three hundred and eighty-one in ninety-two days. Here, also, the fever is slowly but steadily decreasing. At the last-named place, the garrison consisted of 600 soldiers, 150 of whom died of yellow fever; and an opera company of 31 members lost 25 by death. Out of eight doctors, two died. In Manzanello and Mazatlan the fever is rapidly disappearing, as is also the case at points south of these two cities. It is north and west that the disease is travelling, and there is danger of its creeping into Arizona and Upper California, where the great system of railways which here begin to network the country may carry it into the east like a prairie fire." Dr. Main concludes his report of the devastating disease in Mexico by saying, "Few Mexican papers reach the frontier, very few people read them, and fewer still reach or are read or understood in the United States."

Sanitary Inspection of Passenger Trains.—Sanitary Inspector M. F. Price, stationed at Yuma, A. T., reports for the week ending October 20th, that he had "thoroughly inspected all west-bound trains carrying passengers, and that he found neither sick nor persons from points infected with yellow fever."

Sanitary Inspector W. E. Chesley, stationed at Benson, A. T., reports for the week ending October 20th, that no passengers had arrived from Mexico during the past three days, via. the N. M. & A. R. R.

The quarantines established at Yuma and Benson, Arizona, were raised on the 29th of October, and the Sanitary Inspectors relieved from duty on the 30th.

Public Health in Rio Janeiro.—Consular reports from Rio Janeiro, state that but two deaths from yellow fever occurred in Rio during the week ending September 22d. There were forty-one deaths from smallpox, and forty from pulmonary consumption for the same period. Fifty-one cases of smallpox and ten deaths, occurred at Colombo during the month of September.

Sanitary Inspection at Havana.—Sanitary Inspector Burgess at Havana reports, for the week ending

October 20, that bills of health were furnished vessels bound for United States ports after inspection by him as follows: Am. schr. "E. P. Church," for Key West; Brit. str. "Pensher," for Boston; Spanish str. "Castilla," for New Orleans; Spanish str. "Ana de Sala," for Savannah; Brit. str. "Monkseaton," for New York; Am. str. "Saratoga," for New York; Am. schr. "A. Kingsland," for Key West; Spanish bk, "Nueva Lantaro," for New Orleans; Am. str. "City of Pueblo," for New York. Of the above vessels, four only required disinfection, as the others were all clean, and remained in open bay, and did not approach the wharf. The Spanish bk. "Nueva Lantaro," bound for New Orleans, was forty-five days in port, twenty of them discharging at a suspicious wharf. While there, two of her crew had yellow fever, recovered, and sailed with the vessel. There were eighteen deaths from yellow fever at Havana during the week.

The Sanitary Cordon at Pensacola Navy Yard, ordered to be discontinued on the 25th October, was continued until the 1st November, at the urgent request of the Board of Health of Pensacola, seconded by the commanding officer of the yard.

Sanitary Inspection at Vera Cruz.—Sanitary Inspector Mainegra, in his weekly abstract of bills of health, issued at Vera Cruz, for the week ending Oct. 10th, shows that he inspected the following named vessels bound to U. S. ports. Strs.: "E. M. Sidbury," bound for New Orleans; "Explorer," for New Orleans; "City of Pueblo," for New York. All were found to be in good sanitary condition.

The Appointment of Surgeon-General of the Army.—The delay in making the appointment to fill the vacancy created by the death of Surgeon-General Crane is said to be due to the extraordinary pressure being brought to bear on the President and the Secretary of War in the interests of the different candidates for the office. It is expected, however, that the vacancy will be filled during the present week.

Cholera in Egypt.—The reappearance of cholera has revived the panic among the people in Alexandria, and the passengers on vessels from European ports are returning without landing. The fatal cases occur chiefly among the Europeans. Twelve deaths from the disease in Alexandria were reported on the 27th, and six on the 28th, of October. The disease has appeared at Mecca.

The Pasteur Mission, sent to Egypt to study the cholera, left for France on October 2d.

The Koch Mission.—It is stated that the Koch Mission, in its report on the cholera, has decided that the disease was imported into Egypt.

American Public Health Association.—The Eleventh Annual Meeting of this Association will be held at Detroit, Mich., from November 13th to 17th.

The Executive Committee will have rooms at the Russell House, and will hold a session each morning and evening at 9 o'clock.

The main subjects for discussion will be upon Sanitary Science, Malaria, Adulteration of Food, Physical Exercise, Vital Statistics, and Diseases of Animals, and will probably be taken up in the order named. It is expected that there will be two or more papers upon each subject, and from the most eminent sanitarians and physicians in the country.

All papers intended for presentation at the meeting must be in the hands of the Secretary or the Chairman of the Local Committee (Dr. Wm. Brodie) by November 10th, and if any have failed to notify the Secretary, or to furnish a synopsis of such paper, they must do so immediately.

Among the papers expected are the following:

Malaria; the Status of the Germ Theory as to it. By Dr. George M. Sternberg, Surgeon, U. S. A.

Malaria; the Paludal View and its Status. By Dr. A. A. Woodhull, U. S. A.

Malaria. By D. W. C. Wade, Holly, Michigan.

House Drainage and Plumbing. By R. Hering, C. E.

The Regulation of Sanitary Plumbing. By Dr. Raymond, Board of Health, Brooklyn.

Overhead Ventilation of Drains and Sewers. By Dr. Oldright, President of the Provincial Board of Health, Ontario, Canada.

The Identification of Disease by Vital Facts. By Elisha Harris, M.D., Secretary of New York State Board of Health.

Vital Statistics. By A. L. Gihon, U. S. N.

Foods; their Adulteration and Preservation. By Prof. A. R. Leeds, M.D.

Laws as to Foods. By Wm. K. Newton, M.D., Paterson, N. J.

Physical Exercises and their Laws. By Prof. J. M. Watson, N. J.

Systems of Physical Training. By Prof. Sargent, Cambridge.

A Comparative Study of Texas Cattle Fever. By Dr. Salmon, Agricultural Department, Washington.

Animal Diseases. By Dr. Partridge, South Bend, Indiana.

Present Indications as to Vaccination. By Eugene Foster, M.D., Augusta, Ga.

The Massachusetts Coroner Law. By Dr. Abbott, Wakefield.

Health Boards, their Sphere and Methods. By Dr. J. T. Reeve, Wheeling, West Virginia.

These and other papers seem to promise a meeting of unusual interest, and will help to forward sanitary art, as well as contribute to the science.

A number of the western railroads have reduced their rates to members. Information concerning them can be obtained on application to W. K. Muir, Chairman of Transportation Committee, Detroit, Mich.

An Enjoined Medical Work.—Judges Hare, Mitchell, and Fell, on Saturday last, in the Court of Common Pleas of Philadelphia, after a brief argument refused to dissolve the injunction which, in August last, Judge Mitchell, on the complaint of Drs. D. Hayes Agnew and Alfred Stillé, issued against Dr. Samuel M. Miller, restraining him from publishing and selling a medical work containing an "Epitome of Medicine, Surgery, and Obstetrics." The complaint was that the matter contained in the book which the defendant has been selling is made up of a summary of the lectures which those professors have been delivering to their students in the University of Pennsylvania. On behalf of the defendant, it was argued that an oral delivery of matter to persons who attended on invitation or otherwise became common property to those who were present and remembered the subject discussed. He said that the students had never been notified that the lecturers reserved a right of property in their lectures; but, on the contrary, were directed to take copious notes of the lectures, and that the complainants had, in point of fact, corrected in proof various articles for medical publications, such articles having been made up of reports of their lectures. The Court heard no argument on behalf of the complainants, Judge Hare saying that there was not sufficient shown to induce the Court to dissolve the injunction.

Washington Obstetrical and Gynecological Society.—At the First Annual Meeting, held October 19, 1883, the following officers were elected for the ensuing year:

President.—Dr. S. C. Busey.

Vice-Presidents.—Drs. W. W. Johnston and J. Taber Johnson.

Recording Secretary.—Dr. C. H. A. Kleinschmidt.

Corresponding Secretary.—Dr. Samuel S. Adams.

Treasurer.—Dr. G. L. Magruder.

A New Medical Journal.—In response to the expressed desire for a weekly medical journal in Scotland, the first number of the *Edinburgh Clinical and Pathological Journal* was issued on the 13th inst. The journal is under the joint editorship of Drs. Graham Brown, Cathcart, and Berry Hart.

Bequest to the British Medical Association.—The General Secretary of this Association has received from the executors of the late Dr. A. P. Stewart, the sum of £200, in augmentation of the Stewart Fund, which was founded by the lamented Dr. Stewart out of funds raised for the testimonial to him by public subcription. This is said to be the first legacy which has been left to the Association.

Honors to Thuillier.—The French colony at Alexander, desirous of perpetuating the name Louis Thuillier, has decided to erect a monument to his memory. A central committee of subscription has been formed at Alexandria, and sub-committees at Suez, Ismalia, Port Said, and Cairo.

Professor Du Bois-Reymond celebrated, on October 15th, his twenty-fifth year professorial jubilee. A bust of the learned professor was presented and a jubilee-volume of the *Archiv für Anatomie und Physiologie* was issued.

Professor Jaccoud.—By a Presidential decree from the Faculté de Médécine, of October 6th, Prof. Jaccoud has been transferred from the Chair of Internal Pathology to that of Clinical Medicine, made vacant by the death of Prof. Lasègue.

Health in Michigan.—Reports to the State Board of Health, for the week ending October 20, 1883, indicate that dysentery, scarlet fever, tonsillitis, consumption, and influenza have increased, and that diarrhœa, remittent fever, cholera infantum, and neuralgia have decreased in area of prevalence.

Including reports by regular observers and by others, diphtheria was reported present during the week ending October 20, and since, at sixteen places; scarlet fever at twenty-four places, and measles at six places.

Obituary Record.—The death of Prof. Da Costa Alvarenga, formerly Minister of Public Instruction in Portugal, and author of several works on heart disease, is announced.

NOTES AND QUERIES.

A PROTEST AGAINST THE USE OF THE METRIC SYSTEM IN PRESCRIBING.

To the Editor of The Medical News.

Sir: I desire to enter a protest against the use of the metric system of weights in practice, and of metric doses or prescriptions in communications to medical journals, with this one reservation or request, viz., if medical writers desire to show off their foreign education, let them put an English translation with their articles, so they will be easier to understand and require no time for translation by their American readers.

Now I submit these three points in regard to our own and the metric systems:

First. In calculating any given quantity of a drug desired in a prescription, it can be done quicker by our or the English weights—grs., ʒ, ℥, etc.

Second. There is less liability to err in writing the English, as a slight misplacement of a decimal would make a vast difference in the metric system. True, we are all liable to make mistakes, and many have been made under the old system, but a brief comparison will show any one that either druggist or physician is less liable to make any kind of mistake with the old method.

Third. It takes less time or space to write the old method.

I submit two or three prescriptions which are taken from a journal before me:

R.—Arbutini, ...	10 0 grammes.	
Aquæ dest., ...	100.0 "	M.

Now how much quicker, with less liabillty to err, can our own method be written. Again—

R		R	
Morph. muriat., .	.0060 grm.	Chloroformi, . .	ʒij
Tinct. cannab. Ind.	.0800 "	Glycerinæ, . .	℥ij
Chloroformi, .	.1350 "	Alcohol., . . .	ʒij
Ol. menth. pip., .	.0025 "	Spt. menth. pip., .	ʒij
Tinct. capsici, .	.0025 "	Acid. hydrocyanici dil., . . .	ʒij
Acid hydrocyanici dil., . .	.0170 "	Tinct. capsici. . .	ʒij
Alcohol., . .	.3000 "	Morph. sulph., . .	grs. viij
Glycerinæ, . .	.4570 "	Syr. simpl., . .	℥iij
	M.		M.

These two formulæ of anodynes are very much alike, and I am of the opinion that any American reader of your journal can take the one expressed in grains, drachms, and ounces, and find the amount of each, or any one, remedy contained in a given dose of the preparation, thus enabling him to alter the size of the prescription or any of its component parts, quicker express the terms, more briefly, with less liability to err, than he can with the other or metric prescription. These are reasons enough for a protest against the system, to say nothing of the great trouble and inconvenience of translating it by those of us educated in America.

Very respectfully,

James Orr, M.D.

Terrell, Texas, October 20, 1883.

SEPTIC FEVER.

To the Editor of The Medical News.

Sir: The editorial on septic fever in a recent issue of The Medical News reminded me that I had met some similar cases for which I was lacking a name. Scattered over the last four years I have had about a dozen or fifteen such patients, the major part of them being under my care during July and August of 1881. As a rule, but one member of a family was affected. In one instance, however, there were three patients in the same house. A boy, eight years old; the father, thirty-five; and a grandmother, age doubtful, but at least sixty-five. The latter recovered from the fever proper, but not from the exhaustion, dying some two months later.

The following is a fairly typical case. I was called, September 9, 1883, to see J. L. S., aged 33, a laborer in a saw-mill, dwelling-house close to a large pond of water, partially surrounded by a swamp. The pond filled with logs, some of which, with other debris, had been there for years. Water supply from a surface well in the immediate neighborhood. He complained of severe pains in the head, abdominal cramps, and aching of bones. Had indefinite chills for several hours. (In some instances the chill was very marked, followed by considerable fever with weak pulse, 112.) Slight diarrhœa—from two to four passages per diem, sometimes appearing tarry. In no other patient, however, was this latter noticed. By the third or fourth day the diarrhœa had ceased, and further movements of the bowels had to be induced by cathartics. Did not regularly take the temperature, but the highest recorded was 103°. The fever, virtually a continued one with slight irregular remissions, largely abated by the eighth day, though for a week longer he would occasionally have a return of it, lasting a few hours. The tongue during the first week was covered with a thick whitish fur; later, nearly clean. No tenderness over the abdomen; no eruption; no recurrence of the chill (an occasional exception in other cases); loss of appetite; not much thirst. In most of the cases much prostration, the mind torpid and apathetic. A slow convalescence and gradual return of appetite. Average length of attendance about fifteen days. Of two fatal cases, one was the old lady above alluded to, the other a man of thirty-eight, complicated with pneumonia. These outbursts invariably occurred on low, marshy land. We have no typical malaria originating here, and our altitude (2250 ft.) precludes that possibility, yet in these cases one is insensibly led to feel that he is combating a morbific cause very similar to it.

So far as my experience goes, the town has been relatively free from epidemics. Located on the highest point of Cowno Mountain, exposed to stiff breezes the year through, infectious diseases would seem to have little chance for propagation. But along the water-courses large swamps abound, and during very dry weather the water is evaporated, leaving then a mass of decaying vegetation exposed to the direct rays of the sun. I cannot positively affirm that the emanations naturally arising under these conditions are responsible for the trouble; but the night-air, heavily laden with such noxious vapors, enveloping the *tired* and sleeping workman—it was generally such that were attacked—would thus find a favorable field for operation, and the fact that in a large community no cases were observed except in such connection, is strong corroborative evidence. Respectfully,

GEO. H. RHOADS, M.D.

TOBYHANNA, PA., October 24, 1883.

SCHOOL FOR FEEBLE-MINDED CHILDREN.

To the Editor of THE MEDICAL NEWS.

SIR: It is often a very difficult matter for doctors to advise parents what to do with more or less feeble-minded children, especially in the matter of education. If not placed in such an excellent institution as that at Media, I do not know any school where they can be taught, for it is impossible to teach them in ordinary schools with other children.

Lately, Miss Margaret Bancroft, of this city, has felt especial interest in this defective class, and if she can obtain a sufficient number of pupils, she proposes to establish a day-school for their education, giving them then, at the same time, the advantages of home-life.

Miss Bancroft has had many years' experience as a successful teacher, and she is known to me personally as a woman of the highest character, and is eminently fitted for just such a benevolent work. I am permitted also to use the names of Dr. Andrew Nebinger and Dr. J. Solis Cohen as additional references as to her fitness.

She proposes to have one teacher for every five scholars, so that each one shall have that individual attention necessary with such pupils. Any peculiar talent, no matter how slight, or any personal taste, will thus be used as an educational lever. The kindergarten system, so peculiarly fitted to develop the powers of such pupils, will be prominent in her school-work, and she is so fortunate as to have as an associate a graduate of Mrs. Van Kirk's well-known school for kindergartners.

Any one desirous of further information may address Miss Bancroft at No. 1007 South Twelfth Street, Philadelphia.

Very truly yours,
W. W. KEEN, M.D.

1729 CHESTNUT STREET, PHILADELPHIA, PA.,
October 26, 1883.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM OCTOBER 22 TO OCTOBER 29, 1883.

MOORE, JOHN, *Lieutenant-Colonel and Assistant Medical Purveyor.*—To be relieved from duty as Medical Director, Headquarters Department of the Columbia, to proceed to San Francisco, California, and assume charge of the medical purveying depot in that city.—*Par. 10, S. O. 243, A. G. O.*, October 24, 1883.

HORTON, S. M., *Major and Surgeon.*—Leave of absence for one month, with permission to apply for an extension of three months.—*Par. 6, S. O. 216, Department of the Missouri*, October 20, 1883.

WOLVERTON, WM. D., *Major and Surgeon.*—Granted leave of absence for one month.—*Par. 6, S. O. 201, Department of the East*, October 24, 1883.

BARNETT, RICHARDS, *Captain and Assistant Surgeon.*—Assigned to duty at Columbus Barracks, Columbus, Ohio.—*Par. 1, S. O. 240, A. G. O.*, October 20, 1883.

MANS, LOUIS M., *Captain and Assistant Surgeon.*—Assigned to duty at Fort A. Lincoln, D. T.—*Par. 4, S. O. 180, Department of Dakota*, October 15, 1883.

MERRILL, J. C., *Captain and Assistant Surgeon.*—Granted leave of absence for one month.—*Par. 7, S. O. 201, Department of the East*, October 24, 1883.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE, FROM JULY 1 TO SEPTEMBER 30, 1883.

BAILHACHE, P. H., *Surgeon.*—Detailed as member of Board to Examine Candidates for Promotion, August 23, 1883. Detailed as Surgeon-in-Charge, Cape Charles Quarantine Station, September 5, 1883.

MILLER, T. W., *Surgeon.*—Granted leave of absence for twenty-five days, August 31, 1883.

WYMAN, WALTER, *Surgeon.*—Detailed as member of Board to Examine Candidates for Promotion, August 23, 1883.

LONG, W. H., *Surgeon.*—Granted leave of absence for twenty days, September 25, 1883.

SMITH, HENRY, *Surgeon.*—Directed to take charge of Quarantine Service at the Capes, July 29, 1883.

STONER, G. W., *Passed Assistant Surgeon.*—Granted leave of absence for thirty days, August 24, 1883. To inspect the relief stations along the coast of Maine, September 29, 1883.

GOLDSBOROUGH, C. B., *Passed Assistant Surgeon.*—Granted leave of absence for thirty days, August 29, 1883.

BANKS, C. E., *Assistant Surgeon.*—Relieved from duty at Portland, Oregon, and to report to the Surgeon-General at Washington, July 10, 1883.

CARMICHAEL, D. A., *Assistant Surgeon.*—Granted leave of absence for ten days, August 31, 1883.

PECKHAM, C. T., *Assistant Surgeon.*—To proceed to Portland, Maine, for temporary duty, August 25, 1883.

DEVAN, S. C., *Assistant Surgeon.*—To proceed to Portland, Oregon, and assume charge of the Service, September 11, 1883.

KALLOCH, P. C., *Assistant Surgeon.*—To proceed to Philadelphia, Pa., for temporary duty, July 25, 1883. To rejoin his station (New York), July 31, 1883.

YEMANS, H. W., *Assistant Surgeon.*—Relieved from duty at Sitka, Alaska, and to proceed to Portland, Oregon, for temporary duty, July 10, 1883. To proceed to San Francisco, California, reporting for duty to Surgeon Vansant, September 11, 1883.

GLENNAN, A. H., *Assistant Surgeon.*—To remain at Norfolk, Va., until further orders, July 29, 1883.

WASDIN, EUGENE, *Assistant Surgeon.*—To proceed to New Orleans, La., for temporary duty, August 27, 1883. To proceed to Mobile, Ala., for temporary duty, August 27, 1883. To rejoin his station (New Orleans) as soon as practicable, September 25, 1883.

PROMOTIONS.

GUITERAS, JOHN, *Passed Assistant Surgeon.*—Promoted and appointed Passed Assistant Surgeon, by the Secretary of the Treasury, from September 1, 1883. August 31, 1883.

WHEELER, W. A., *Passed Assistant Surgeon.*—Promoted and appointed Passed Assistant Surgeon, by the Secretary of the Treasury, from September 1, 1883. August 31, 1883.

RESIGNATION.

O'CONNOR, F. J., *Assistant Surgeon.*—Resignation accepted by the Secretary of the Treasury, to take effect August 1, 1883. August 2, 1883.

APPOINTMENT.

WASDIN, EUGENE, M.D., of South Carolina, having passed the examination required by the Regulations, was appointed an Assistant Surgeon, by the Secretary of the Treasury, August 2, 1883.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. XLIII. SATURDAY, NOVEMBER 10, 1883. No. 19.

ORIGINAL LECTURES.

HÆMATURIA OF THREE YEARS' STANDING,

PROBABLY OCCASIONED BY A VILLOUS TUMOR OF THE VESICAL SURFACE OF THE PROSTATE AND POSTERIOR WALL OF THE BLADDER.

A Clinical Lecture.

BY JOHN ASHHURST, JR., M.D.,
PROFESSOR OF CLINICAL SURGERY IN THE UNIVERSITY OF PENNSYLVANIA.

(Reported by Louis J. Lautenbach, M.D.)

GENTLEMEN: The patient who comes before us this morning is a man who presented himself at the Medical Out-patient Department, and who has been referred to me by Dr. Musser. The case is interesting as concerns the question of diagnosis. The patient has a very anæmic appearance; in fact, he has more than this, he has a cachectic appearance—such an appearance as is usually connected with grave visceral disease.

His history is that for the last three years the urine which he passes has been very thick and red; it is now, as you see by this specimen, full of blood, with a number of clots. At times the clots, during micturition, become wedged in the urethra, forming an obstruction, and causing for the time being retention of urine, and it often occurs that it is only by prolonged straining that the passage is cleared. Sometimes the urine is clear, as far as blood is concerned, but there is always a large deposit on standing. It is evident that this hæmaturia must have a definite cause, and it is this which we will endeavor to determine. The presence of blood in the urine may signify a great many different things. The blood may come from the kidney, being associated with some disease of that organ; in this case, unless there were very free bleeding indeed, it would not give such a bright color as we have here. The color of the urine when bleeding occurs from the kidney is usually a smoky hue. We notice this "smoky urine" frequently in the Bright's disease following scarlet fever. Unless the bleeding from the kidney is very profuse, we do not have the tint deep enough to be even a decided red. Sometimes from the appearance of the clots in the urine, we can get an idea of where the bleeding comes from. If the bleeding comes from the kidney, the clot, when floated out in water, may assume the shape of the pelvis of that organ; but in order to allow a clot of this size to pass, the ureters must be much dilated. Sometimes we find a long, thin clot, assuming the shape of the inside of the ureter itself; and then it is a fair inference that the bleeding comes from the ureters. Here, in this case, however, the clot has no definite shape.

Besides these two sources, the blood may come from the bladder itself. If in examining these clots we find that they are soft and easily torn, showing them to be recent, and that they have no definite shape, they may probably come from the bladder. Vesical hemorrhage may be due to the presence of stone, but this is not very usual in adults, occurring more frequently in children. Especially is stone liable to occasion hæmaturia when the stone is composed of oxalate of lime or when its surface is made up of sharp crystals of uric acid, which sometimes form little prongs or projections. The bleeding from calculus is increased by taking exercise, and especially by horseback riding, or by driving over a rough road. Stone is, however, much less frequently the cause of bleeding than would at first be supposed.

Vesical bleeding, again, may come from acute inflammation—cystitis—causing hemorrhage just as we see it produced in other inflammations of mucous membranes, as in very severe sore-throats, and in the early stages of pneumonia. Were this patient suffering from acute cystitis, however, he would have fever, and his general condition altogether would be different. He would beside have intense pain in the region of the bladder, nor could the disease have lasted as long as he has had the hemorrhage. Other causes of hemorrhage from the bladder are villous growths, which are very vascular, bleeding upon the slightest touch, or even without any external injury, simply from excessive congestion.

Carcinoma of the bladder as a primary affection is excessively rare. I have seen but one case of it, and in that case there was at no time any hemorrhage, the patient dying before the growth had involved the vesical mucous membrane. Were this a case either of carcinoma or sarcoma of the bladder, we would probably feel a decided tumor immediately above the pubis, but here there is no tumor to be felt. Another source of vesical bleeding may be tubercle of the bladder, which, however, is rare, and probably never exists except in cases of general tuberculosis.

Hæmaturia again may be occasioned by disease of the prostate or of the urethra. Were the hemorrhage caused by disease of the urethra, the blood would come before the urine. Should the hemorrhage come from a diseased prostate, while some blood would still precede the urine, another portion would be more thoroughly mingled with the urine than would be the case were the bleeding dependent upon urethral disease, but it would not be so intimately mixed as we find it in disease of the bladder. Here the blood is tolerably well mingled, and yet the clots come before the urine, as the patient tells us that, when he first attempts to pass water, they sometimes prevent urination by their lodgement somewhere along the course of the urethra.

In this case, then, the diagnosis narrows itself down to either some morbid condition of the prostate, or some morbid condition of the neck of the bladder, probably a villous growth.

The prostate may be the seat, either of some malignant growth or of simple enlargement. Hemorrhage from the prostate does not necessarily imply the existence of malignant disease. I remember a case in which the catheter was introduced, where there was an enlarged prostate, and in which pure blood flowed in a stream through the instrument. The patient dying some time afterwards, the autopsy revealed a simple hypertrophy of the gland.

This man had an instrument passed two or three weeks ago, and it gave him a great deal of pain; I have therefore promised him to pass the sound with which I intend to explore his bladder as gently as possible, and, if its use should prove very painful, to desist from its employment. On making a rectal examination without the use of the sound, I find that there is certainly no very great enlargement of the prostate in the direction of thickness; certainly not more than we frequently find at this age (forty-eight years). Now, on introducing this sound, which is a very small one, I find that there is a very irritable condition of the urethra, this being first noticed just within the glans.

Having introduced the sound, I will again examine the prostate and neck of the bladder by placing a finger in the rectum. I know by the way that the instrument went in that there is enlargement of the prostate, and this is also shown by the position of the sound, deeply buried in the urethra, while the handle only is visible. There is no marked enlargement in the direction of thickness, but there is decided increase in the long axis. It is very probable that there is here a villous tumor involving both the neck of the bladder and the vesical surface of the prostate, which, as we know, are frequently similarly involved.

While the instrument is in the bladder, I will take the opportunity to ascertain, if possible, whether a stone is present. I find no stone, but cannot make a thorough exploration, as every movement of the sound is met with considerable resistance, and gives the patient pain.

Our diagnosis, as far as it can be made, is that, besides the obvious prostatic hypertrophy, there is a tumor involving the surface of the prostate, and probably also the posterior wall of the bladder. Of the precise nature of the tumor we cannot be certain. By microscopic examination of the urine, we might possibly find fragments of a villous tumor; but if such fragments were not found, still their absence would only be negative evidence, and would not prove that the tumor was not of that character. The growth is probably neither a scirrhus nor a sarcoma, both of these being attended with a greater degree of hardness. If it were possible, moreover, for either of these diseases to exist for three years without destroying its subject, we would probably find other parts also involved; but there is not the slightest evidence of this here. The growth is probably a villous tumor, or perhaps a papillary form of epithelioma; the exact diagnosis could be made by the microscope alone.

As regards treatment, the tendency in recent years has been to resort to an operation in these cases, to confirm the diagnosis; and, if a tumor is found, to endeavor to remove it. One operation which has been employed is the opening of the bladder above the pubis; another is to make the incision as in lateral lithotomy. Either of these operations would be attended with considerable danger. Suprapubic cystotomy is always accompanied with risk, and the lateral operation, requiring division of the prostate, would in a case like this be followed by very free bleeding. A better operation, under these circumstances, would be that recommended by Sir Henry Thompson. A median incision is made in the perineum, opening the urethra in front of the prostate; this incision would not involve any part of the tumor, but would allow the introduction of a finger to explore the bladder, and, if a tumor were found, probably a considerable part could be scraped away with a small scoop or curette. A palliative mode of treatment, which, however, would be contra-indicated here by the very irritable condition of the urethra, would be the frequent injection, through the catheter, of nitrate of silver solutions, or other astringents, of gradually increasing strength.

THE USE OF CASCARA SAGRADA IN HABITUAL CONSTIPATION.

By HERBERT C. ROGERS, M.D.,
SURGEON TO THE LONG ISLAND COLLEGE HOSPITAL DISPENSARY.

Cascara sagrada was brought to professional notice about the year 1878. In small doses I find it has a tonic action. It gives tone to muscular tissue, and exerts some influence on the liver. In large doses it is a purgative, acting specially on the large intestines. It increases the intestinal secretions, and also the peristaltic action of the bowels. The extract of belladonna and purgatives increase its action. I have, during the past year and a half, prescribed cascara a great many times, and have found it a reliable and valuable medicine. It is chiefly in chronic constipation that I prescribe cascara. In habitual constipation, it is one of the very best laxatives we possess. To persons of a sedentary occupation, with constipation and general sluggishness of the bowels, the administration of the fluid extract of cascara sagrada, in small doses, will generally be very beneficial.

I usually give the fluid extract in from twenty to thirty minims, in a little coffee, night and morning, until it begins to act, when I diminish the dose, and also omit giving it in the morning. Some persons may object to taking the fluid extract on account of its bitterness. To such persons I am in the habit of giving the cordial of cascara, and I think that it is also better suited for children and babies. The only reliable preparation that I have been able to find is that made by Parke, Davis & Co., of Detroit, Mich. Their preparations of the fluid extract and cordial have given me entire satisfaction.

The following are a few of the cases in which cascara has been used with success:

Case I.—Chas. Z., aged 9; U. S. From birth he appeared to be a strong, healthy baby. When eighteen months old, he had summer trouble, which left him in a weakened condition. At the age of five years, he had what the doctors called typhoid fever; he was sick two months. Since that time he has had more or less trouble with his bowels. He would go a week without any movement; then, after taking a cathartic, he would suffer from a diarrhœa, which would last a week or ten days, and would leave him in such a weak condition as to compel him to go to bed.

March 3.—Present condition: loss of appetite, cachectic, with yellow, anæmic complexion; pain over abdomen; bowels distended; has not had a movement since February 28, although the mother has given him several cathartic medicines. I told the mother to give the patient a sponge bath, night and morning; to commence with warm water, and gradually lower the temperature until the thermometer indicated 60° Fahr.; to give him milk and lime-water. Ordered the fluid extract of cascara sagrada in fifteen minim doses, in a little coffee, every three hours, till the bowels moved freely; also to take thirty minims of dialyzed iron three times a day.

5th.—Mother reports that the boy's bowels have moved three times since the morning of the 4th, the last time very freely. Told her to keep on as before, with the exception that she is to give of the cascara fifteen minims night and morning, and report to me in one week.

13th.—Patient called with his mother this morning at my office. He looks better, and says he feels better. The bowels have moved two or three times a day since last note; appetite improved; sleeps better at night; complained of the bad taste of the medicine, and asked me if I cannot give it in pill form. If I cannot, he will try and take it. Will not give it up, as he says it is the only thing that has helped him since he began to suffer from this trouble. I gave the cordial in place of the fluid extract.

April 2.—Met the patient on the street. His mother says he was never better; his bowels move once or twice each day; appetite is good; has not taken any of the medicine for the last week. I advised the mother to give him the medicine whenever he showed signs of a return of his old trouble.

Here was a case of constipation in a boy which had lasted nearly four years. He had taken various remedies and combinations with little or no success. I must confess I had but little faith in the preparation. The result, however, has been most gratifying, both to the parents of the child and to myself.

CASE II.—Harry O., male, aged ten months; has suffered from constipation ever since birth. The mother has tried several domestic remedies, with but little success. I told the mother to give him thirty minims of the cordial of cascara sagrada night and morning, every other day, until his bowels moved naturally. A few days later, the mother called at my office, and said that the medicine not only helped baby, but herself also, who was troubled with constipation.

CASE III.—Frank B., aged 50, called at my office July 6. He has been on a *spree* for the last week. He has been unable to keep anything on his stomach for the last two days. Bowels have not moved for nearly a week; muscles flabby and tremulous. Ordered fluid extract of cascara for his constipation, and ten minims each of tr. capsicum and tr. of nux vomica in Vichy water three times daily—the cascara to be taken night and morning.

July 7.—Patient says he is better; vomited the first two doses of the capsicum and nux vomica; has been able to retain the cascara. Bowels have not moved, although he has some pain. I told him to continue as before, and report to me in two or three days.

10th.—Patient called at my office this morning. He said that his bowels had moved freely on the afternoon of the 7th. Has been taking one dose of cascara daily since. I told him to omit the medicine as long as his bowels moved freely once a day, but to continue on with the nux vomica and capsicum for another week. Met patient a few days ago. He told me he never had taken such medicine; that both he and his wife had been great sufferers from constipation, but that the medicine had cured them completely.

CASE IV.—*May 3.*—Was sent for to see H. R., a young lady, aged 24, suffering from obstinate constipation, which had continued for a period of over two weeks. She had been treated previously to my visiting her by purgatives, which produced pain and vomiting, and a feeling of general uneasiness, together with ineffectual efforts to have an evacuation. Ordered milk and lime-water and one teaspoonful of cordial of cascara every three hours, until the bowels begin to move.

4th.—Patient's bowels have moved once since yesterday; is suffering some pain; has not vomited since last evening. Advised the same treatment to be continued as was ordered yesterday.

5th.—Patient says she feels better. Since the afternoon of the 4th, her bowels have moved four times, the last time very freely. I told the patient to omit the cascara as long as the bowels moved once daily, but to resume it whenever she went over one or two days without a movement.

A family, consisting of father, mother, and two daughters, one thirty, the other seventeen, all sufferers from constipation, took cascara with the best of results.

I might go on naming case after case, but I think the few above quoted are sufficient.

It is well to remember that the medicine is to be used in small doses, and special attention should be given to see that the preparation is reliable. I have been disappointed two or three times in the use of what proved to be poor preparations.

ON THE VALUE OF A LOTION OF SULPHIDE OF ZINC IN THE TREATMENT OF SUPERFICIAL LUPUS ERYTHEMATOSUS.[1]

BY LOUIS A. DUHRING, M.D.,
PROFESSOR OF THE DISEASES OF THE SKIN IN THE HOSPITAL OF THE UNIVERSITY OF PENNSYLVANIA.

I DESIRE to direct attention to the value of a certain zinc sulphide lotion in the treatment of some forms of lupus erythematosus. It may here be stated that I have found it useful in what may be termed the inflammatory superficial form of the disease, occurring either in discrete or in confluent patches of recent or of long duration. Where the morbid process has settled deeper in the cutaneous structures, and where there is but little tendency to variation from month to month, other more stimulating remedies will prove more serviceable. Every practitioner has doubtless encountered instances of this disease in which the usual, for the most part stimulating, remedies have been of no value. In the majority of these cases they will be found to be positively injurious, inflaming the skin, and causing the diseased areas to spread. Such has been my experience. Any new remedy or formula, therefore, which for these peculiar cases offers hope of relief, must prove welcome to both patient and physician. The striking good which has followed the use of this remedy in several cases that have recently been under my care induces me to present this note. I do not wish to claim for it any specific power over the disease, nor to say that it will cure. I merely wish to speak of it as a highly useful remedy, which in some cases has proved the only application that has at all benefited the disease. I was first led to prescribe it because of the service it had rendered in the treatment of seborrhœa of the face.

---

[1] Read before the American Dermatological Association, at the Seventh Annual Meeting, August 29, 1883.

The lotion consists of equal parts of sulphate of zinc and sulphuret of potash, in the strength of from five to fifteen grains each to the ounce of water, together with the addition of a variable quantity of alcohol. Ether may also often be added with benefit. I am in the habit of using the following formula: Take of sulphate of zinc and sulphuret of potash each thirty grains; rose-water, three fluidounces and a half; alcohol, three fluidrachms. If this strength agree with the skin, the two active ingredients may be increased to the amount of a drachm each to four ounces of the fluid. More alcohol may also be used, to the extent of one ounce to three of water. A few minims of glycerine to the ounce may sometimes be added with advantage. The lotion, which contains a light-grayish, pulverulent sediment, should be shaken before using, and applied lightly to the part for from five to twenty minutes by means of a sponge or a rag mop, allowing the sediment to adhere to the surface. The immediate effect is usually cooling and soothing. The application may be repeated two or more times in the twenty-four hours. The skin should first be cleansed of scales by means of soap, the milder soaps sometimes proving more beneficial than the stronger soft soaps.

The following note by Dr. L. Wolff, pharmaceutical chemist, of Philadelphia, explains briefly the chemistry, as well as the best method of making the compound.

"When equal parts of zinc sulphate and potassium sulphide are mixed together in the presence of water, a double decomposition takes place, resulting in zinc sulphide, potassium sulphate, and precipitated sulphur. The zinc sulphide thus formed is a hydrate, and of a white, pulverulent appearance.

"When the two are to be combined in a lotion with water, they are best dissolved separately in half the prescribed quantity of water each, and then the two solutions poured together. When the liquid, however, consists of alcohol, or alcohol and ether, the two salts must be rubbed down fine first, whereupon a small quantity of water is added, just sufficient to allow the reaction to take place, which is known by the white appearance of the mass; the alcohol is then added, and lastly the ether.

"As there are five potassium sulphides, according to the quantity of sulphur in the combination, the results will vary as to the amount of precipitated sulphur present. Of these sulphides, the trisulphide and the pentasulphide are the most common. The potassa sulphurata of the United States and British Pharmacopœias are, according to their composition, principally trisulphides, and if these are employed, two equivalents of sulphur will be formed, as shown in the following formula:

"$K_2S_3+ZnSO_4+H_2O. = K_2SO_4+ZnS.H_2O+2S.$

"Again, if potassium pentasulphide is employed, an excess of four equivalents of sulphur would be precipitated, as follows:

"$K_2S_5+ZnSO_4+H_2O = K_2SO_4+ZnS.H_2O+4S.$"

I shall now briefly refer to three cases in which the beneficial effects of the lotion were striking:

About a year ago, Mr. W., aged 45, presented himself to me, exhibiting six or eight dull-red, chronically inflamed, slightly scaly, irregularly rounded, ill-defined patches of lupus erythematosus. The lesions were the size of peas and small beans, and were scattered over the face. They had existed eight months, and were subject to considerable variation. The patient had, at different times, been under the influence of arsenic, mercury, and iodide of potassium, and locally had used mercurial ointments—all without benefit. I prescribed an ointment of precipitated sulphur, one drachm to the ounce, which in a few days caused heat, and increased redness. Subsequently, tar ointment; oil of cade; liquor carbonis detergens; an ointment of calomel, thirty grains to the ounce; ointments of pyrogallic acid, thirty and sixty grains to the ounce; an ointment of iodoform; tincture of iodine, were all used, with the result that, in every instance, the disease was made worse. The zinc sulphide lotion was now ordered, and gave almost immediate relief, the skin, in the course of a few days, becoming paler and less scaly, accompanied by a decrease in the subjective symptoms. Improvement continued under the use of the remedy, but, as cure did not follow, other applications, including solution of chlorinated soda, acetic acid, lead and mercurial plaster, alcoholic solution of salicylic acid, carbolic acid, ether and rhigolene spray, and the use of the curette, were resorted to. All proved of not the least value, while many were injurious. The zinc sulphide lotion was the only remedy that in any degree favorably influenced the disease. Some of the lesions disappeared under its use, and all were benefited.

Another case, of the butterfly form of the disease, in a gentleman from Virginia, forty-six years of age, of two years' duration, who has lately been under treatment, was very markedly benefited by the remedy, other applications having previously failed to influence the disease favorably.

A third case may be mentioned, that of a man, aged 30, who was admitted to the clinic of the University of Pennsylvania a few months ago with an unusually extensive development of the disease of five years' duration, involving the greater part of the face. The erythematous element was marked, there being but very little sebaceous glandular involvement.

In the course of a week, a remarkable change for the better took place under the lotion; in three weeks the improvement was even more decided, so much so that the patch was broken up here and there, and apparently sound skin was in some places beginning to show itself.

AN EXTRAORDINARY CASE OF POPLITEAL ANEURISM.

By J. F. HEUSTIS, A.M., M.D.,
PROFESSOR OF SURGERY, MEDICAL COLLEGE OF ALABAMA, MOBILE.

FRANK R., a mulatto man, thirty-one years old, while lifting heavy timber, in June, 1882, felt something give way in his ham, and soon after noticed a small pulsating tumor (no larger than an English walnut, at first) in the popliteal space. In August (1882) it began to grow rapidly; and in another month became so large, and caused so much pain, that he had to give up work and take to his bed.

When he was first seen by me, in April, 1883, the tumor not only filled the popliteal space, but bulged so largely as to cause great tension. It was elastic, and presented to the touch an undecided feeling of fluctuation, but no pulsation on pressure or manipulation; but when the ear was applied to it, a strong, deep *bruit* was heard.

The tumor was so large and tense, that it was feared that, if ligature of the femoral artery were resorted to immediately, gangrene of the limb would result; and it was determined to apply compression for a while; not so much with the expectation of effecting a cure by it, but to establish a sufficient collateral circulation to maintain the vitality of the limb after ligature.

The means employed for keeping up compression were very simple and efficient. A small solid India-rubber ball, set into and screwed fast to a square block of wood, was placed upon the artery in Scarpa's triangle, and a small tin can (holding about a quart) partly filled with shot was set on it and held in place by the patient. The quantity of shot in the can was measured by the disappearance of the bruit. As soon as the pain caused by the pressure became severe the ball was moved a little higher or lower, and in this way continuous and steady pressure was kept up during the day, but left off at night. For seventeen days compression was kept up (and very seldom could any *bruit* be heard while the ball and shot were in place), but at the end of that time the blowing sound could be heard as distinctly as at first.

A few days after discontinuing compression, the femoral artery was tied at the apex of Scarpa's triangle, and immediately all sound disappeared. But there was no diminution in the size of the tumor, nor did it solidify. And although the man was easier than before the operation, he still suffered severe pain at times.

As the pain continued, the size of the tumor remained undiminished, and the feeling of fluctuation remained, the idea that the tumor had suppurated grew stronger, and it was determined to lay it open and turn out its contents.

Six weeks after the ligature of the femoral artery, the operation of cutting open the tumor was performed. To guard against hemorrhage, Esmarch's rubber cord was applied a little above the tumor, and an incision about three inches long was made into it. At first, only soft black coagulated blood was removed (which had given the sensation of elasticity and fluctuation), but the coagulæ became firmer and firmer in the deeper part, until they became as firm as flesh and strongly adherent. So strongly did the deepest layer adhere, here and there, it was thought best not to tear it away, for fear of hemorrhage or other damage. There was no sac, and it was evident that it was a diffused aneurism. Circumscribed at first, and becoming diffused by bursting, reaching up and filling all the space between the flexor tendons of the thigh above, and down to the bulge of the calf below; and the mass of blood, coagulating, effaced the distinctive sign of an ordinary aneurism, viz., expansive pulsation. The quantity of coagulated blood and solidified fibrin removed amounted to apparently a quart. After the clearing out of the whole popliteal space a great cavity was left reaching to the bone, which could be felt at its bottom. This was syringed out with carbolized water (ʒij to the Oj) and the rubber cord was removed. There was no hemorrhage. A large wisp of horsehair soaked in the same carbolized water was inserted, doubled on itself to the bottom of the cavity, and the ends left out for drainage. Over this a thick layer of marine lint and a bandage were applied.

No trouble of any kind followed the operation—no hemorrhage, inflammation, or suppuration. Contraction and healing went on rapidly, with as little disturbance as possible by repetition of dressings, they being changed only when soiled. The cavity was syringed at each change of dressing with a solution of permanganate of potash in chlorinated soda (ʒj potass. permang. dissolved in liq. sodæ chlor. ℥iv, and ℥ss of this diluted with water Oss at time of using), and oakum soaked in the same was substituted for the marine lint. This was kept up until the cavity and wound closed, which was in about a month. The man is now (October, 1883) quite well, and is at work. No thickening, induration, or enlargement marks the site of the formidable aneurism, and there is only a tender cicatrix where it was laid open to remind him of the danger he has passed.

The points of interest in this case are, 1st, the obscurity of the signs of aneurism, accounted for by its becoming diffused, and consequently having no sac, the large quantity of blood suddenly extravasated and coagulating acting as a buffer to prevent pulsation, and having no cavity to receive an expansive impulse. 2d, the same cause, viz., diffusion, preventing any benefit from compression. 3d, the absence of hemorrhage upon removal of all the coagulated blood and hardened fibrin filling up the hollow of the ham. 4th, the antiseptic treatment pursued kept the large cavity left from suppurating, and the system free from all disturbance, and conduced to progressive and painless healing; and, 5th and lastly, the great gain of time in restoring the limb to its full usefulness by the removal of the tumor, which was too large ever to have been absorbed, and would have continued to produce lameness by its presence.

MEDICAL PROGRESS.

PORRO OPERATIONS.—DR. BONI recently performed this operation at the St. Nicholas Hospital at Arezzo, for grave rachitic deformity, profuse hemorrhage coming on from rupture of the membranes and threatening life. The patient was in excellent condition on the seventeenth day after the operation.

PROF. ANTONIO MARTINO has also performed the operation quite recently, at the Maternity Hospital in Naples, for rachitic deformity. Both mother and child were saved.—*L'Indipendente*, Oct. 15, 1883.

REPORT OF THE GERMAN CHOLERA COMMISSION.—DR. ROBERT KOCH, Chief of the German Scientific Commission, has presented a preliminary report, dated Alexandria, September 17, 1883 (*Deutsche med. Wochenschr.*, October 17, and *Med. Times and Gazette*, October 20, 1883), in which he says:

"As the cholera epidemic was already rapidly subsiding when the Commission arrived in Egypt, it was hardly to be anticipated that that country would supply the material necessary to complete the investigation. And, moreover, as the period when an epidemic is on the wane is hardly the best suited for inquiry into its etiology, the original plan was changed, and it was decided to make only the preliminary researches in Egypt, with the view, in case the epidemic should extend to Syria, of rectifying them in places which had been but recently attacked by the cholera, and which would therefore be likely to afford a favorable basis for the inquiry.

"The first portion of this plan has hitherto been carried out with very satisfactory results, for, during its stay in Alexandria, the Commission has found opportunity to collect the material necessary for preliminary inquiry.

"The material so far used for the research has been obtained from twelve cholera patients, and from ten cadavers dead of the disease. Of the patients, nine were under observation in the Greek Hospital, two in the German, and one in the Arabian. In all cases the symptoms corresponded in every particular with those of true Asiatic cholera. Portions of the blood, of the vomit, and of the dejections of these patients were examined. As it very soon became evident that the blood was free from micro-organisms, and the vomited matters contained comparatively few, while in the dejections they were found in considerable numbers, the last-named were chiefly used in the inoculation experiments on animals.

"Although the quantity of post-mortem examinations was not large, we were happily favored in obtaining from them extremely valuable material for the preliminary inquiry. The autopsy was made in most cases immediately after death, or at the outside only a few hours later. The changes which putrefaction produces in the organs, and with especial rapidity in the bowel, and which render microscopical examination of these parts most extremely difficult, could under these circumstances be excluded with certainty. I would lay especial stress upon this fact, because in other countries it would be scarcely possible to obtain material so well adapted for microscopical examination. The pathological appearances, like the symptoms during life, left no doubt that we had to deal with true cholera, and not, as was maintained in several quarters, with a so-called choleriform or choleroid disease.

"No organized infective material could be demonstrated in the blood, or in those organs which, in the case of other infective diseases, are usually the seat of micro-parasites, viz., the lungs, spleen, kidneys, and liver. In some cases bacteria were found in the lungs, but these, as we saw from their peculiarities of form and position, had nothing to do with the peculiar disease-process, but had found their way into the lungs by the inspiration of ejecta from the stomach.

"The contents of the bowel and the dejections of the cholera patients contained extraordinary quantities of micro-organisms belonging to the most different varieties, none of which appeared in preponderating proportion. There was also an absence of other indications of a relationship to the disease-process.

"The bowel itself, on the contrary, gave most important results. In all the cases except one, which had died of a consecutive disease several weeks after recovery from cholera, bacteria of a definite form were found in the coats of the bowel. These bacteria are rod-shaped, and belong therefore to the bacilli; in size and shape they most nearly resemble the bacilli found in glanders. In those cases in which the bowel showed the slightest changes to the naked eye, the bacilli were found to have penetrated into the follicular glands of the mucous membrane, and had there given rise to very considerable irritation, as shown by the increase in the lumen of the gland, and the collection of many nucleated round cells in its interior. In many cases the bacilli had also penetrated behind the epithelium of the glands, and had proliferated between it and the basement membrane of the gland. They had, moreover, collected in considerable quantities on the surface of the villi, and had often penetrated into their substance. In the severe cases, which had been characterized by hemorrhagic infiltration of the intestinal mucous membrane, the bacilli were found in large numbers, and were not limited only to the interior of the follicular glands, but had passed into the surrounding tissues, into the deeper layers of the mucous membrane, and here and there even into the muscular coat of the bowel. The villi were also in such cases extensively invaded by the bacilli. The chief seat of these changes is the lower portion of the small intestine. Had not this investigation been made on quite recent cadavers, the result would have been of little or no value, for putrefaction is able to produce in the intestine exactly similar bacterial growths. A year ago I had found these same bacilli, with a similar distribution, in a choleraic bowel which I received direct from India; but I had not been able to attach any value to it on account of this very reason, for it was always possible that they might be confounded with post-mortem putrefactive changes. Now, however, that any error arising from putrefactive phenomena can be positively excluded, this earlier discovery, made in four different Indian cholera cases, acquires extraordinary value. Nor is it an unimportant fact that the agreement in the appearances of the bowel in Indian and Egyptian cholera furnishes a further proof of the identity of the two diseases.

"The number of cadavers examined is certainly small; but, as the bacilli were met with in all recent cases of cholera, while they were absent in the single case examined after the cessation of the cholera process, as well as in several other cases dead from other forms of disease, and examined with special regard to this point, there can be do doubt that they stand in some sort of relation to the cholera process. It cannot, however, as yet be concluded that they are the cause of the cholera. The relationship may be quite the reverse; it being quite as possible that the cholera process produces such changes in the intestinal mucous membrane as to admit the penetration into its tissues of a definite bacillus variety of the many parasitic bacteria which are constantly met with in the bowels. Which of these two hypotheses is the correct one—whether the infective process or the bacterial invasion is the primary event—can only be decided by attempting to isolate the bacteria obtained from the diseased tissues, to cultivate them, and then to reproduce the disease by inoculation experiments on animals. For this purpose it is absolutely necessary to have at one's disposal animals which are susceptible to the infective material in question. Hitherto, however, in spite of every endeavor, we have not succeeded, in an indisputable manner, in conveying cholera to animals.

"The most varied attempts were made, and the animals fed with the vomit, with the cholera dejections, and with the contents of the bowel obtained post-mortem—given in some cases quite fresh, in others after it had stood for a time in a cold or a warm room, in others again dried—but in no case did choleraic symptoms appear; on the contrary, the animals continued perfectly well. Besides this, the bacilli found in the contents of the bowels and in the intestinal walls were cultivated, and animals were fed, and in some cases inoculated, with the product. In some cases septic manifestations followed inoculation, but in none was cholera reproduced.

"That the *materies morbi* in an active form is very often contained in the dejections of cholera patients is shown by numerous facts, especially by the frequent infection of washerwomen who have had to wash the soiled linen. A case of this kind occurred in the Greek Hospital during the present epidemic—a washerwoman, who was exclusively employed on the linen of cholera patients, having sickened of the disease.

"It may therefore be regarded as certain that of the many substances used in the experiments, some at least must have contained infective material; and the fact that no result was obtained may be attributed either to the animals used being completely insusceptible of cholera, or to the proper mode of infection having yet to be discovered. The experiments shall be continued, and modified in both directions, but there is little prospect of any result being obtained with the material at present at our disposal.

"For it is not very probable that the reason of the failure of the infection experiments is to be found in those circumstances only. There is still a third explanation, for the correctness of which there is much to be said. It is well known that, in any given place attacked by cholera, the disease subsides long before all the inhabitants have been affected by it; and although the morbid material may be concluded to be distributed widely over the whole neighborhood, yet fewer and fewer people fall ill, and the epidemic dies out while many individuals still remain capable of infection. This phenomenon is only to be accounted for on the hypothesis that towards the end of the epidemic the infective material declines in activity, or at least becomes uncertain in its action. If, then, when the epidemic is declining, even human beings cease to be susceptible to the infection, it is hardly to be expected that the contrary should be the case with the animals experimented on, concerning whose susceptibility to cholera we as yet know nothing. In our researches only such subjects were available as were to be collected towards the end of the epidemic, and their incapability of conveying the infection was to be expected with more or less certainty. It still remains possible that, under favorable circumstances—*i. e.*, at the commencement of an epidemic—one might succeed in infecting animals, and by that means one would at once discover whether the bacilli which I have shown to exist in the intestinal mucous membrane are the true cause of cholera.

"Though, therefore, the results so far obtained by the Commission are still far from completely solving the problem, and though they have little practical value in the struggle against cholera, yet, considering the unfavorable circumstances, and the short duration of the investigation, they may be considered as very satisfactory. They completely answer the original aim of the inquiry, and, indeed, exceed it, inasmuch as the constant discovery of characteristic micro-organisms satisfies the first condition which must be fulfilled in the investigation of an infectious disease, and thus secure a definite goal for further research."

THE USE OF STRYCHNIA IN LABOR.—DR. EMILE DEGHILAGE recently used sulphate of strychnia in a case of uterine inertia in which all the usual remedies, friction, irritation of the cervix, injections, ergot, baths, etc., had failed, twenty-five minutes being sufficient to complete the labor, without any untoward circumstances. The pains of labor seemed to be diminished. The motor action of the drug on the muscular tissue of the uterus was very evident. The method of using it is very simple. Every ten minutes a granule containing gr. $\frac{1}{130}$ of sulphate of strychnia is given. As the head descends, the interval between the doses is increased. It should not be given until the cervix is dilated. It would seem that this medication is especially indicated in cases of uterine inertia, and the author claims that it is preferable to forceps-delivery in these cases, as not being liable to be followed by hemorrhage. Deghilage has had several cases in which the results were as satisfactory as in the case reported. —*Journ. de Med. de Paris*, October 13, 1883.

ETIOLOGY OF PUERPERAL INVERSION OF THE UTERUS. —In a paper by FUERST in the *Archiv für Gynäkologie*, Bd. xx. Hft. 3, the author describes the following as the conditions which predispose to the occurrence of inversion of the uterus in the puerperal state: 1. Feebleness of uterine action as a result of prolonged labor, cases in which delivery is often completed by the forceps. Out of one hundred and forty-eight cases collected by Lee, in twenty the labor was exceptionally slow, and in twenty-five very quick. 2. Attachment of the placenta to the fundus uteri. Considering the large part which want of tone in the uterine muscular fibre plays in producing, or rather in permitting, inversion of the organ, and having regard to the exceptional presence of this atony in primiparæ, Dr. Fürst is of opinion that the accident occurs more frequently in first labors than would be expected—a fact which he attributes to the greater frequency of fundal implantation of the placenta in these cases, as shown by the comparative rarity of placenta prævia in primiparæ. 3. Comparative rigidity of the vagina, opposing descent of the uterus in response to downward pressure on it, and thus favoring the production of inversion by a force acting on the fundus, this being a condition also met with chiefly in primiparæ. According to Schatz, the opposite state, laxity of the vagina, is one of the conditions which bring about inversion. 4. Narrowness of the vulva, preventing the easy exit of blood, so leading to distention of the uterus, in the sudden emptying of which inversion is likely to occur. Adhesion of the placenta is known to be frequently associated with inversion. Thus, out of Lee's one hundred and forty-eight cases, in sixty-seven the placenta was attached to the inverted organ, its manual removal being required in fifty-three of them.—*Medical Times and Gazette*, October 20, 1883.

ALTERATIONS OF THE VENA CAVA COMPLICATING CIRRHOSIS OF THE LIVER.—In cirrhosis of the liver, says DR. GIOVANNI, ascites appears before œdema or anasarca; in diseases of the heart the reverse is true, as a rule. There are, however, many exceptions in cases of cirrhosis. Œdema may appear in the lower extremities and in the whole lower half of the body, before the mechanical conditions producing intra-abdominal pressure are produced. It may appear in the first period of the affection, when its course is subacute, and marked abdominal symptoms are presented, as hepatic and intestinal pain, dyspepsia, vomiting, albuminuria, etc. Œdema may also be slow in making its appearance in cirrhosis whether before the symptoms of the hepatic affection are well defined or when it has already arrived at an advanced stage.

The intra-abdominal pressure may, on the one hand, be very considerable without there being a trace of anasarca, and, on the other hand, the œdema may be very strongly marked with a very small or even no abdominal pressure. The intra-abdominal pressure may be regarded then as the principal cause of the anasarca. It seems that the vena cava inferior in its passage between the lobes of the liver, ought necessarily to be a little obstructed during the period of shrinking of the organ, but this cannot be held as an explanation of the œdema which appears in the first periods of the affection.

According to Dr. Giovanni, the principal cause of this œdema is a special lesion of the inferior vena cava which, in these cases, is always found in a very marked state of hydræmia and dilatation, with well-defined lesions of peri- and endo-phlebitis, and with considerable thickening of the vein walls. When, on the contrary, no œdema appears during life, the vena cava is found in a perfectly normal state.—*Journal de Méd. de Paris*, October 13, 1883.

Arterial Lesions in Varicose Ulcers.—The difficulty of interpreting the relations of associated changes constitutes one of the most beneficial exercises for the development of a logical state of mind. Cornil and Ranvier have observed endarteritis frequently in the tissues of wounds, ulcers, and inflammations of the connective tissue. Some new investigations on varicose ulcers by MM. Arnozan and Boursier have revealed a remarkable degree of change in the arteries of the parts bounding the ulcer. In the smallest vessels an increase in thickness of the muscular coat has been measured. In the larger arteries areas of endarteritis were discovered together with hypertrophy of the muscular coat. What is the sequence of events in such a varicose ulcer? Is the ulceration dependent on the arterial disease, or are the vascular changes secondary in point of time to the ulceration? Are all the changes the result of increased venous congestion, or is there some other cause at the root of the whole of the alterations?—*Lancet*, October 20, 1883.

Catheter Fever.—In inaugurating the autumnal session of the Clinical Society of London, the President, Sir Andrew Clark asked from the surgical members of the Society information on one subject. In 1870 a man, who was otherwise in good health, consulted him for slight incontinence of urine. He consulted a specialist, who found his prostate enlarged and his bladder unable to empty itself, and advised him to use a catheter. Four days later he was taken ill; urine contained a little pus; pulse 120; temperature 100°. After two days the temperature rose higher, the pulse became more frequent, and in eight or nine days he died; the bladder was inflamed, and the kidneys were reported to be healthy. Since 1870 he had seen four or five such cases every year. He had not been able to gather sufficient information on this malady, which was not very uncommon. He was not alluding, of course, to the slight rigors after catheterism, but to a fever which generally ended fatally. The catheter had sometimes been tied in, and at others only passed occasionally.

The first thing that suggests itself, *The Lancet* (October 20, 1883) says, in considering these cases is the fact that they are not met with as a sequel to catheterism in men who have been previously free from disease of the urinary organs. The history always is that there has been long-standing stricture, or enlargement of the prostate, with atony of the bladder and chronic retention of urine, or calculus in the bladder; and that then, on some slight irritation of the urethra or bladder, such as is caused by the passage of a catheter, this serious chain of symptoms ensues. This undoubtedly throws great light on the pathology of the cases. The condition which is common to these various evils is a chronic interstitial inflammation of the kidney, especially of the cortex. The kidneys thus diseased may be little altered in their general appearance, but the capsule is a little less readily stripped off than usual, and leaves the surface of the organ irregular, and the cortex itself is abnormally pale. With the microscope, however, the change is at once to be detected in a cellular and fibrous intertubular infiltration and a granular condition of the epithelium. There may or there may not be superadded to this absorption of the pyramids the result of the pressure of urine dammed back in the pelvis of the kidney. When the cortex of the kidney is in this condition, a slight irritant is sometimes sufficient to light up an acute and fatal inflammation. This irritant may act directly upon the organ, as when the urine in the pelvis undergoes putrefaction; or indirectly in a reflex manner, as in the passage of a catheter or other instrument along the urethra, or in the performance of any operation upon the urinary tract. This acute interstitial nephritis tends to run on to suppuration, and causes lines and spots of pus or larger abscesses to be scattered through the cortex; the organ is at the same time swollen and greatly congested. The symptoms to which this acute affection gives rise are fever, usually attended with one or more rigors, nausea, often vomiting, dry brown tongue, loss of appetite, drowsiness, absence of spontaneous pain, though in some cases there are tenderness in one or other loin, failure in the pulse, and then, later on, cold clammy skin, deepening stupor, perhaps diarrhœa, coma, and death. Convulsions are very rare; œdema is absent; and as the urine is secreted in moderate quantity up to the end of life, the symptoms do not present a likeness to those familiar to physicians in Bright's disease. In the chronic form of the disease the urine is secreted in considerable quantity, is of low specific gravity, and only rarely contains a very small trace of albumen, and an occasional hyaline cast may be detected in it. In the acute form the urine is generally less abundant and more albuminous. But as there is often an added catarrh of the bladder, it is impossible to determine accurately the state of the urine as secreted by the kidneys. We would suggest, then, that the cases referred to by the President of the Clinical Society are those of chronic interstitial nephritis set up by chronic disease of the bladder, prostate, or urethra, in which an acute renal inflammation is induced by the passage of a catheter. The subject is a very important one, and now that attention has been called to it in so prominent a way, it is probable that the true nature of these cases will be more generally recognized.

Solution of Bromide of Arsenic in Diabetes.—Dr. Pekai, Clinical Assistant to Prof. Karanyi, of Buda-Pesth, has recently made a series of researches as to the value of bromide of arsenic in the treatment of diabetes. He was led to these experiments by the publication of several cases cured by Dr. Clément, of Frankfort-on-Main, in 1882. Dr. Pekai's results have been very satisfactory.

A young man, so feeble that he could scarcely go upstairs, was, after three months' treatment, enlisted as a soldier. Between February 15th and May 7th, his weight increased from one hundred and twenty to one hundred and forty pounds. The sugar which, on the first day, amounted to five per cent., had disappeared. The medicine was then discontinued, and the patient placed on gluten bread. At the beginning of the treatment gtt. iij of the medicine were placed in ℥j of water, and this taken in three doses. The quantity was increased by the addition of one drop every three days until gtt. x were taken daily. Before commencing this treatment the patient was placed on an exclusively animal diet, and the sugar diminished, but at the end of seventeen days there was still a large quantity of sugar. The medicine was then ordered, the flesh diet being kept up, and in eleven days the sugar had almost completely disappeared. In another case, the result, though not so brilliant, was very satisfactory. The solution is prepared as follows: grs. iss āā of arsenious acid and carbonate of potash are placed in a brine measurer (éprouvette); gtt. v of water are added, and treated until the liquid is limpid. Then add sufficient water to make ten grammes (ʒiiss by weight). Add then grs. iss of bromine and leave for twenty-four hours.—*Journ. de Méd. de Paris*, October 13, 1883.

Large Cystin Calculus—Removal by the Hypogastric Operation.—Mr. John Tremearne presented a record of this case to the Medical Society of Victoria on July 4th.

This calculus, measuring 2½ inches long, 1¾ inches broad, and 1 inch thick, with a circumference of over 7 inches, and a weight of 2½ oz. 54 grs., or 1254 grains, is composed of pure cystin, a form of stone not only rare, but, I believe, the largest of its kind that has ever been taken out of the bladder by operation. It was removed from a very tall, thin man, aged 47, who had been troubled for several years with dyspnœa and pleurodynia (?), as well as occasional sudden stoppage of urine whilst in the act of passing it, and on some occasions very small gravel had come away, resembling the calculus in color. Eighteen months previously he fractured his leg, and whilst lying on his back had no trouble whatever with the water. On rising from bed after the union of the bones he found great difficulty in micturition, and very soon the dyspnœa developed into severe spasmodic asthma. The water trouble increased, so that in November, 1882, he could not retain his urine beyond an hour, rarely that, and suffered much pain in the perineum and end of the penis. Every time previous to passing his urine he had half an hour of fearful forcing pain, and was obliged to rest on his knees and elbows until the bladder was emptied.

On November 27th, chloroform was administered, and an examination made. Directly the sound entered the bladder it struck a stone. A finger was introduced into the rectum, and the stone pushed forwards, so that it could be distinctly felt by pressing the fingers of the other hand on the abdomen just above the pubes. On introducing a lithotrite, instead of the sound, the size of the calculus was pretty accurately determined.

Three days afterward he was again put under chloroform, when the stone was successfully extracted by the supra-pubic or high operation. A tube was then put through the wound into the bladder, and fastened by tapes with long pieces of strapping around the abdomen. The tube was a large one, so that the bladder contracted around it and prevented extravasation. At the end of a week it was removed, and on the twelfth day urine commenced to pass through the urethra.

Within five weeks of the operation he gained thirty pounds in weight, and had apparently completely recovered his health.

In this case the large size of the tube introduced into the wound is particularly to be noticed. In the lateral operation I always adopt the same method (the vaginal pipe used with Higginson's enema apparatus answering the purpose very well), and leave the tube in the bladder usually four or five days.

In addition to preventing extravasation, it is a great help in checking secondary hemorrhage, should anything of the kind occur, and renders washing out the bladder easy.

Dr. Allen said that the largest cystin calculus noted by Coulson was in the University College Museum, and weighed 850 grains; another at Bartholomew's weighed 740 grains. Heath once exhibited nineteen taken from a single patient. Cystin calculi are formed originally in the kidney, the nucleus being sometimes uric acid, sometimes pure cystin. Their color on removal was usually honey yellow, becoming greenish on exposure; as a rule they were friable, and could be crushed without difficulty. With the present specimen the fingernail sufficed to make a white scratch; hence it would be interesting to know whether any attempt was made to crush it. Surely when the stone was once caught in the grasp of the lithotrite, a surgeon would be tempted to try the effect of a squeeze. Cystin is very rich in sulphur, being nearly related to the taurin of the bile. Such calculi often ran in families, and it would be well to learn if there was any hereditary predisposition in the present case.—*Austral. Med. Journ.*, July 15, 1883.

Inflammation of the Thyroid in Diphtheria.—Dr. Brieger reports two cases of inflammation of the thyroid gland occurring in the course of diphtheritis. The first patient was a young woman æt. eighteen years, who had no fever when first seen on the seventeenth day. Two days afterward, and while the diphtheritic membrane was still present, quite a high fever came on, with pain and swelling of the thyroid gland, and aphonia and dyspnœa. Antipyretic treatment seemed to have no good effect, but a good deal of relief was obtained by poulticing the swelling. Twenty days later Brieger made an incision at the point of fluctuation, and about one ounce and a half of pus was evacuated. The patient recovered under careful treatment.

In the second case, of a woman æt. thirty-two, the inflammatory process was aborted by energetic antipyretic treatment, and by leeches in the early stage. The thyroid inflammation subsided in both cases before the diphtheritic process. Brieger thinks that there is no doubt that the thyroiditis was the direct consequence of the invasion of the gland by the diphtheritic microbes.—*Centralbl. f. klin. Med.*, June 23, 1883.

Removal of Foreign Bodies from the Stomach.—To the case of the *homme à la fourchette* and the extraction of a spoon from the stomach of another patient, described in the *Semaine Médicale*, October 5, 1882, Dr. Hagens, of Dantzic, adds a third, recently described by him in several German medical journals. The operation, however, is not recent, for this third case was performed by Daniel Schwaben, "lithotomist and surgeon," at Dantzic, in the early part of the seventeenth century. A countryman, in endeavoring to produce vomiting for the relief of colic, was tickling his palate with a penknife, when he suddenly let go of the handle of that instrument, which was accidentally swallowed forthwith. Six weeks later, Schwaben made a very free incision through the abdominal walls and the anterior part of the stomach, and extracted the knife. The patient recovered, and was able, for several years afterwards, to work hard in the fields, never suffering from any local symptoms. The original manuscript description of this remarkable case is in the hands of Dr. Hagens. The surgeons of Dantzic and Königsberg appear to be the most dauntless pioneers of the desperate departments of operative surgery; last December we had occasion to refer to an unsuccessful case of excision of a phthisical lung by a surgeon practising in the former city.—*British Medical Journal*, October 20, 1883.

Interstitial Bacterial Nephritis in Children.—Dr. Ludwig Letzerich reports cases, seen during the spring and summer of this year, of a peculiar inflammation of the kidneys, epidemic and primary in children, and absolutely independent of any acute exanthem. The number of cases seen was twenty-four, the same symptoms being presented in all, and which showed the same fungi in the urine. Three children died of acute uræmia. The fungi found in the urine were carried through four successive cultivations, and then inoculated on rabbits. The rabbits were killed after a short time, and the same fungi found on microscopical examination. The fungi were somewhat similar to the bacilli of typhus; they were somewhat broader and larger, however, and showed no globular forms. They had a disposition to become elongated, and form threadlike bodies, in which spores, developed and in irregular masses, were seen lying at various distances apart. During the spore formation, the threadlike bodies could be seen separating into rods of different sizes.

In the interstitial tissue of the kidneys were found very large deposits of micrococci. The kidneys were markedly hyperæmic, and the stellate points were of a dark-red color, with black diagonal lines running through them. There were numbers of wandering cells in the interstitial tissue.—*Allg. wiener medizin. Zeitung*, October 9, 1883.

Mazanita.—Mazanita is a plant indigenous to California, and the leaves are the part of the bush used in the preparation of the fluid extract. This has an astringent and somewhat bitter taste. It is said to be an astringent tonic with a special action on the urinary organs, and has been recommended as a valuable agent in the treatment of gleet, vesical catarrh, incontinence of urine, etc.

Dr. H. W. Rand reports fourteen cases, twelve being cases of gonorrhœa and two of gleet. In about one-half of the cases there was improvement on doses of gtt. x–ʒiss three times a day. In other cases there was no perceptible improvement after a week's administration and the treatment was changed. The appetite seems to improve under the use of mazanita, and no gastric disturbances are produced. Although it is said to be astringent, it does not seem to cause constipation. Dr. Rand thinks that it is contraindicated in acute cystitis, and he would hesitate to use it in a case of irritable bladder. From his limited experience he thinks that it may be advantageously used during the stationary or decreasing stage of gonorrhœa, or in a long-standing gleet where the older and well-tried drugs had failed to relieve or had disturbed the stomach.—*Proc. of Med. Soc. of Kings Co.*, Nov. 1883.

Gartner's Ducts in Women.—In a paper published in a recent number of the *Archiv für Gynäkologie*, Dr. J. Kocks, of Bonn, describes certain fine canals which he has been able to find in about eighty per cent. of those women in whom he has searched for them, and which he believes to be the remains of Gartner's ducts. These canals open close to the posterior margin of the meatus urinarius, and a probe of one millimetre (about one twenty-fifth of an inch) in thickness can be passed into them for a distance of from half a centimetre to two centimetres (about one-fifth to four-fifths of an inch). Their orifices are often situated a little distance behind the urethral orifice, so that the canal has to be held open in order to see them; but generally, says Kocks, the openings are to be found at the summit of the little lips of mucous membrane which bound the posterior part of the meatus to right and left. They are generally both present, but one may be absent. Dr. Kocks compares their appearance to that of the lachrymal puncta. They run in the urethro-vaginal septum, and end blindly. They are found most easily in young adults. In the newly born they are relatively larger, but absolutely smaller than in adults. In old women they become obliterated or lessened in size. Dr. Kocks regards them as the homologues of the ejaculatory ducts in the male. In the following number of the same journal, Professor C. Böhm, of Vienna, writes to say that he, like Kocks, has been able to demonstrate the presence of these ducts; and, further, that he has seen cases of acute and chronic inflammation of them. Sometimes this inflammation is but part of a similar process affecting the vagina, vulva, and urethra, but sometimes it exists by itself. In the latter case, owing to the presence of redness and swelling of the meatus, discharge of pus from it, and pain on making water, the disease may be taken for gonorrhœa. From this it is to be diagnosed by everting the margins of the meatus, and noticing that the pus issues from the ducts in question. It is to be cured by applications of solid nitrate of silver to the inflamed ducts. Unless proper diagnosis is made, and this treatment employed, the disease may prove obstinate.—*Medical Times and Gazette*, October 20, 1883.

Therapy of Basedow's Disease.—From his personal experience in the treatment of seventy cases, and from the united and concordant observations of Von Dusch, Eulenberg, Meyer, Erb, and others, Chvostek regards the rational employment of galvanism as the most important item in the therapeusis of ophthalmic goitre.

As the best methods of administering the electricity in these cases he recommends the following: 1. The ascending constant current should be applied to the cervical sympathetic on either side, for one minute at most. 2. The ascending constant current should be applied to the spinal cord—the anode being placed about the fifth dorsal vertebra, and the cathode high up in the cervical region. 3. A constant current should be applied, at the longest for one minute, through the occiput, one pole being placed on each mastoid process, and in some cases also through the temples; the current should be so weak that the patient only feels the slightest sensation of burning. In some cases, also, local galvanization of the thyroid, for about four minutes, with a weak constant current, which is reversed at the end of each minute. If possible, the applications should be made every day. Chvostek obtained very good results, as a rule, a cure or marked improvement resulting even in the worst cases. Three patients died of anæmia or other complications.—*Central. f. klin. Med.*, June 23, 1883.

Unusual Malformation of Heart.—At the meeting of the Pathological Society of London, on October 16th, Dr. Howard Tooth showed the heart of a boy, æt. 6 years, who had been a patient of Dr. Gee's at St. Bartholomew's Hospital. The signs were marked cyanosis, especially of the lips and tongue, clubbing of the fingers and toes. There was bulging in the præcordial area, and a loud systolic murmur all over, but loudest at the apex. The child was admitted for enteric fever, and died from peritonitis. On autopsy, the characteristic lesions of enteric fever were found in the intestines. The heart weighed eight ounces and a half. The foramen ovale was not quite closed. The right ventricle was dilated, and the aorta arose from it, and went over to the root of the left lung as usual. The septum between the ventricles was deficient at the base, and the space thus formed was divided into two holes by the columnæ carneæ. The endocardium was thickened at the edge of this hole. The pulmonary artery, which was of fair size, and guarded by only two sigmoid cusps, also arose from the right ventricle. The ductus arteriosus was closed. The left auricle was smaller than the right. The left ventricle was small and had no vessel arising from it, and must therefore have propelled the blood contained in it into the right ventricle. He believed that this was a decidedly rare form of malformation of the heart. The existence of endocarditis was a further evidence of the well-known tendency to it in these cases.—*Med. Times and Gaz.*, October 20, 1883.

THE MEDICAL NEWS.
A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

Address, HENRY C. LEA'S SON & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA, PA.

SATURDAY, NOVEMBER 10, 1883.

AIR IN THE VEINS AS A CAUSE OF SUDDEN DEATH IN PUERPERAL WOMEN.

SUDDEN death of women soon after labor, while not a frequent event, is one so startling that inquiries into its cause, or causes, are of great importance. It may be that in some cases the event is unexplained, while in others, possibly, a wrong explanation is sometimes given.

Maurice Coste, in a monograph published in 1876, regards myocarditis as the most frequent cause of sudden death in the puerperal state. The late Dr. Charles D. Meigs attributed it to heart-clot, his first publication upon the subject being made in 1849 in the *Medical Examiner;* and he was not anticipated, as stated by Playfair in his *Midwifery*, by Paget.

The cases which Dr. Meigs has given in illustration of his views in his well-known and invaluable *Treatise*, are instances of rapid, rather than of sudden, death. None of them occurred immediately after labor; in some the interval between delivery and death was several days. Admitting pulmonary thrombosis, or heart-clot, as the cause of death occurring some days after labor, and occurring usually *rapidly*, rather than *suddenly*, is this the probable cause of death just after, or a few hours after, delivery? The *Medical Record* last year reported three cases of death of women after delivery, two within two hours, and one whose labor ended in the evening and who died the next morning; two of the deaths are attributed to pulmonary, and the other to cardiac embolism; in each the verification of an autopsy was not obtained.

The entrance of air into the uterine veins is probably, in some cases, the cause of sudden death occurring soon after delivery. In January of this year, Dr. Draper reported in *The Boston Medical and Surgical Journal*, two cases where instant death occurred from efforts to cause criminal abortion; post-mortem examination proved in each case the presence of air in the veins.

In a recent number of the *Wiener medizinische Wochenschrift*, Braun gives three fatal cases from the introduction of air into the uterine veins; in two of these cases the uterine douche was used, in one to produce abortion, in the other after delivery of twins, and the patients died in a very short time, one indeed within twenty minutes; post-mortem examination showed air in the uterine veins, in the ascending vena cava, and in the veins of the heart.

The third case was that of a woman who had been delivered lying upon her left side, and was then turned upon her back; massage was made upon the uterus, she gasped, and died in a few minutes. Braun suggests that in the change of position a volume of air entered the uterus, and the manipulation, instead of driving it outside, forced it into the uterine veins.

According to Dr. John Rose Cormack (*Prize Thesis*, Edinburgh, 1837), Brown Langrish was the first to prove that air injected into the jugular vein of a dog caused almost instant death; this was in a communication made to the Royal Society of London about 1746. Since that time many similar experiments have been made, not the least important of which were those of Magendie, which showed that it was not so much the quantity as the rapidity with which the air was introduced that brought immediate danger.

The first instance where air entering a vein during a surgical operation was the cause of sudden death occurred in 1818, at the Hôpital Saint-Antoine. Beauchene was extirpating a tumor from the right shoulder of a patient and a part of the clavicle was removed; as shown by the autopsy, a piece of the jugular vein, an inch in length, and comprising half its thickness, was cut away, when there was suddenly heard a *bruit* quite similar to that of air entering by a small opening the chest of a living animal. The patient uttered the pathetic words, *Mon sang tombe dans mon cœur, je suis mort;* he became pale, his head thrown back, eyes fixed, vision lost, pulse small, frequent, irregular, the body covered with a cold sweat, some convulsive movements, and in fifteen minutes was dead. Since that time similar cases of death have been observed both in Europe and in this country. In surgery there has come to be recognized what is called a dangerous zone, within which thoracic aspiration may cause the entrance of air into a wounded vein. Marey observes, in *La Circulation du Sang*, that this dangerous zone extends beyond the neck. Surgeons have met with cases of the entrance of air into the veins from a wound of the axillary, and even of the facial, near the angle of the jaw. In a foot-note Marey further states that thoracic aspiration may be exerted in the venous sinuses and in the canals of the cranial bones, and that Bernard has often spoken of the production of this accident in his vivisections, where the veins of the spine were opened. It is obvious that the dangerous zone is much larger than commonly thought, the bearing of this fact in explaining the spontaneous entrance of air into the uterine veins is also plain. In 1829, Legallois saw three cases of sudden death occur from the introduction of air into the uterine veins in animals upon whom he was studying the effect of abstinence and bleeding upon pregnancy.

Since these observations many obstetric authorities have held that the spontaneous entrance of air into the uterine veins may be the cause of sudden death in a woman after labor. Nevertheless, it is by no means a settled question. Hervieux, for example, in his *Traité Clinique et Pratique des Maladies Puerperales,* concludes his chapter upon the presence of gas in the heart and large vessels of lying-in women as follows:

1. The indisputable reality of cases of sudden death caused by the presence of gas in the circulatory system of lying-in women.

2. The impossibility of attributing the presence of these gases to a cadaveric effect, to a beginning putrefaction.

3. The identity chemically demonstrated of these with those of the blood, and the probability of their spontaneous development during life.

4. The necessity of carefully watching women who have had uterine hemorrhage, and although the introduction of air by the uterine veins is far from proved, it is the duty of the practitioner to resort to intra-uterine injections only with extreme reserve, strictly conforming to all the precepts of the art.

From what has been previously stated it does not seem improbable that thoracic aspiration may exert its force in drawing air into the uterine veins. It is to be remembered too that these veins in case of uterine relaxation after labor are in a condition, as to patency, similar to that of some other veins, which, when opened, admitted air with fatal result; they are so fastened to the muscular walls of the womb, through whose interspaces and meshes they pass, that without the firm contraction of those walls they cannot close, but are kept distended. Then, too, their great size at the end of pregnancy, is another condition to be borne in mind. Burton in his *New System of Midwifery,* published in 1751, observes that the uterine sinuses "in the ninth month of gestation are so large as to admit the end of the biggest finger, and their orifices that open into the cavity of the womb will, at the same time, admit the end of the little finger." And the late Dr. McClintock has stated that if the uterus be examined soon after delivery at the full term the majority of the orifices of the uterine veins at the site of the placenta will readily admit a goose-quill, and some will allow the little finger to penetrate them without laceration.

Various explanations have been given as to how air in the veins causes death. Marey accepts that of Mercier, published in 1839, which attributes the death to this, that the blood mixed with air becomes frothy, enters the pulmonary capillaries, and obstructs them. Physicists know that a capillary tube which readily permits the passage of air, or of water, offers a great resistance to a mixture of air and water; this mixture causes a series of bubbles separated by minute diaphragms of liquid. Poiseuille has shown, by a series of experiments, that such in fact is the cause of death when air mixed with blood has obliterated the capillaries of the lungs, the right heart remains gorged and cannot be emptied.

A recent number of the *Gazette Médicale de Nantes* contains an interesting paper upon this as a cause of sudden death in puerperal women. Its author, DR. ALFRED ROUXEAU, after a theoretical consideration of the question, from which he concludes that spontaneous penetration of air in the uterine sinuses may occur, next directs his attention to the clinical aspect of the subject. He states that many alleged cases had nothing in their symptoms or in autopsies justifying the diagnosis. In addition to these, there are some others reported so incompletely in an anatomico-pathological point of view that they do not carry complete conviction. But there are others finally which seem conclusive, such as those of Draper. He also refers to the case of Davidson, reported in *The Lancet,* June 9 of this year. In this case the patient had a perfectly natural labor, and there was no post-partum hemorrhage. Three-quarters of an hour after the labor she was taking some nourishment, when she suddenly fell back and died. At the post-mortem examination, two hours after death, the uterus was found empty, with large and somewhat distended veins; the right side of the heart contained a quantity of air, mixed and churned up with blood, which escaped in bubbles; the lungs were congested; all the other organs were healthy.

Dr. Rouxeau gives the following as the usual characteristics of the accident: Soon after delivery the patient is suddenly seized, often without appreciable cause, with anxiety, and trembling; she groans, or utters a cry of fright; becomes livid, and there is entire loss of consciousness; respiration, at first hurried and spasmodic, soon ceases; the pulse, small, rapid, in turn fails, a convulsion occurs, and the patient is dead.

As the symptoms are those of pulmonary embolism, too, the diagnosis, according to both Draper and Rouxeau, is determined by the time when the accidents occur. Embolism is a late accident, occurring usually during the second or third week, but not so the entrance of air into the uterine veins.

As to curative treatment, one can hardly do as Magendie did in the case of animals into whose veins he had injected air; withdraw it by means of a syringe, or as now would be done with an aspirator. Rouxeau observes that the treatment must be purely preventive; that is to say, one ought to hasten the retraction of the uterus after labor by hypogastric compression, ergot subcutaneously, and other measures.

Let us add a word to this treatment. When a patient is delivered of her child, while she is lying upon her side—and wherever rupture of the perineum is feared, such position is certainly the best one—let her be turned upon her back before the delivery of the placenta. A horizontal position should be strictly observed for at least several hours after labor. Intravaginal, and especially intrauterine injections, if the latter should be considered necessary, must be made most carefully to prevent the possible entrance of air with the fluid used. Deep inspirations should be avoided, for, as pointed out by Marey, they increase thoracic aspiration. Finally, the practitioner should remember that the accident may occur where there has been no unusual flow of blood after the delivery of the placenta; hemorrage was not its forerunner in some of the cases that have been reported.

PRELIMINARY REPORT OF THE GERMAN CHOLERA COMMISSION.

In another column will be found the full details of the preliminary report of Dr. Robert Koch, the Chief of the German Commission appointed to investigate the recent cholera outbreak in Egypt.

The Commission reached Alexandria after the disease had commenced to decline. Notwithstanding this, the blood, vomit, and dejecta of undoubted cholera cases were minutely studied. The blood was found free from micro-organisms, the vomited matters contained comparatively few, while they were quite numerous in the dejecta. These included the most different varieties, none of which seemed to preponderate or have any relationship to the disease-process.

Autopsies were made upon ten cadavers, either immediately after death or within a few hours, so that the post-mortem putrefactive changes which take place so quickly in the bowel were avoided. No organized infective material could be found in the blood or in those organs in which, in other infective diseases, micro-parasites are commonly found, viz., the liver, spleen, and kidneys. In some cases, bacteria were found in the lungs, but it was evident that they had nothing to do with the peculiar disease-process, but had found their way there by the inspiration of ejecta from the stomach.

But in the bowel, results, deemed most important, were met with. In all cases, except one which died of a consecutive disease several weeks after recovery from the cholera, bacteria of a definite form were found in the coats of the intestine—in the follicular glands, in which they had given rise to considerable irritation, behind the epithelium of the glands, between which and the basement membrane they had proliferated, and on the surface of the villi, and in its substance. In severe cases, characterized by hemorrhagic infiltration of the mucous membrane, the bacilli invaded, in large numbers, the deeper layers of the mucous membrane, and even the muscular coat. The chief seat of the invasion was the lower portion of the small intestine.

The bacteria were rod-shaped, and were, therefore, bacilli. They resembled in size and shape most nearly the bacilli of glanders. What is most interesting and important is that Koch had found these same bacilli, with a similar distribution, in a choleraic bowel which he had received directly from India. He had not, however, been able to attach any value to this discovery, because he had not been able to exclude the possibility of putrefactive changes. These were, however, excluded in the Egyptian cases, in which the autopsies were made promptly after death. Control investigations were made, and the intestines of persons dying of other causes were found not to contain the bacilli described.

In the crucial test concerning the specific nature of these bacilli, the Commissioners failed. They were unable, after repeated trial, to produce the disease in lower animals, including mice, dogs, monkeys, and chickens, by feeding the dejecta and vomited matters, or by inoculating the bacilli. In view of the acknowledged fact that the *materies morbi* of cholera lies in the dejecta, Koch attributes the failure to one of three circumstances—the insusceptibility of the animals experimented upon to cholera, or to the fact that the proper mode of infection has not yet been discovered, or that at the end of the epidemic the infection materialy declines in activity, or at least becomes uncertain in its action. He expressly states that we dare not, as yet, look upon these bacteria as the cause of cholera. On the other hand, they may be its consequences.

It may be admitted that the Commission in discovering a definite kind of bacillus in the intestines in cholera, has advanced us a step onward in our knowledge of the disease. It is gratifying to know that the request of the Commission, that they may be allowed to continue their investigations in India, has been granted, because the experience already gained, together with the skill in manipulation which Dr. Koch has acquired, gives us a combination of qualifications which may reasonably be expected to accomplish important results.

In the same report, Dr. Koch says he has examined, post-mortem, two cases of dysentery dying in Alexandria, and has found in the diseased bowel a peculiar parasite which does not belong to the group bacteria, and has not been heretofore described. He also examined an Arab who had died of malignant pustule of the intestine, probably contracted from Syrian sheep, of which large numbers are imported into Egypt. He also made autopsies upon three typical cases of bilious fever, and proposed to study this thoroughly. Examinations of the air and drinking water of Alexandria had also been made.

THE ORIGIN OF YELLOW FEVER AT PENSACOLA.

The report of the Naval Court of Inquiry upon the recent outbreak of yellow fever at the U. S. Navy Yard at Pensacola, which is given in full on another page of this journal, is a fresh illustration of the difficulties which are often met in attempts to trace the first steps of this disease in a community. The first cases are mistaken for something else, as appears to have been the case in this instance, and the investigation is undertaken too late to obtain positive and satisfactory evidence.

It will be observed that the Court indicates four possible sources of infection, but applies the term "probable" to only one of these, viz., the ballast derived from infected vessels during the two preceding years. The preservation of the specific cause of yellow fever in ballast, which has been exposed to the weather for several months through a winter season, would not seem to be a probable occurrence, in view of what are commonly supposed to be the effects of cold and of fresh air upon this cause. Nevertheless, there have been several outbreaks of yellow fever, both in ships and on shore, which have been attributed to infected ballast, chiefly because no other source could be considered possible, and although such an origin has never been proved in any case, it is a possibility that must always be considered.

That the specific cause of yellow fever may be preserved in connection with bedding, clothing, etc., if these are kept so that there is little change of air and not too low a temperature in their vicinity, there is little reason to doubt. There are a number of well-authenticated instances in which the poison has thus been preserved, and even transported for long distances, and has then produced its effects after an interval of several months. How long it may be thus preserved we do not know, the longest period known to us being less than a year, but, if the disease is due to a specific organism which multiplies outside the living body, and this is at present the most probable hypothesis, there seems no improbability that it may survive under such circumstances for several years as well as for several months. The suggestion of the Court that the recent outbreak may have been due to fomites preserved in the equipment storehouse since 1867 or 1874, or in the marine barracks since 1875 seems, however, barely within the limits of possibility.

The possibility of the spontaneous origin of the disease does not seem to have been considered at all by the Court, nor is anything said as to the sanitary condition of the Yard, the presence or absence of contaminated soil, etc.

One thing seems evident from the report, and that is, that the outbreak cannot be charged to any defect in the quarantine system of the present year, and, therefore, that this system cannot afford protection against such occurrences. We do not mean to imply by this that quarantine against yellow fever is useless, but only that it is by no means an infallible preventive.

It seems to us that the most certain and least expensive method which the Government could adopt to prevent yellow fever in its military and naval stations on the Gulf coast, would be to retain in them during the summer months the smallest possible force consistent with the preservation and care of government property and stores, and to have this force composed entirely of persons who have had the disease, and are therefore insusceptible to it.

WILLIAM HARVEY.

It is impossible to convey to a layman the feeling with which a physician, who honors his craft, regards the great man whose remains have been lately rescued from further decay and placed in the chapel above the vault where they rested so long unnoticed and almost forgotten. Standing, as every doctor should who goes to London, before the admirable portrait, by Jansen, in the College Hall—something of Harvey's true presence returns for any imaginative person. The face is grave, but gentle too, with a not unkindly cynicism in the lines about the mouth. The head, well-moulded, rises above watchful eyes of hazel, the hair is gray and scanty, the features elegant and slight like the form. It is not a face which disappoints you. It is not unworthy of the great thoughts which lay behind its shapely forehead, nor of the wise words which must have parted those lips. The hands crippled with gout can be seen in the picture; but they are finely formed and have the look of skilled use they ought to have had, to have been the artful servants of that marvellous brain to which God had given the power to unravel the mystery of the flow of blood through artery and vein.

It is pleasanter, somehow, to think of him as resting in the church where he was laid by the merchant brothers who were proud of his fame, and where he, no doubt, had often knelt, than in the crowded aisles of Westminster, to which at one time it was proposed to move him. The Harveys were new people in James the First's day; but getting money in trade built them a manor house in Essex, and laid their bones there, and in time carried thither the greater brother's remains.

To reach Hempstead, you drive from the quaint, old town of Saffron Walden, and climb a short hillside to a lonely little church, where the Harveys seem to possess all the monuments, and where the illustrious William is the single memory of any value.

He was, as some think, the greatest of all great physicians. We know what he did, and we can only grieve as we vainly guess how much more of what he did was lost forever when his house was sacked and his papers burned.

His manner of work was essentially modern and experimental. His speculations on his difficulties and results were humbly reverent, for he was of those who conceive that into the kingdom of knowledge, as into the Kingdom of Heaven, they who come with the submissive and ductile ways of childhood, will enter most easily.

One could wish that among those who bore the remains of Harvey to the new home which his medical brethren and heirs have provided, there had been some one out of the many who venerate his memory on this side of the ocean.

For surely with us this esteem for Harvey is deep and abiding, and we strongly feel that, as doctors, and as of English blood, we have a right beyond that of the German or the Frenchman to feel pride in the great thing he did, and to be thankful for the truth, the purity, and the manliness of him who did it. Strangely enough, his face, with its fine lines, is unlike the English visage of to-day, and is far more like some of the studious faces which haunt the elm shades of Harvard or Yale than those which are to be met among the monastic courts of his own Cambridge.

REVIEWS.

The Diseases of the Prostate, their Pathology and Treatment. By Sir Henry Thompson. Fifth edition. 8vo. pp. 157. Philadelphia: P. Blakiston, Son & Co., 1883.

French and German writers and readers have long enjoyed the advantage of unbound books, enabling author and student to come together when they otherwise could not. Happily this plan of book-making has, like so many other excellent notions of Europe, made its way across the Atlantic; and in this country we have a certain number of medical publications put in such cheap form that any one may own them. The best that can be done in this direction has not been attained yet, but it will be in time.

The book before us is an illustration of what we have been saying. Of its literary and scientific merits it would be superfluous to speak; these are too well known to need praise. But it is a new departure to have them offered, in paper cover, for less than a dollar, to all who would like to have them at hand. We can understand the pleasure that the distinguished author has taken in seeing the cheap English edition offered to the public, with especial reference to the necessities and conditions of students, and we are glad to see here this same edition in a shape which, while cheap, is not mean. The form and illustrations of the more costly editions are preserved, and the paper cover is stiff enough to be quite serviceable.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, November 1, 1883.

The President, Fordyce Barker, M.D., LL.D., in the Chair.

The minutes of the last meeting were read by the Secretary, but before they were adopted Dr. John S. Adams read

A PROTEST

against the approval by the Academy of that portion of the minutes recording the adoption of the resolution of Dr. Loomis to rescind the resolutions of Dr. A. Flint, Jr., in regard to the admission of new members, which were adopted in April last, on the ground that the motion to rescind was clearly out of order, and should not have been permitted to come before the Academy. The reasons which he assigned for this opinion were the following:

That a question once put to a deliberative assembly could not again come up except through a motion for reconsideration, and, consequently, the motion to rescind was out of order.

That legislative bodies had the power to regulate their modes of procedure.

That Section 6 of the XXV. By-law of the Academy, referring to rules of order, read as follows: "After any question has been decided, except one of indefinite postponement, any two Fellows who voted in the majority may at the same or next stated meeting move for a reconsideration thereof; without which no discussion shall be allowed." At the same meeting at which Dr. Flint's resolutions were adopted, two Fellows who had voted with the majority in favor of them, moved their reconsideration, and the reconsideration being thus before the Academy, a motion was then passed that it should be postponed indefinitely.

That a motion to rescind was unparliamentary under these circumstances, and that if the ruling of the chair was allowed to be established as a precedent, resolutions of every kind could be adopted and rescinded by the Academy in the most trivial manner, unworthy of its dignity. That a motion to rescind could in any case only have been in order after a motion had been made to reconsider by two Fellows, in accordance with the provisions of Rule of Order No. 6, and that no such motion had been made.

For these reasons, Dr. Adams said, he regarded Dr. Loomis's motion as an evident violation of the By-laws, and submitted that the action of the Academy in regard to it was consequently null and void. In conclusion, he requested that the protest should be entered in full on the minutes.

On motion of Dr. Laurence Johnson, the protest was laid on the table; the Chair having stated before putting the motion, however, that, whether it was carried or not, the protest would be entered on the minutes in accordance with parliamentary usage. The minutes were then adopted.

Brief reports were made by the Corresponding Secretary, the Librarian, and the Committee on Admissions, and the latter recommended for resident membership the names of Drs. R. W. Taylor, C. H. Judson, R. W. Amidon, M. Josiah Roberts, and L. Emmet Holt, all of whom were elected Fellows during the evening.

The Chair requested that some member would hand him the name of a gentleman competent, on account of his familiarity with the deceased, to prepare a memoir of

THE LATE DR. CHARLES WRIGHT,

an honored Fellow of the Academy. At the time of his death, Dr. Barker said, he was engaged in preparing a very important paper, which was to have been read before the Academy on the twentieth of December, on the subject of "The Duration of Life after the Appearance of Albumen and of Sugar in the Urine, after Repeated Examinations." This paper would no doubt have been of extreme practical value, on account of the immense experience of Dr. Wright in connection with one of the largest life insurance companies in this country; and he had shown that he had carefully considered the subject in all its bearings by the fact that he had prepared a preface to it on the danger of fallacy in drawing inferences from medical statistics. The latter he had read to Dr. Barker during the past spring, and the excellence of its composition had strikingly reminded him of the style of Dr. John Forbes.

In regard to the late Dr. Lente, he remarked that he also had been preparing a paper for the Academy, which was to have been read on the seventeenth of May last, but on account of the precarious condition of his health, he had asked to have the time postponed until the autumn. This had accordingly been done, and the date that had been assigned to him was this very evening, November 1st. The subject which he had selected was "The Duration of Life as Affected by Climatic Influences in Consumption," and it certainly seemed a curious coincidence that two members who were engaged in preparing papers for the Academy at the time of their death should both have chosen titles commencing with the words, "The duration of life."

Dr. T. Herring Burchard then read a

MEMOIR OF THE LATE FREDERICK D. LENTE, M.D.,

which was an eloquent eulogy of the deceased. In many respects, he said, Dr. Lente's professional career was anomalous, as were the rare simplicity and purity of his personal character. Extreme conscientiousness was described as his distinguishing characteristic, and his feeling of professional accountability and keen sense of justice, even in the most trivial matters, were dwelt upon. At Saratoga, at one time, he had been treated with the most vicious intolerance, but he had borne the trial with admirable magnanimity, and had only wondered that such smallness and bigotry could be found in a profession like that of medicine. All that he did was done with rare thoroughness. His mind was a living thesaurus of information; yet, studious as he was, his investigations never led him into idle and profitless speculation. He was eminently practical, and as a diagnostician he was painstaking, thorough, and exact, always declining to express an immature opinion. As a therapeutist, his intimate acquaintance with the action of drugs, often tested by elaborate physiological researches, made him distinguished, and as a practitioner his skill in various departments of medicine was widely recognized. In the broadest sense of the word, he was "the good physician." He was an honored member of most of the medical societies, and was one of the founders of the American Academy of Medicine, as well as its first president. He had always been a distinguished contributor to medical literature, and perhaps the three most important of his papers were those on the treatment of intermittent fever by hypodermic injections of quinine, on the sedative influence of calomel, and on intrauterine medication. Dr. Lente was born at Newberne, North Carolina, in 1823, graduated at the University of that State, and, after having been an office-student of Dr. Alfred C. Post during his residence in the city, received the degree of Doctor of Medicine from the Medical Department of the New York University in 1849. For two years he served under Dr. Valentine Mott, at the New York Hospital, and then received the appointment of surgeon to the West Point Foundry, at Cold Spring, on the Hudson. There he achieved extraordinary success as a practitioner, and soon became known as a consulting physician and surgeon from New York to Albany. In 1871 he decided to remove to the city of New York, and he here received the appointment of Professor of Gynæcology and Diseases of Children at the University Medical School, as well as that of Assistant Surgeon to the Women's Hospital. On account of ill-health, however, he was obliged to return to the country in the following year, and he remained at Cold Spring until 1875. He was then compelled to make another change by reason of physical disability, and from that time began to practise at Palatha in the winter and Saratoga in the summer. He died at Cold Spring, on the 13th of October, in the sixtieth year of his age, and a wife and several children survive him.

The scientific paper of the evening was then read by Dr. Fessenden W. Otis, with the following title:

ON THE RAPID EVACUATION OF STONE FROM THE BLADDER AFTER CRUSHING; WITH PRESENTATION OF A NEW AND SIMPLIFIED EVACUATOR.

He commenced by saying that the revolution which had occurred within the last five years, in regard to lithotrity, might be said to be now complete. The method of Prof. Bigelow had been finally accepted in Europe as well as America, and the distinguished surgeon had found enthusiastic imitators everywhere. He then proceeded to quote from Dr. Bigelow's paper before the International Medical Congress, in London, in 1881, in which he gave a careful *résumé* of the past history of the subject and referred to his own achievements with characteristic modesty. From the time of Civiale up to 1878, there had been little change in the operation of lithotrity and the duration of each sitting was kept as brief as the skill of the surgeon, with the fear of cystitis always before him, could make it. Three minutes was about the time usually allowed for a sitting, and the use of anæsthetics was exceptional. Now, however, anæsthetics are almost universally employed, and the sittings were indefinitely prolonged, sometimes extending even more than three hours. Dr. Otis described the original evacuator of Sir Philip Crampton, devised in 1846, and its modification by Mr. Clover, of London, by the attachment of a glass receiver to the bulb; large drawings of these and the later instruments described having been hung upon the wall. Clover had subsequently made a further modification of the apparatus by the addition of a vertical chamber, and Dr. Bigelow cheerfully granted that his instrument was the only one in the possession of the profession of any value until the time that he brought forward his own. The reasons that Bigelow had achieved such extraordinary success were, because he understood the remarkable tolerance of the bladder and because he employed a large catheter for evacuation.

There was, however, a well-marked hiatus between Clover and Bigelow, and this Dr. Otis claimed to have filled himself by the results established by his researches in regard to the true size of the urethra. Up to the year 1874, all the standard authorities placed the normal calibre of the male urethra at twenty-one millimetres; but in that year by means of his urethrometer he had demonstrated indisputably that the normal calibre was thirty-two millimetres. In his earliest monograph Prof. Bigelow had stated that whether the views of Otis were adopted or not, there could be no doubt that the urethra could admit a much larger tube than that commonly attached to Clover's or the French instrument. Before the announcement of the result of his (Otis's) investigations in 1874 and 1875, no one had ever claimed that the urethra was as large as it was now universally conceded to be. At the International Medical Congress, Bigelow had declared that the small catheter of Clover's instrument had retarded progress for half a century; so that the hiatus was thus completely and satisfactorily filled.

Dr. Otis now related two cases occurring as long ago as March, 1876, and November, 1877, in one of which, although the patient was sixty-four years of age, one hour and ten minutes were consumed in the operation, while in the other it took one hour and a quarter. He felt sure that many other surgeons also had resorted to equally long sittings before the method of Bigelow was published. He claimed, therefore, that the latter did not discover the tolerance of the bladder under surgical procedure. Bigelow did much more than this, however. He utilized all the points that he had gained by study and experience, and thus achieved one of the most brilliant surgical triumphs of modern times.

The relation of the size of the urethra to the size of the penis, as first formulated by him (Otis) in his paper of 1875, was practically invariable, and deviation from this rule was abnormal. Before performing lithotrity it was his practice to put the urethra in the best possible condition, and to remove any obstructions that might exist, as the chief danger from the operation was the liability of injuring the deep portion of the urethra. The smallest evacuating tube that ought to be used was No. 27 of the French scale, and the largest, No. 32. Bigelow, however, advised that the tube should not be less than 25 millimetres, nor more than 31 millimetres. Dr. Otis then stated that with a tube of 30 millimetres he had evacuated 300 grains of crushed coral (which closely resembled the mixed calculus in its structure) from a bottle fitted up to represent the bladder, in 30 seconds, while with a No. 27 tube, only 3 millimetres smaller, he had evacuated only 180 grains in the same period of time. As a rule, the tube should be two or three sizes smaller than the calibre of the urethra.

Prof. Bigelow recommended the straight tube in preference to the curved. The objection to the straight catheter was the difficulty of introduction, especially if there was any prostatic enlargement; and in order to obviate this, Dr. Otis had constructed an instrument which was straight throughout its length, but had a small curve just at the extremity. Notwithstanding the fact that Bigelow had stated that the large catheter was the single agent to which progress in lithotrity was due, there was still another element of success, and that was the more powerful evacuating instrument now employed, and for this advance the profession was indebted to Prof. Bigelow. The objections to his first instrument were that it permitted the return of the *débris;* and also the too free passage of air into the bladder. Dr. Otis next described Sir Henry Thompson's instrument, devised in 1879; which was provided with a receiver into which the fragments dropped directly, and also with a metallic connecting-tube and stop-cock. The same objections were found in this, and in 1880 he introduced certain changes in it to prevent a return of the *débris* into the bladder. Thompson's chief aim was to secure as direct a route as possible from the bladder to the receiver.

Dr. Otis remarked, however, that for a long time he had used Bigelow's original instrument with much satisfaction, and in the present year Mr. Reginald Harrison, of Liverpool, had made the statement that, after trying several modifications, he had found none that he liked as well as this. After describing the various changes that Prof. Bigelow had made from time to time in his instrument, which had rendered it more perfect in its action, but also more complicated and expensive, he went on to say that in the early part of 1883 he had achieved a brilliant success in his latest evacuator, which he exhibited. In this, the route of the fragments between the bladder and the receiver, was greatly shortened, and the prevention of their return was accomplished by a strainer, which was prolonged to the centre of the bulb. Dr. Otis had used it in one case, and its action had appeared to him to be perfect. When describing Sir Henry Thompson's last apparatus, he remarked that the weight and expense of both these instruments seemed to him to be objections, and he had therefore devised one himself, which was considerably lighter, simpler, and less costly.

The apparatus consisted of a strong annealed glass bulb, two inches in diameter, into one side of which entered a tube connected with a rubber air-bulb, the tube projecting within the glass bulb, and extending nearly to its tip. Into the bulb, on the other side, the tube connecting with the evacuating catheter projected, and passed downward nearly to its bottom; while beneath it was a glass receiver attached by a strong bayonet-joint. The entrance of air into the bladder was cut off by means of a stop-cock. The glass-bulb could be filled either by pouring the water into it, or by exhausting the air from it, and then allowing it to fill itself. When it had been filled, the evacuating catheter was to be introduced into the bladder, and the removal of the fragments accomplished by making pressure on the air-bulb. Dr. Otis had prepared a bottle to represent the bladder, and had placed a quantity of crushed coral in it; when regular pressure was made by the hand on the air-bulb, the fragments of coral were seen to pass down into the vacuum without exhibiting the slightest tendency to return. This Dr. Otis explained to be due to the direction of the current, which was controlled by the position of the two orifices of the two tubes in the glass bulb, a dead point being produced at the top of the receiver.

The apparatus was perfectly simple, no strainer being required to prevent the return of fragments, as in Bigelow's instrument. The strainer was liable to become clogged with mucus, and Prof. Bigelow always insisted on the necessity of keeping it perfectly clean.

The price of Otis's instrument was just one-half that of Bigelow's.

Dr. Edward L. Keyes, being called upon by the Chair, remarked that, as far as he could see, very little discussion was possible about the admirable apparatus which had been exhibited this evening. In regard to one or two points touched upon in Dr. Otis's paper, however, he would like to say a few words. The tolerance of the bladder had certainly been known as long ago as Civiale's time, for he and others sometimes occupied as much as half an hour at a sitting. But as they could not evacuate, and as there was considerable danger of injuring the bladder with the instruments then employed, they found it advisable to shorten the sittings to three or four minutes. Civiale, while he shortened the sittings, also shortened the time between the sittings, and found that he could get better results in this way than by protracted sittings at greater intervals.

As to the size of the evacuating tube now used, this was undoubtedly due to the labors of Dr. Otis; but at the same time this was not, in his opinion, the main element in Bigelow's success, although the latter had distinctly stated this to be the case. Prof. Bigelow's brilliant achievement was, in fact, the result of the crystallization in his mind of all the ideas to which moden lithotrity owed its birth; and among the elements contributing to it, he thought, ought to be mentioned the more perfect instruments for crushing now in the hands of the surgeon. The operation could be performed perfectly well with a No. 12 English tube; though, of course, the larger the tube the shorter would be the time required for evacuation.

He never yet had had to cut a urethra as a preliminary to lithotrity, except just at the meatus; but if he were to meet with a case of stone in which there was organic stricture, he should much prefer external incision to the operation of crushing. In one case, where there was prostatic enlargement, he had operated very successfully, using a small evacuating tube; but the same patient had afterwards suffered from severe inflammation after having lithotrity performed by so careful an operator as Prof. Bigelow. This, he believed, was solely due to the larger tube which the latter had employed. The only authorities of high reputation who used the very large tubes were Otis, Bigelow, and Harrison, as most surgeons were apprehensive of causing injury to the urethra with them.

As to Dr. Otis's new instrument, he had never seen it until that morning; but he could only express himself as highly delighted with its efficiency, simplicity, cheapness, and portability. Among its chief advantages seemed to him to be the employment of air-pressure instead of water-pressure, and the construction of the bulb of glass so that the operator could see exactly what was going on at every stage of the operation. The small size of the bulb was certainly a great advantage in most respects, but there might be cases, he thought, in which more water than it could hold would be desirable. One other point occurred to him. If the fragments were of any size, there seemed to be no doubt that there would be no danger of their return into the bladder; but he did not know how this would be if there were a fine phosphatic dust, such as was found in certain instances.

Prof. Bigelow's latest apparatus he had used repeatedly, and with perfect satisfaction; but his first instrument he thought very objectionable, because it allowed so much frothy swashing in the bladder that the operator could not tell how he was progressing.

Dr. Otis, in replying to Dr. Keyes, remarked that it might perhaps be true that Sir Henry Thompson, as a rule, adhered to the old practice of using small tubes, but it was also a fact that he repeatedly employed a No. 30 instrument. Where there was prostatic enlargement, he (Dr. Otis) had invariably inculcated the advisability of using as small a catheter as would evacuate the fragments. Where there was either a contraction at the meatus, or a stricture more deeply seated, he always cut the urethra some little time before performing lithotrity, so that the wound might be entirely healed and the urethra in the best condition possible when the operation was done. The object in having the bulb of his instrument so small was on account of its greater portability and greater freedom from the danger of breaking. It could be readily inverted, so that water could be poured directly into the bulb when desirable.

At the conclusion of Dr. Otis's remarks the Academy adjourned.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

Stated Meeting, Thursday Evening, Oct. 25, 1883.

The President, James Tyson, M.D., in the Chair.

Dr. Thos. J. Dunn, of West Chester, Pa., presented the report of the

AUTOPSY OF A CASE OF PLEURO-PNEUMONIA IN A COW.

The disease was of ten days' duration, and the prognosis being hopeless, the animal was killed. The rectal temperature was 104.8°, respiration 89, pulse 42, eyes sunken, ears drooped, back somewhat arched, great difficulty in walking, slight exertion causing dyspnœa and coughing. Respiration was jerky and shallow; there was slight muco-purulent coryza. Percussion gave absolute dulness over entire right side and lower part of left, while over the upper portions resonance was normal or slightly exaggerated. Auscultation: absence of vesicular murmur on right, and even bronchial breathing only could be detected over circumscribed areas; over upper part of left side, auscultatory signs normal; below, nothing could be heard.

Autopsy.—Much emaciation; muscular tissue of a deep mottled red, exuding on pressure much venous blood. The pleural cavities contained about six quarts of clear serum, with a few flakes of lymph. Both layers of the pleura were covered with from one to three inches of thick, tough, unorganized lymph, the membrane itself being rough and congested. The weight of the membrane was estimated to be twelve pounds. The left lung was crepitant throughout, but congested below; the right lung was completely carnified, while some of the largest bronchi were filled with plastic plugs, which, on removal, left the mucous membrane rough and swollen. The other bronchi had their mucous membrane swollen and congested. Frothy muco-pus exuded from the cut lung surface when scraped. The solidified lung was estimated to weigh fifty pounds, the normal being three and a half pounds. Right heart was dilated and its tissue soft; as the animal had been bled after death, the vessels were nearly empty. Other organs healthy. Microscopical examination of the blood (× 680 to × 1,000) from the heart showed innumerable globular or oval micrococci from 0.35 to 0.5 mm. They were rarely grouped in colonies, more frequently in pairs, but usually single. Lung scrapings showed granular cells, shreds of tissue, and innumerable micrococci. The cells contained bodies resembling the micrococci of the serum; they were insoluble in ether, neither did they stain with aniline-green nor hæmatoxylon, whether in an acid or alkaline solution, while the remainder of the cell readily colored. Aided by Dr. Martin, of West Chester (who assisted him in the microscopical examinations detailed), he has commenced culture experiments which in one instance have succeeded.

The President said that he had seen a similar case sixteen years ago, but at that date attention was not paid to the presence or absence of micrococci.

Dr. H. M. Fisher presented the specimens from

A CASE OF TYPHOID FEVER, WITH ABORTION IN THE THIRD MONTH; DEATH; ULCERATION OF PEYER'S PATCHES, AND HIGHLY FATTY KIDNEYS.

L. K., æt. 43, married, German, was admitted to the Episcopal Hospital September 15, 1883.

The following notes were taken by Dr. George M. Boyd, Resident Physician: She stated, on admission, that she had been sick two weeks, that the trouble began with general lassitude and headache. Her bowels had been loose, and she had passed blood in small quantities. The abdomen was somewhat tympanitic on percussion, and there was pain complained of on pressure over the right iliac fossa, and gurgling on pressure over this region. The patient seemed rather unusually prostrated; tongue coated with brownish fur and very dry.

Sept. 17.—Evening temperature, 103°; bowels loose. She complains of pain in both lumbar regions, apparently along the course of the colon.

19th.—Heart's action weak, but otherwise patient seems to be doing well.

20th.—Temperature 103°. Heart very feeble and irregular. Patient presents all the symptoms of profound shock. Menstruation stated to have come on suddenly this morning, with much loss of blood. Vaginal examination reveals widely open os and large uterus. Several large clots were removed, but failed to remove placenta, which was tightly adherent. Hot-water injections and ergot were ordered, with alcoholic stimulants, but no reaction took place, and the patient died at 9 o'clock the same evening.

The post-mortem examination revealed numerous enlarged and ulcerated Peyer's patches in the lower portion of the ilium; inflammation also of the solitary glands and so-called mesenteric glands. The uterus seemed about the size of a uterus at the beginning or middle of the third month of pregnancy.

The kidneys were highly fatty.

N. B.—An embryo, it seems, had been passed, but was unfortunately thrown away by the nurse with the other discharges.

Dr. Woodbury stated that he had a case of profuse bleeding, due apparently to menstruation, in the course of typhoid fever. This is contrary to what usually occurs, suppression of the menses being more common.

Dr. Edwards said that in one of his cases, of typhoid fever during pregnancy, the woman recovered, and was delivered of twins.

Dr. Fisher related another case in which the woman died when at full term. In articulo mortis she gave birth to a child that looked like a seven months' child. Its growth seemed to have been delayed by the presence of the disease.

Dr. Dunn said that he had a case of delivery accompanying the development of scarlet fever. The woman recovered.

Dr. Seiler read a paper on the

PATHOLOGY OF PHTHISIS AND ITS LARYNGEAL COMPLICATIONS,

in which he gave his views regarding the pathology of tuberculosis, and of phthisis, and of the laryngeal complications of the two diseases. He defined tuberculosis as an auto-infectious disease, manifesting itself primarily by the production of minute neoplasms, called miliary tubercles, which rapidly undergo retrograde metamorphosis ending in caseation, being due to the dissemination of infectious material throughout the lymph channels. This infectious material consists in cheesy matter due to scrofulous inflammation which may remain encapsulated for a long period. He then described the histological characteristics of tubercles, and showed how they could produce consolidation of the lung tissue by exciting secondary inflammation.

He then entered upon the consideration of the disease known as phthisis, and gave the following definition of it: Phthisis is a progressive consolidation of the lung tissue due to a more or less localized inflammation affecting primarily the apices, and undergoing retrograde metamorphosis; it is an inflammatory disease. He then gave a description of the pathological processes as they are observed in the lung tissue during the progress of the disease, and gave it as his opinion that the different forms and stages of phthisis, as they are described by many authors, are merely differences in the severity and extent of the ulcerative process. As etiological factors, he mentioned the various causes which produce a lowering of the vitality of the general system, thereby producing a predisposition on the part of the respiratory organs to chronic inflammation; among others he named hereditary peripheral nerve irritation, hypertrophic nasal catarrh, insufficient aeration of the blood, etc.

An elevation of the vitality of the system at large would prevent an outbreak of the disease, and lead to recovery in cases where not too much lung tissue had been destroyed. This elevation was to be produced by proper feeding and healthful exercise in the fresh air, more than by the exhibition of drugs. On the other hand, tuberculosis was always fatal and treatment was of no avail; but a great deal could be done to prevent the formation of the initial lesion of cheesy deposit by elevating the system of scrofulous patients early in life, thus preventing the outbreak of tuberculosis later. The laryngeal complications of both diseases were then considered in detail, and their differences pointed out. According to the reader, the laryngeal lesions never appear prior to the lung disease in phthisis; they are characterized by peculiar pallor of the mucous membrane; the tumefaction generally affects the posterior portion of the organ, and the ulcerations are shallow and have a tendency to spread over the surface; and tubercular or cheesy deposits are never found in the tissues of the larynx in phthisis. In tuberculosis, on the other hand, tubercular deposits have been found in the larynx prior to the lung implication; the mucous membrane is of a livid-red color; the tumefactions are more commonly observed in the anterior portions of the larynx, and the ulcerations are deeper with raised edges and often extensive destruction of tissue.

The paper closed with the remark that the indiscriminate use of the terms phthisis and tuberculosis, when speaking of lung disease, in our literature, was calculated to mislead the student, and make careful investigation into the pathology and etiology of these diseases extremely difficult, if not impossible.

Dr. J. C. Wilson said that he had listened with interest to the reading of the paper. The field covered by the writer is too great to permit the points to be discussed in detail. Two points, however, appeared to warrant comment. First, Dr. Seiler had several times used the expression, "tubercular material not derived from the exterior." If he had understood the paper aright, Dr. Seiler had not indicated his views as to the nature and source of this "tuberculous material." Does he follow the older doctrine—that of Beebe? Or has he some new opinion as to the etiology of tubercle? Secondly, Dr. Seiler failed to make clear his means of recognizing tubercle, either clinically or in the laboratory. It would be of interest to have the writer's views upon this vexed question. In a recent work, Hamilton, of Aberdeen, again seeks to establish a histological criterion for tubercle—the presence of giant-cells under a peculiar arrangement. This pathologist points out two modes of degeneration for tubercle: 1. Caseous; 2. Fibrous. To the latter, Dr. Seiler makes no allusion.

He thought, further, that the author of the paper had scarcely emphasized with sufficient force the presence of tubercle among the lesions in the various forms of phthisis as seen in post-mortem examinations.

He heartily concurred in the hopeful view as to the curability of certain forms of chronic lung disease when treatment is instituted at an early period. Nothing has exerted a more unfavorable influence upon the therapeutics of such diseases than the false view that the constitutional tubercular diathesis invariably antedates the local lesions of pulmonary consumption.

Dr. F. P. Henry remarked that he was not inclined to draw so broad a line of distinction between that form of pulmonary disease in which miliary nodules predominate and that in which the deposit is in larger caseous masses. Like Dr. Seiler, he was by no means convinced of the primary importance of the bacillus as a cause of tuberculosis; but was inclined, however, to attribute to it a prominent part in the production of the secondary symptoms of phthisis, those of systemic infection, which are largely septic in character. The symptoms of interference with oxidation, caused by extensive destruction of pulmonary tissue, are subordinate to those of systemic infection caused by absorption of the contents of cavities. The presence of the bacillus in the contents of these cavities is indispensable to the production of changes capable of producing this systemic infection. A small, ulcerating cavity communicating with the absorbent vessels is more disastrous in its effects than a larger cavity shut out from the absorbents by a lining membrane or wall of fibroid tissue. He understood Dr. Seiler to deny the existence of the giant-cell, and to make the statement that cross sections of blood- and lymph-vessels have been mistaken for it. Dr. Henry did not agree with him in this view, but thought the irregular contour of the giant-cell and its granular protoplasm were sufficiently characteristic.

Additonal evidence of the existence of this cell was furnished by the experiment of introducing beneath the skin of an animal, two thin glass covers fastened together. In the interspace of the glasses giant cells have been found, and in such an experiment there can be no cross-section of vessels. Dr. Seiler had several times referred to what is known in this city, and elsewhere, as Formad's theory of tuberculosis, which is, that in certain animals predisposed to phthisis, and presumably in some human beings, the lymph spaces are abnormally small, or, in other words, that in a given area of tissue there is to be found a greater number of endothelial cells than in non-strumous animals. Dr. Henry did not think this theory should be so extensively quoted until some more serious attempt had been made to establish or refute it. This might, he thought, be readily done by counting the cells in a given area of the tissue of strumous animals, and comparing their number with that contained in the same area of tissue of non-strumous animals. He did not think any greater difficulty would be met with in this attempt than has been successfully encountered in the enumeration of the blood cells.

Dr. Bruen said that he believed in a hopeful prognosis in the early stages of many varieties of phthisis, even when the process of phthisis was advanced; the management of cases was more successful when the lesions are localized; less advanced lesions are more grave when the lesions are widely disseminated. Dr. Bruen thought that it had been proved that phthisis could be produced by inhalation of inorganic irritating particles, especially if there was inherited predisposition to phthisis, or an artificially damaged constitution. May not bacterial elements be among the irritants capable of developing phthisis when inspired in larger numbers? and he thought they might be even more capable of creating damage than inorganic materials, because they possess the power of proliferation. Dr. Bruen agreed with Dr. Seiler in his views in the main, and considered his paper most instructive and interesting.

Dr. Mills thought it worth while to note the frequent occurrence of tuberculosis among those afflicted with chronic nervous and mental diseases. At the institutions for the feeble-minded and insane, phthisis or tuberculosis is a common cause of death. This fact, he thought, would lend support to the views of Formad rather than to those of Koch.

Dr. J. T. Eskridge had observed that some who had participated in the discussion referred to the views of the pathology of tuberculosis expressed in the paper of the evening, and to those entertained by Dr. Formad, in order to prove the same thing. He regarded the theories of each of these men as widely different. If tuberculosis is the result of inflammation in a person whose lymph-channels are abnormally narrow, as claimed by the latter, he could not see that phthisis differed from tuberculosis, as maintained by the former. In regard to tuberculosis being frequently developed in chronic diseases of the brain and cord throwing light on the pathology of the former, he thought the association of these diseases proved nothing more than that a prolonged period of lowered functions of the body was a favorable condititіon for the development of tuberculosis. He confessed that he did not know what to believe with reference to the pathology of tuberculosis; enough, to his mind, had not been proved to firmly establish any theory yet advanced so that it might be accepted as positive fact. Dr. Eskridge agreed with Dr. Shakespeare in demanding more pathological investigation following the clinical observation of the disease, before he could accept any view as positive of the pathology of tuberculosis. Dr. Eskridge called attention to the fact that many of the best clinical observers of large experience, such as Flint, DaCosta, and Hughes Bennett, considered tuberculosis and phthisis to be identical.

Dr. Davis asked Dr. Seiler if he taught that tubercle was caused by a caseous focus? He was answered, yes. It is important to know whether this is the case or not, as the German surgeons excise caseous glands not so much for the deformity they produce, as to obviate the liability to general infection. Would Dr. Seiler sanction this practice? As regards the possibility of cure, he believed with Koster, Billroth, and König, that tubercle is a local affection and not a general disease. He has seen tuberculosis as marked in the knee as in the lung, the miliary tubercles being within an eighth or quarter of an inch of each other. He has also seen tumor albus of the knee recover without operation. If the tuberculosis can get well in the knee, he believes that it can, in some cases, get well in the lung also.

THE PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, October 24, 1883.

The President, William M. Welch, M.D., in the Chair.

Dr. James Farrar Stone presented a paper on

THE RELATION OF PHYSICIANS TO LIFE INSURANCE.

In the year 1859, he said, the regular life insurance companies of the United States, reporting to the New

York Insurance Department, had in force, in round numbers, 50,000 policies, representing a total insurance of $140,000,000. At the close of 1882, according to the same authority, the number of policies in existence exceeded 660,000, insuring more than $1,600,000,000. During last year, these companies, thirty in number, issued about 92,000 new policies, and distributed among their policy-holders or their representatives over $52,000,000—an average of almost $150,000 for every day of the year, Sundays included. Nor do these figures, large as they are, fairly measure the growth and extent of this business.

Within the period covered by these statistics, and not included in them, new forms and methods, calculated to bring insurance to the notice and within the reach of all classes in the community, have been devised and introduced with such success, as to make it altogether safe to assert that but a moiety of the volume of business, and a yet smaller proportion of the persons carrying insurance of some sort, is represented in the returns quoted above.

Life insurance was, in its origin, essentially an outgrowth of medical science. Whose brain it was that first conceived the thought, we do not know, but we do know that until the law of the absolute uniformity in the average duration of life, when large numbers are compared, was demonstrated, life insurance, as a science or a business, was an impossibility. The mortuary records and observations which furnished the data from which this law, the corner-stone of life insurance, was at length deduced, were mainly the result of the labors of the medical profession, and life insurance is still dependent upon medical aid for its safe existence and healthy growth.

Important contributions to vital statistics may be confidently anticipated from the rapidly accumulating mortuary experience of the companies. These records are kept with a care and accuracy unattainable elsewhere, and the deductions drawn therefrom will be correspondingly valuable.

Already it has been demonstrated that the average longevity in civilized countries is gradually rising. The experience of American companies seems to be slightly more favorable than the British, but it would be premature, as yet, to conclude that this is due to greater longevity in the community at large. Indications point to a slight decrease in the ratio of deaths from phthisis, and an increase in those due to kidney affections. That greater results have not already been reached is due to the brief time and limited experience covered by the records. These observations must throw light upon such questions as the greatest duration of human life, the geographical distribution of diseases, the effects of race, occupation, hereditary tendencies, and physical condition and configuration, and many kindred topics.

The special relations the physician assumes in becoming the medical examiner of a company, and his duties in that capacity, are at once the most practical and difficult parts of my subject.

Regarding the ethical relations of the position, it is evident that he owes paramount allegiance to the interests of the company whose officer he is. The well-being of the company—and by this term is not meant any corporation, but the whole membership constituting it—demands the maintenance of a longevity at least equal to that of the general population. Under present conditions, those seeking insurance fall below that standard. This adverse selection the medical officer is appointed to prevent. To fulfil this trust he must weigh every candidate in the scales of physical fitness alone, and be blind to every alien consideration whatsoever. But while thus loyal to the company, he must not lightly regard the claims of the applicant. To deny to any man the privilege of insurance is never a trifling thing, and it may be a serious and lasting injury.

How shall we decide, in view of the conflicting claims of the applicant and company, those border-line cases which so often arise? But one reply can be given. When doubt remains after full investigation, always give the company the benefit of the doubt. When compelled to deny an application for insurance, the examiner may occasionally render a more than compensating service to the candidate, by revealing his timely discovery of an unsuspected disease, amenable to treatment in its early stage. Many valuable lives have thus been saved, or prolonged, and it is worthy of mention as an incidental benefit of insurance examinations.

The relation of the examiner to the agent ought to be, and generally is, one of coöperation, yet of absolute independence. The aim, the true interests of both are identical, however they may sometimes seem to clash. But the motives that sway the one must never be allowed to influence the judgment of the other.

How can the medical examiner best discharge the practical duties of his office? The first and obvious answer is, by having a clear conception of what those duties are. In general, they may be comprised in the obligation to recommend none but healthy lives for insurance. But inasmuch as perfect health is a condition most rarely, if ever, met with in actual experience, it is evident that something less than this ideal standard must serve for his working rule. What shall it be? Some companies have solved this problem by establishing a sliding scale, according to which all risks are graded into classes, extra good, good, fair or average, and poor. Others encourage the examiner to report mainly on the physical condition and habits, leaving points of hereditary influences, and other general questions, to be decided at the home office. This plan relieves the local examiner of a certain amount of responsibility, and has the apparent advantage of referring to experts the weighing of points, upon which the average medical man has had but little experience. As the whole application comes under the review of the medical board in any event, it may be questioned whether the judgment formed from personal contact, in view of *all* the circumstances affecting the risk, is not of more value to the company than one with certain elements ignored.

I cannot do better, just here, than to quote the formal question, closing the medical examiner's certificate on the application of a prominent company: "Is the person, in your opinion, as good a life for insurance as the average of persons of *the same age, who are of sound constitution, in good health, and whose family history is good*, and do you, acting in the interest of the company, advise the acceptance of the risk?"

To my mind, this is the most fair, logical, and comprehensive statement of the object of the examiner's work with which I am acquainted. To answer the question fairly requires a balancing of all circumstances affecting the life favorably and unfavorably, and an unqualified decision upon the relation of the risk to the standard assumed. With a clear conception of the purpose of his examination, the physician will do well to remember that the applicant for insurance stands in a relation the very reverse of that occupied by a patient. The latter comes for relief, and is ready to aid, so far as he can, in the discovery of his ailment. The former approaches with the assumption of health, and the examiner must detect, unaided, any fallacies in that assumption. The task is, not infrequently, made vastly more difficult by the deliberate purpose to gain the end by deceit.

One of the knottiest questions to answer satisfactorily, in many instances, is that respecting the applicant's use of liquor and narcotics. The importance of the information sought is commensurate with the difficulty of obtaining it. According to Neisson's statistics, as quoted in *Parke's Hygiene*, "In intemperate persons, the mortality at twenty-one to thirty years of age is five times that of the temperate; from thirty to forty it is four times as great, becoming gradually less with advancing age."

But what is a temperate use? To quote from an English writer on insurance: "Whatever may be our doubts as to the injurious effects of small quantities of narcotics and stimulants upon the system, we should have little hesitation in declaring that when they are long used, and in large quantities, they must, in the vast majority of cases, impair health and shorten life, so that a life so exposed needs higher rates."

Practically, then, it is not sufficient to trust to general statements, but it is important to learn just how often and in what quantities stimulants are taken. With all possible care, the examiner will sometimes be most egregiously deceived.

The family history presents difficulties, often insuperable, in the lack of knowledge of the causes of death among the immediate relatives. When we push our inquiries a generation further back, it is remarkable how little the average citizen can tell of his grandparents. Yet much may be learned or excluded by persevering inquiry. It is worth the effort if it be true, as Ribot asserts, that "Longevity depends far less on race, climate, profession, mode of life, or food, than on hereditary transmission, . . . and will assert itself above many influences generally fatal to a high average duration of life."

It is in the physical examination that the best work of the examiner is demanded. Closeness of observation, system, thoroughness, accuracy, must be his watchwords. He must insist on favorable surroundings, quiet and privacy, on time sufficient for examination without haste, on repeated interviews when needed, and, above all, on entire freedom from outside pressure or dictation in making up his verdict. But his whole duty is not fulfilled in the recognition of existing morbid states. It is required of him to detect latent tendencies to disease, to foresee the coming evil in the shadow it casts before.

What, then, have been the results of the medical examination of lives, as tested in the experience of American companies? In general the medical selection may be said to effect a diminution in the death-rate among insured lives as compared with the whole population, which continues at a lessening ratio for about six years, after which its influence disappears, and the mortality approximates that of the community at large.

Three propositions are regarded as established in the experience of the largest American company:[1]

1. That the advantage of selection diminishes at all ages with the duration of the policy.

2. That it decreases very rapidly among those who insure at the younger periods of life.

3. That it decreases more slowly at middle life and among older insurants, and probably never entirely disappears.

Dr. O'Hara then read a paper on the

USE OF CACTUS GRANDIFLORUS IN CARDIAC AFFECTIONS.

He was called to see E., æt. seventy-four, May 19, 1883, who had bronchitis and some œdema of the lungs; his feet were slightly anasarcous; there was no kidney difficulty, though he passed but little water; he had a mitral regurgitant murmur; some irregularity of heart's action; occasional intermission; pulse 90; he had arcus senilis and atheromatous arteries. The diagnosis was dilatation and failing heart, compensation gone by. He was given digitalis, iron, and nux vomica. He became more swollen generally, had orthopnœa, suffered very much, heart becoming very intermittent on the least effort. The treatment was kept up, with addition of saline laxatives for extreme costiveness. He was going downwards daily, and on June 22d the pulse was very intermittent, and only thirty-four beats to the minute; very water-logged in the lungs and over whole body. Thinking that he could be no worse off with any other medicine, and recalling the fact that I had seen in *Flint's Clinical Medicine*, the statement made that the cactus grandiflorus, in from three to five minim doses, is a valuable heart tonic, I concluded to give it a trial. I ordered it in five minim doses of the fluid extract (Parke, Davis & Co.), every four hours. In a few days every symptom improved, the dropsy disappeared, he could lie down at night to sleep. He has been taking the medicine now for five months—the last month fifteen minims, three times daily, with marked improvement; the dropsy has left him; he has the mitral murmur yet, and some irregularity, but rarely an intermittent pulse.

On another occasion (in a patient similarly affected) I used digitalis, and it failed me. Rev. Mr. V. has hypertrophy with dilatation, commencing mitral degeneration, also commencing aortic valve disease; has pronounced mitral valve regurgitation; he had violent palpitations, irregularity of pulse, and intermissions; pulse between 40 and 50. Here, I am satisfied, digitalis and convallaria aggravated matters, while the cactus relieved the pain, stimulated the heart, and removed irregularity. The heart never comes up above 50 to the minute, but the horrible feelings of death, with the sudden stoppages, are relieved.

In the case of Mrs. L.—dilatation, with failing heart from age, sixty-five years—I have used nothing else, and it has satisfied me. This person had vertigo, anæmia of the brain, dropsy, etc., all due to the failing heart, and the use of cactus inclines me to think that it was a good cardiac tonic.

I introduce cactus to the notice of the Society, because I have found it to have been little used. Many physicians, if they have like experience to mine, must recall the fact that digitalis at times diappoints them, and I would ask them to try this under those circumstances as a substitute. Of course, I have not had much experience with it, and I would like the result of my experience to be confirmed by that of others.

There are two preparations—cactus grandiflorus (night-blooming cerus), and cerus Bonplandii—of apparently same qualities, the latter of which I have made no use.

My limited experience goes to show of cactus grandiflorus:

1. That it is a pure cardiac tonic, whether for functional or organic disturbances, especially in cases of mitral regurgitant disease.

2. Convallaria, though not of service in cases accompanying mitral regurgitation, appears, from Dr. Bruen's paper in *Pennsylvania State Medical Society Transactions*, to be a supplement to digitalis, not replacing it; specially serviceable in backward distention of the lungs, from mitral obstruction, and a tonic for nervous and functional diastole of heart.

3. Belladonna and strychnia will frequently serve to substitute digitalis.

4. Caffeine citrate has been found to be of no effect in my experience for heart affections, functional or organic.

[1] Report of the Mortuary Experience of the "Mutual Life" of N. Y., from 1843 to 1874, pp. 18 *et seq.*

CORRESPONDENCE.

THE TREATMENT OF VESICAL CATARRH.

To the Editor of The Medical News:

Sir: In your issue of October 8th appears an editorial entitled "The Treatment of Vesical Catarrh," in which the usual resources of the profession employed in the treatment of this rebellious malady are enumerated, and their frequent failure referred to. Two additional remedies, not ordinarily used perhaps, you suggest to the practitioner as being worthy of trial in this condition—namely, chlorate of potassium and salicylate of sodium.

Now what estimate will be placed by the profession upon the value of these remedies in the treatment of vesical catarrh I will not venture to predict: for myself I will say that I have little, if any, confidence in their being able to effect better results than those following the employment of many other medicines prescribed for this disease. I base this opinion upon the fact that other germicide and antifermentative agents, such as the bichloride of mercury (now stated to be the best of this class), carbolic acid, borate of soda used locally, and benzoic acid and benzoate of ammonia internally, have been proved, in the great majority of the cases in which they have been exhibited, to possess but feeble properties, so far as regards any permanent benefit they may have conferred upon the patients.

If, therefore, future experience with the drugs you suggest confirm my expectations as to their curative value in vesical catarrh, it may be concluded that, so far as can be learned from your editorial, the treatment of this disease yet remains as ever, one of the glaring opprobriums of our art, which the energies of the profession should endeavor to remove as speedily as possible.

Apropos of this sentiment, I desire to call your attention to the fact that in your enumeration of the various methods of treatment for vesical catarrh, you have overlooked what many good practitioners consider to be the most prompt and potent means yet suggested for the cure of this troublesome malady, and a long step in advance of the conventional modes of treatment. I allude to a method of treating catarrh of the bladder by strong injections of nitrate of silver, brought to the notice of the profession by Prof. T. G. Richardson, of New Orleans, in a clinical lecture published in The Medical News and Abstract in 1879. As opposed to the weak injections of the nitrate recommended in your enumeration, Prof. Richardson injects a four ounce solution of the strength of twenty to sixty grains to the ounce of water, according to the urgency of the symptoms. If this cause much pain—a result by no means constant—a solution of common salt or of the iodide of potassium is injected into the bladder, which modifies the so-called caustic action of the nitrate. No excessive reaction, if any whatever, followed this procedure.

It is but fair to state that this treatment has been characterized by a leading specialist in this country as "irrational and extremely injudicious," but this criticism, I think, is sufficiently met by the published experience of Prof. Richardson and of others who have boldly employed it with the most gratifying results. My own limited experience in its use was gained in the following way:

I had under treatment a case of vesical catarrh in a man, forty-six years old, of intemperate habits, a native of Ireland. The condition had existed in a mild from for some years as the result of a stricture in the membranous portion of the urethra. The latter was thoroughly dilated, when a most acute cystitis immediately supervened. So intense was the incipient congestion of the walls of the bladder that an active hemorrhage ensued, which quite filled the organ with clotted blood, the presence of which gave rise to the most atrocious suffering in the way of tenesmus I have ever witnessed. Following the breaking up and expulsion of this bladder-clot, the inflammation of the mucous surface commenced. Large quantities of ropy muco-pus digested in foul-stinking ammoniacal urine were frequently voided. Soon there were observed portions of exfoliated mucous membrane also floating in the urine, indicating ulceration of the bladder. The constant suffering, despite the treatment employed, began early to tell upon the nervous system, previously rendered unstable by a life of intemperance and abuse. The patient was almost maniacal at times from the unrelenting tenesmus experienced while voiding the contents of the bladder. He ate and slept but little, rapidly lost flesh, and altogether became truly an object of commiseration and sympathy.

During the four weeks of my attendance, I had used every means of which I had any knowledge to relieve the case. The bladder was frequently washed out with warm water and warm water carbolized. Injections were made of borate of soda (Thompson's), nitrate of silver, two grains to the ounce of water; nitric acid in water, and finally of normal urine, recently passed, and this left in the bladder. Such measures gave only transient relief.

Internally were administered alkalies, acids, triticum repens, buchu, hyoscyamus, benzoate of ammonia, and large quantities of milk. Opium and belladonna, in maximum doses, were exhibited per orem, per rectum, and hypodermically. Morphia hypodermically, at frequent intervals, often reinforced by the inhalation of chloroform, was required to keep the tenesmus in check, and secure sleep.

At this juncture, Dr. S. Eagon, of this city, was called in consultation, and urged an immediate resort to the Richardson method. With much apprehension as to the result of what I then considered to be a heroic measure, I consented. An injection of four ounces of pure water, containing one hundred and sixty grains of nitrate of silver, was promptly injected into the bladder. Opium and alkalies were continued, with the addition of quinine and stimulants, and especial attention given to systematic feeding. From this moment, the case began to improve. All hemorrhage ceased; the tenesmus was almost entirely relieved; long intervals of rest from micturition were secured; mucus and pus disappeared from the urine; the patient slept well; his appetite returned; and he expressed himself as fully realizing his changed condition. On two subsequent occasions, when small amounts of glutinous mucus showed in the urine, the latter was promptly cleared up by the use of a weaker injection of the nitrate, twenty grains to the ounce of water. In about three weeks from the time of the employment of the first injection, the patient resumed his business, and, so far as I know, has had no relapse.

Dr. Eagon informs me that he has successfully employed the same treatment in a number of cases, two of which have come to my knowledge, and that, at some future date, he will publish them in a systematic form with the purpose of furnishing his quota of evidence towards establishing the safety and efficiency of the method as claimed by its originator. In a most readable brochure, entitled "Chonic Inflammation of the Bladder and its Treatment," Prof. Richardson goes fully into the pathology of vesical catarrh, expounds the philosophy of his method of cure, and illustrates by cases the success which has attended its use in his hands.

Respectfully, Henry K. Leake, M.D.

Dallas, Texas.

NEWS ITEMS.

THE CAUSE OF THE RECENT YELLOW FEVER OUTBREAK AT PENSACOLA. FINDING OF THE COURT OF INQUIRY.—The Court of Inquiry, convened in compliance with the telegraphic orders of the Secretary of the Navy, dated Washington, D. C., August 21, 1883, has presented the following report:

The Court of Inquiry has diligently and thoroughly inquired "into all the circumstances connected with, or which led to, the recent outbreak of yellow fever at the U. S. Navy Yard at Pensacola, Fla."

The Court has also carefully inquired:

"Whether or not proper measures were adopted to prevent the introduction of yellow fever into the navy yard aforesaid."

And the Court transmits herewith its proceedings, the testimony taken, and, after mature deliberation, reports that the following facts are deemed established by the evidence adduced:

First, "as to the circumstances which led to outbreak of fever."

Prior to August 1st it does not appear that there were any cases of yellow fever of any suspicious nature on the Naval Reserve. While we are not prepared to say that yellow fever really existed in Pensacola this season, it is not unlikely that fomites and bedding that were not destroyed during the epidemic of 1882, generated mild sporadic cases which eluded the vigilance of the attending physicians, and owing to the constant communication between the City of Pensacola and the Naval Reserve, the fever may have been introduced either through the medium of persons or fomites.

On August 3d, a commercial traveller named Frank French, visited the house of Mrs. Lucy Thompson in Warrington, whom she describes as having the appearance of having been lately very sick, and as then weak and sallow. Persons are known to have visited more or less between the two places, and some have been employed in Pensacola during the summer. There is a possibility that the marines may have visited Pensacola, although there is no evidence that they did so.

There are quantities of equipment stores in the equipment storehouse, which have been in store for many years, and were probably there during the years 1867 and 1874, and have never been broken out and opened until this year.

It is ascertained by evidence that the marines' barracks, lately occupied by them, had at least one case of yellow fever in it in 1875, and there is a possibility that it has remained infected ever since.

A number of men have by necessity been employed on the harbor improvement jetties at Fort McRae, who belonged in Warrington and Woolsey, mostly the latter village, and have been in the habit of visiting their homes once or twice a week. These men have been at work handling ballast for filling mattresses and other labor, near to a large quantity of ballast, which is shown to have come from at least one of the quarantine ballast cribs, used by the Pensacola quarantine authorities during 1881 and 1882, and the Burns's crib at Live Oak is shown to have had ballast from an infected vessel discharged into it late in October, 1881.

On August 3d, Wm. Kelley, a laborer in the Equipment Storehouse, and on August 5th, E. P. Chaffin, storekeeper in the Engineer's Storehouse, which adjoins that of the Equipment, sickened with symptoms sufficiently suspicious in our opinion to be classified as yellow fever, although not so diagnosed by the attending physician. In connection with these cases, it is shown by the evidence of Kelley himself that he had come in contact with men from Fort McRae coming home from their work weekly or semi-weekly, and that Chaffin visited him while sick before being attacked himself. It is shown that on the day Chaffin was taken sick, he was on a wharf in Woolsey, fishing with Mr. Wm. Langley, the son of Mrs. Langley, the grandmother of a child who was the first case of death by the disease; he was also a frequent visitor at her store in Woolsey.

The first case of death from yellow fever was Charles H. Thompson, a child of Mrs. Lucy Thompson, in Warrington, who died August 14th; the attending physician then believed the case to be inflammation of the bowels, but since, he has concluded that it was yellow fever. The funeral of this child was very largely attended by both adults and children of Warrington and Woolsey, by reason of which the disease was rapidly spread, more especially to the latter village. The house of Mrs. Thompson is situated on the principal street and thoroughfare of Warrington, and a lower room in it was used as an ice cream saloon, which was visited freely on Sunday evenings by the young people of the villages, including some of the marines. There was also a club-room on the same street, frequented by the marines and their friends of the reserve. On the evening of the eleventh of August, Private William Flaherty, of the Marines, complained of being ill, and on the twelfth was put on the sick-list; three days later his sickness proved to be yellow fever. It is shown by evidence, that on the evening of the eighth of August, he, with other marines, was in company with two men, Burkhardt and Ordway, at the club-room, when these two men were on their way to their homes in Woolsey from Fort McRae, where they had been at work handling ballast and had not changed their clothes, but wore them home through the streets, passing, among other places, the house of Mrs. Lucy Thompson, in Warrington; her child being taken sick on the tenth; feeling ill on the ninth. Her children are proved to have been playing on the side-walk at the time.

Having reviewed the evidence, we are now of opinion that the epidemic of yellow fever, now near its close, prevailing on the Naval Reserve, may be traceable to one or more of four origins, viz.:

1st. Possible infection from Pensacola by communication of persons, and by articles brought from that city.

2d. Articles in Equipment and Steam-Engineering Storehouse possibly infected in former epidemics.

3d. Possible infection of Marine Barracks since 1875.

4th. Probable infection from the ballast used and handled at Fort McRae jetties by men who lived in and visited the villages of Warrington and Woolsey weekly and semi-weekly in their working clothes.

Second: "Whether or not proper measures were adopted to prevent the introduction of yellow fever into the Navy Yard."

The first case of yellow fever having appeared in the Marine Barracks within the Navy Yard previous to the death of the first case in Warrington, and not finally diagnosed and decided to be yellow fever until three days after attack, any precautions that could have been taken at that time to prevent the introduction of the disease into the Navy Yard would have been unavailing, as the Marine guard and the surgeon himself were already infected.

THE YELLOW FEVER MICROBE. — Dr. Domingos Freire, whose researches into yellow fever were noticed before, has begun, according to the *New York Herald*, the practice of vaccinating persons with a culture of his yellow fever microbe attenuated by six transplantations in gelatine. Five out of six of the first batch suffered slight symptoms of yellow fever, and the Doctor expressed his conviction that they will not be attacked again, or, if they be, will escape with a very mild touch.

Yellow Fever in Mexico.—Assistant Surgeon Main, under date of October 22d and 28th, states that yellow fever still continued at Guaymas up to the 15th October, about five cases, with an average of two deaths occurring daily. The disease was decreasing and would finish its course, it was thought, by the last of the month (October). At Hermosillo the fever was considerably less, only one or two new cases occurring daily, with but one death daily from all causes. No new cases appeared at Mazatlan, but there were many sick with intermittent and typhoid fevers. The Governor of the State of Sinaloa has issued stringent orders prohibiting the exhumation of bodies of those who died of yellow fever. In Culiacan the disease had nearly disappeared, and the people who fled were returning. In the villages near the mountains the fever was still doing much mischief and seemed to have abated but little; the reported mortality was two deaths in three cases. At one of the mines there were ninety-one deaths out of one hundred attacked. The disease had been carried to the mouth of the Colorado River on the coast of Sonora, and no town in that State is known to have escaped the disease. It is said that La Paz has had five thousand cases, but it is impossible to state the mortality; the fever, however, is reported to be extending through the State of Lower California with little change in its general character. The fever was carried by refugees to Tepec, a place of fifty thousand inhabitants located on the highway to the City of Mexico, twelve hundred feet above the level of the sea. The disease was not so severe at this place, due to the prompt manner with which it was met and treated. The authorities at once isolated the infected districts, burnt furniture, clothing, and everything liable to carry the germs; quarantine was established, and every patient with the disease was watched with suspicious care, while the doctors were active and untiring. At San Blas the epidemic was over, and every vessel touching there was kept in quarantine until all danger passed. At Acupulco a number of cases occurred, but no satisfactory statement can be made as to their severity, etc.

The governors of the Coast States have decreed that all available agents shall be used at the expense of their respective States for the relief of the needy and suffering sick, that all interments shall be absolutely free, and that charity funds be raised to aid in the work.

Yellow fever continues at Yuki and Atai, in Sonora, not far from the border of Arizona. It is reported there were 4,000 cases and 500 deaths. In Altata, Sonora, all employés of the custom house were down, and only two out of seventeen recovered; of 150 soldiers but 2 escaped the fever and 41 died. In Ixcallan, State of Oaxaca, a town of 13,000 inhabitants, yellow fever appeared with great severity, 35 new cases daily, mortality not stated. At Manzanillo, a city of 76,000 inhabitants, the fever averaged 292 new cases daily up to the 18th of October, mortality 11 in 100. Its principal interior commerce is with Guadelajava, a city of 210,000 inhabitants, and apprehension is felt it may be carried there notwithstanding quarantine is rigidly enforced, and all railroad enterprise and commercial relations temporarily suspended. In Jalisco the fever appeared among the cotton pickers, brought there, it is supposed, by pedlers, two of whom sickened and died there; five days after, the disease was declared epidemic, every workman being sick. On the railroad the entire force of 30 men was taken down and work ceased. One case of yellow fever came to Bazos de St. Iago, and died there aboard the schooner Hattie, which sailed from Mobile. She is quarantined at Bazos, though no other cases appeared on board.

Assistant Surgeon Main adds a postscript, saying he had just received a telegram from Guaymas, dated October 26th, stating that yellow fever had broken out afresh at that place, and was alarmingly fatal, the report being that eight cases in nine die, and new cases rapidly occurring, with a large number of relapses.

Yellow Fever at Havana.—Sanitary Inspector Burgess, in his abstract of bills of health, furnished vessels bound for the United States, for the week ending October 27, and reports inspections as follows: Am. schr. "Nonpareil," for Key West; Span. brig "Vilasar," for Charleston; Span. brig "Maria Teresa," for New Orleans; Span. brig "Guadalquiver," for Doboy, Georgia; Am. str. "Niagra," for New York; Am. str. "City of Alexandria," for New York; Am. schr. "Grover G. King," for Key West; Span. str. "Pedro," for Charleston; Span. str. "Apolo," for Savannah. The Spanish brigs "Vilasar" and "Maria Teresa," above mentioned, have been in port at a suspicious wharf discharging, the former twenty-five days and the latter thirty days. He regards them both as dangerous, notwithstanding disinfection by him before departure. He reports twenty deaths from yellow fever for the week.

Yellow Fever at Vera Cruz.—Sanitary Inspector Mainegra reports having inspected the following-named vessels up to October 28th: Str. "City of Alexandria," for New York; bk. "St. Cloud," for New Orleans; str. "California," for New Orleans; bk. "Chapman," for Galveston; bk. "Keewardin," for Mobile; str. "City of Mexico," for New Orleans; schr. "Seguin," for New Orleans; schr. "Forest Home," for Pascagoula; str. "Whitney," for New Orleans; str. "City of Washington," for New York. All the above vessels were in good sanitary condition.

Quarantine Regulations at Gibraltar.—The quarantine restrictions at Gibraltar have been somewhat modified, and the Board of Health of Gibraltar has made the following order, repealing all former orders in that behalf, viz.:

"It being considered expedient to assimilate, as far as possible, the regulations respecting arrivals from the Brazils, to those in force in Spain, all arrivals from those latitudes with clean bills of health and health on board, shall, between 1st July and 30th September, be allowed to coal under strict quarantine regulations."

It has also been proclaimed that, "among other things ordered, any merchant vessel or boat from whatever part of the world arriving, shall, on sailing from Gibraltar, receive a bill or certificate of health, according to the circumstances of each particular case, from the Captain of the Port, or his assistants, in such form as shall be from time to time directed by any order or orders of the Board of Health of Gibraltar, any which certificate or bill of health such Captain of the Port or his assistants are thereby authorized and required to give; and further, that the order or orders from time to time made by the said Board of Health in pursuance of the said order of his late Majesty for carrying into effect the regulations and provisions thereof shall be duly published at Gibraltar by proclamation."

Consular Health Reports.—The U. S. Consul at La Paz, Mexico, in a letter to the State Department dated the 18th of October, says that prior to the date of previous letter (September 15th, ultimo), and during the whole month of September the yellow fever in La Paz reached the highest pitch of its malignant effects, also on the coast of the Peninsula, and more so at Mazatlan and Guaymas. The mortality in La Paz for the month of September, was yellow fever 114, other causes 8. It is impossible to get an approximate number of the mortality which occurred at the towns of the upper and lower coast of Lower California, but I am sure of its being over 300. He says, speaking of furnishing weekly reports, "no accurate register has been kept by the authorities, and the members of the Board of Health deserted the city for the mountains to avoid the disease, besides we have been entirely without communication with the border States." The Consul, who suffered with yellow fever in September, adds that the disease was then (Oct. 18th) disappearing from the city.

The Consul at Mazatlan, Mexico, under date of October 13th, states that the Board of Health of that place declared the epidemic over, and that clean bills of health will be given to vessels sailing from Mazatlan from and after the 13th of October. Leading physicians pronounced the disease to have been bilious remittent fever.

Consular reports from Rio Janeiro up to the 29th of September, indicate a continuance of the epidemic of smallpox. There were 77 deaths from that disease for the week ending September 29th, in a total of 278 from all causes.

At Matanzas the yellow fever has about disappeared, only two cases having occurred during the week ending October 26th.

The Cholera at Mecca.—A despatch from London, dated November 5, states that there have been 240 deaths from cholera at Mecca in one week.

Georgetown Medical College.—Surgeon-General John B. Hamilton, U. S. Marine-Hospital Service, has accepted the Chair of Surgery in Georgetown (D.C.) Medical College, vice Dr. Beale. It will be remembered that Prof. Hamilton temporarily filled the Chair of Surgery in Columbia Medical College, Washington, D. C., last year, during the absence of Prof. J. Ford Thompson in Europe.

Office of Surgeon General of the Army.—The question of filling the office of Surgeon General of the Army was not disposed of at the Cabinet meeting on Tuesday, as was anticipated.

Royal Gift to Dr. Grant, of Ottawa.—Her Royal Highness the Princess Louise, before leaving Ottawa, presented Dr. Grant with a very handsome despatch box as a recognition of his kind services to her during her stay in Ottawa. It is rumored that a knighthood is also to be conferred upon Dr. Grant.

National Hygienic Congress.—The first session of a National Hygienic Congress was held in the city of Mexico on the 10th of October: it presented a petition to the Government, asking that an article be added to the Constitution, placing all sanitation in the power of the general Government, instead of in the States.

The Health of the Army.—The report of the Surgeon-General of the Army for the fiscal year ended June 30, 1883, prepared by the late Surgeon-General Crane, has just been made public.

Among the white troops, the total number of cases of all kinds taken on the sick list was 37,697, being at the rate of 1.802 per thousand of mean strength; total number of deaths, 214; total number reported to have been discharged the service for disability, 879. Among the colored troops, the total number of cases of all kinds reported was 4,689; total number of deaths, 26; total number reported to have been discharged for disability, 101.

As an indication of the peculiar hardships to which the troops are exposed, the rates of admission for wounds, accidents, and injuries are 122 per thousand higher than those reported for the German army, and 142 per thousand higher than the decennial rate of the British army. The colored troops make a favorable showing in the small number of admissions for alcoholism and its results, exhibiting a rate of only 4 per thousand to a rate of 76 per thousand of mean strength among the whites. On the other hand, in diseases of the nervous system, they have an unexplained preponderance.

The additions to the library include 3,912 volumes and about 5,000 pamphlets, making the total number in the collection about 60,900 volumes and 68,700 pamphlets. It is believed that this library has now become of such importance and utility and is so widely consulted, that it should have the means of placing on its shelves as soon as published every new medical work, great or small, in all languages. Estimates for $10,000 have been forwarded. To the collection of the army medical museum 638 specimens were added. Of these, 94 were purchased and 544 were contributions. The Surgeon-General renews the recommendation of his predecessor for a new fire-proof building for the army medical museum and library.

There are now 9 medical officers on sick leave of absence; of these, 3 have been found incapacitated for active service and recommended for retirement, viz., Assistant Surgeons T. F. Azpell, J. W. Buell, and W. R. Steinmetz; one has been recommended to be brought before an Army Retiring Board, with a view to his retirement from active service, viz., Assistant Surgeon Z. V. De Hanne, and three more are regarded as permanently disabled. Four medical officers are on ordinary leaves of absence after a tour of duty on the frontier, leaving 162 medical officers for duty on October 1, 1883.

The Removal of the Remains of Harvey.—The desire which has at times animated many Fellows of the Royal College of Physicians of London, and others, to remove the remains of Harvey from the position in which for some 226 years they had lain in the vault at Hempstead, Essex, to a more honored position, has at length been realized. On Thursday afternoon, the 18th of October, St. Luke's Day, the transference took place, with appropriate and reverential ceremony. It may be recollected that Harvey's death occurred when he was in his eightieth year, on June 3, 1657, and that the funeral took place on June 26th, when the body was attended far beyond the walls of the City of London by a long train of his friends of the College of Physicians, and the remains were finally deposited in a vault at Hempstead, some fifty miles from London, which his brother Eliab had built. He was lapped in lead, and on his breast, in great letters, was his name, "Dr. William Harvey." Where thus placed the coffin has since remained, together with the leaden shells which contain the remains of several other members of the Harvey family. The vault, some five and twenty years ago, was in a very neglected condition, and the leaden case containing Harvey's remains was suffering from its exposure to the elements, and possibly the inroads of the village boys. In 1859, Drs. Quain and A. P. Stewart visited the remains at the request of the College of Physicians, and found the leaden case full of dirty water, which had penetrated through a crack in the metal. The vault was afterwards made clean, and the open window securely barred, but the leaden case was not repaired.

The leaden case was roughly shaped in the form of a body, having a head, neck, and shoulders, from which it gradually tapered towards the feet, where it was turned up as if to receive the feet at a right angle to the body. At the centre of the body, the upper surface of the lead had collapsed, so that on the inner side the upper and lower layers of lead almost touched. The extreme length of the case from head to heel was six feet three inches, which must have been longer than was actually necessary, as Harvey is always described as having been of small stature. On the breastplate of the leaden case was the following inscription:

Doctor
William . Harvey .
deceased the 3
of June . 1657
aged . 79 . years.

The condition of the coffin did not allow one to suppose that more than the skeleton remained in the case, and possibly even all that was not now preserved. In regard to the other leaden cases in the vault, one need not here dilate; except to say that most of them were in a better state of preservation than was that of the doctor; and that the two cases which lay immediately next to the doctor's coffin had been completely flattened by visitors to the tomb standing upon them when stooping down to read the above inscription on the breast of Harvey's case.

On January 28, 1882, the whole tower of Hempstead Church fell towards the southwest into the churchyard, fortunately without inflicting bodily injury on any person. Dr. B. Ward Richardson went down and examined the remains of Harvey. He found that the chapel had not been touched by the fall of the tower, but that the lead of Harvey's shell was going fast, and that there was water in the shell. This he reported to the Royal College of Physicians in February, 1882, showing them drawings and illustrations of the whole thing, and adding the suggestion that the remains should be raised to the Harvey Chapel above the vault, or brought to Westminster Abbey. A committee was formed at once to report upon the whole subject, and advise thereon, and it was decided to keep the remains at Hempstead, and remove them to the chapel above the vault. The necessary consent to this procedure was given. A marble sarcophagus for the reception of the leaden case was decided upon, and an architect was sent down to examine the state of the floor and vault, in order that the floor of the chapel might be sustained if necessary, in order to bear the weight of the sarcophagus and the leaden shell and its contents. Under his direction, pillars were built in the vault to strengthen the floor, and a plain sarcophagus, cut out of pure white Carrara marble, was constructed.

The following inscription was placed at the head of the sarcophagus:

William Harvey
Born 1578
Died 1657

The following was engraved on one side:

The remains of William Harvey
Discoverer of the Circulation of the Blood
were reverentially placed in this Sarcophagus by
the Royal College of Physicians of London
in the year 1883.

A leaden case was also prepared, in which might be placed the edition of the works of Harvey published in Latin by the Royal College of Physicians of London in 1766, and edited by Drs. Akenside and Lawrence. On one side of this was engraved:

Gvlielmi Harveii
Opera Omnia
Edita
MDCCLXVI

On the other side was inscribed:

The complete works of William Harvey,
deposited October 18th, 1883.

A memorial bottle, hermetically closed, was also prepared and wrapped in lead. In the bottle was placed a memorial, engrossed on vellum. The leaden case enclosing the bottle had inscribed upon it—

SCROLL.
Deposited October 18th, 1883.

The following is a copy of the memorial itself:

"The body of William Harvey lapt in lead simply soldered was laid without shell or enclosure of any kind in the Harvey Vault of this Church of Hempstead, Essex, in June, 1657.

"In the course of time the lead enclosing the remains was from exposure and natural decay so seriously damaged as to endanger its preservation, rendering some repair of it the duty of those interested in the memory of the illustrious discoverer of the circulation of the Blood.

"The Royal College of Physicians of which corporate body Harvey was a munificent Benefactor and which by his favor is the possessor in perpetuity of his patrimonial Estate at Burmarsh, Kent, did in the years 1882–83 by permission of the representatives of the Harvey family undertake that duty.

"In accordance with this determination the leaden mortuary chest containing the remains of Harvey was repaired and as far as possible restored to its original state and on this 18th day of October 1883 in the presence of four representatives of the Harvey family and of the President, all the office-bearers, and many other Fellows of the College of Physicians, was reverently translated from the Harvey Vault to this Sarcophagus raised by the College for its reception and preservation."

A special train conveyed the office-bearers, Fellows of the College of Physicians, and representatives of the Harvey family to Hempstead, where a large number of persons were assembled. The President and the officials of the College immediately assumed their robes of office, and a visit was made to the vault to view the chamber and Harvey's shell with the other coffins lying there. Harvey's leaden coffin was then raised to the churchyard up an inclined plane made by placing boards over the flight of steps. The eight Fellows of the College who acted as bearers, Sir Risdon Bennet, Drs. Owen Rees, Quain, Sieveking, Richardson, Shepherd, Duckworth, and Moore, then ranged themselves on either side of the coffin, and carried it through the churchyard, and up the nave and aisle, into the Harvey Chapel. Preceding the remains of Harvey were the officiating clergymen, Mr. Eustace, Vicar of Hempstead, and Mr. Escreet, the curate. Following the remains was a procession which included the four representatives of the Harvey family, the President of the College, carrying the silver emblem of his office, the College officers in their gowns, and the Fellows of the College, conspicuous among whom were Drs. Acland and Paget, the Regius Professors of Medicine, in their scarlet robes; besides these gentlemen were Dr. Broadbent, Dr. Hubert Airy, Mr. George Eastes, and Mr. Stear. Whilst the procession was passing up the church, the dead march in *Saul* was played. A service was then held, after which the remains of Harvey were lowered into the sarcophagus, and Sir William Jenner placed the metal case containing the scroll sealed in a glass bottle, and the metal box containing the copy of Harvey's works in a bottle, beside the leaden coffin in the interior of the sarcophagus. The vicar read the collect from the burial service ("O merciful God"), and concluded the service with the Benediction. The cover of the sarcophagus was placed in position after some little delay.

Thus within the last few years full honor has been done by Englishmen to the memory of Harvey. A noble statue, subscribed for by all classes of people, has been erected in his birth-place, Folkestone, Kent, and now the Fellows of his own loved College of Physicians have, with their own hands, placed his remains in a tomb which will for centuries demonstrate to the world the admiration which, in 1883, they entertained for the signal services rendered to Mankind by Harvey.—*British Medical Journal*, October 20, 1883.

A NEW DEPARTURE IN SOCIETY USEFULNESS.—On taking the chair at the Ophthalmological Society of the United Kingdom, MR. JONATHAN HUTCHINSON proposed that memoranda dealing with the treatment of many common affections of the eye should be prepared and issued to the members of the medical profession under the guidance of the Ophthalmological Society. In order clearly to understand the nature of the proposal, it is necessary, and will conduce to perspicuity, to discuss, first, the reasons for the issue of such memoranda; secondly, the method by which these documents should be distributed; and, lastly, why this kind of thing should be carried out rather by a corporate body than by other means. This subject, it will thus be seen, has to be treated from the points of view of theory, practice, and ethics.

There can be no doubt that a large number of cases of corneal ulcer do continually get worse mainly from the want of knowledge of the existence of simple remedies, and more especially of that valuable preparation the dilute yellow oxide ointment of mercury. Again, as Mr. Hutchinson urged, the number of instances of loss of sight from acute glaucoma which occur every year even now must be considerable, and this may be chiefly attributed to the lack of information regarding the proper time for the employment of iridectomy. Many excellent general practitioners do not realize the fact that, notwithstanding the presence of acute inflammation, the immediate performance of iridectomy is precisely the remedy, not only because the tension of the globe is thereby relieved, but also because the inflammatory state associated with the glaucoma must disappear by the same act. When we consider that it is hardly possible for the busy practitioner to have much time to devote to the acquisition of special knowledge of ocular diseases, and when we reflect on the amount of mischief and loss to the nation which annually accrues from such, in a measure excusable, lack of knowledge, we think enough has been put forward to show that the theory of Mr. Hutchinson's new departure rests on a sure basis. From the standpoint of ethics there can be nothing savoring of quackery in the carrying out of the scheme under the auspices of the Society. All individual names would be suppressed in the idea of the issue of instructions under the abstract title of Therapeutic Memoranda of the Ophthalmological Society, so that no accusation could be made against the proposal on this score. There is yet the further argument, also alluded to by Mr. Hutchinson, that advertising quacks may establish a lucrative business out of the knowledge of one or two simple remedies, which, however powerful in doing good, are also probably for the most part powerless to do evil. Altogether, we think the suggestion of Mr. Jonathan Hutchinson is of considerable importance, and hope that the Society mentioned, and possibly other more or less special societies, may see their way to the adoption of his overtures.—*Lancet*, October 20, 1883.

THE VALUE OF KOCH'S RESEARCHES ON THE BACILLUS TUBERCULOSIS.—DR. BURDON SANDERSON, in a lecture recently delivered in the Museum of the University of Oxford, said that Koch's discovery of the bacillus tuberculosis would, beyond the possibility of doubt, serve as the foundation for an efficient prophylaxis against pulmonary consumption and the other less familiar forms of tubercular disease connected with it by community of origin and of issue.

HEALTH IN MICHIGAN.—Reports to the State Board of Health, for the week ending October 27, 1883, indicate that dysentery, consumption, diarrhœa, bronchitis, tonsillitis, influenza, and rheumatism have decreased in area of prevalence.

Including reports by regular observers and others, diphtheria was reported present during the week ending October 27, and since, at fifteen places; scarlet fever at eighteen places, and measles at five places.

OBITUARY RECORD.—PROFESSOR J. A. H. DEPAUL, Professeur Agrégé in the Faculty of Medicine of Paris, has recently died of pneumonia, after an illness of three days. Prof. Depaul was born in Pau, in 1811. At the age of seventeen he went to Paris, and after many hardships completed his medical course. He received the degree of Doctor in Medicine in 1840, was created Professeur Agrégé in 1847, Surgeon to the Hospitals in 1853, having been elected to the Académie and the Société de Chirurgie in the previous year. He devoted himself more especially to obstetrics and gynecology; his work in this department of medicine, and his position as a teacher, need only be mentioned. In 1862 he was called to the chair of Clinical Midwifery, which he filled until his death.

Among his better known works may be mentioned his *Traité theorique et Pratique de l'Auscultation Obstetricale* and his *Traité de Clinique Obstetricale;* the latter, unfortunately, remains unfinished. He founded and was the editor of the first obstetrical journal in France, the *Archives de Tocologie*, and was one of the collaborators of the *Dictionnaire des Sciences Encyclopediques.* Notwithstanding his age his professional and scientific work was kept up almost to the day of his death.

He was elected President of the Académie of Médicine in 1873, and upon the announcement of his death, at its meeting of October 23d, that body immediately adjourned, as a mark of respect to the memory of its distinguished member.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM OCTOBER 29 TO NOVEMBER 5, 1883.

MCKEE, JAMES C., *Major and Surgeon.*—Relieved from duty in the Department of California and assigned to duty as Medical Director, Department of the Columbia.—*Par. 5, S. O. 249, A. G. O.*, October 31. 1883.

PRICE, CURTIS E., *Captain and Assistant Surgeon.*—Assigned to duty at Fort Custer, M. T.—*Par. 1, S. O. 187, Department of Dakota*, October 25 1883.

ORIGINAL LECTURES.

MALPOSITIONS OF THE UTERUS.

A Clinical Lecture, delivered at the Long Island College Hospital.

By ALEXANDER J. C. SKENE, M.D.,

PROFESSOR OF GYNECOLOGY, AND SURGEON TO THE LONG ISLAND COLLEGE HOSPITAL.

(Reported by Edward Develin, M.D.)

GENTLEMEN: You will remember that in my last two or three didactic lectures, I discussed, at some length, flexion of the uterus, giving you the nature and history of this deformity of the uterus, and also its pathology, as I understand it. I have here several cases of flexion and retroversion which will clinically illustrate some of the points which I endeavored to bring to your notice.

The first case is that of a young married woman, who has all of her menstrual life suffered from dysmenorrhœa, and has remained sterile since her marriage. The character of her dysmenorrhœa is precisely that which I described to you as occurring in flexion of the uterus. In making digital examination, I find that the os uteri points forward to an abnormal degree; in fact, it is directed almost towards the introitus of the vulva, whereas, as you know, it should point towards the sacrum. I also observe that the anterior portion of the cervix is almost on a line with the anterior vaginal wall; in fact, there is imperfect invagination of the cervix anteriorly, as if there had been arrest of development at this point; posteriorly, the invagination of the cervix is unusually great. Through the anterior vaginal wall I can detect the fundus of the uterus pointing towards the upper portion of the symphysis pubes. From this you will see that the cervix and body of the uterus are flexed forward; in passing the sound into the uterus, you will observe, by the sweep of the handle of the instrument externally, that it first passes backwards towards the upper portion of the sacrum, and then abruptly at the internal os, as I carry it along, it turns towards the symphysis pubes, thus proving, by the course of the sound, that the signs of anteflexion obtained by the touch are correct.

This case well illustrates two points to which I would call your attention—viz., that this form of flexion has associated with it almost invariably dysmenorrhœa, and also sterility.

CASE II.—Our next patient, also a married lady, before marriage suffered slightly from dysmenorrhœa. After her marriage, she became twice pregnant, and miscarried on each occasion. Since her first miscarriage, her dysmenorrhœa has been greater.

In making digital examination of this case I find the cervix in the normal position, but in pursuing my investigations backward behind the cervix I find a mass which feels like the fundus uteri, and which dips down in the cul-de-sac of Douglas almost as low as the termination of the cervix. These physical signs then indicate retroflexion, but in order to confirm this evidence I pass a sound into the cervical canal, which, you will observe by the handle of the instrument, passes in the normal direction until I reach the internal os. I then am compelled to turn the curved point of the sound backward, and it readily passes into the body of the uterus; the direction being downward and backward. In order to do this I am obliged to elevate the cervix upon the sound, so as to bring it more on a line with the body and fundus. Here we have, then, a case of well-marked retroflexion which, in all probability, existed to a slight extent before her marriage, but became aggravated during her few months of pregnancy, or was developed subsequent to her miscarriages.

You will remember that I told you, that in anteflexion sterility was most marked, and that in retroflexion there were some cases in which pregnancy occurred, but that in this deformity there was a liability to miscarry, unless the deformity was treated during gestation, so as to raise the fundus up into the normal position, and sustain it there while the development of the uterus is going on. Often when this is accomplished a complete cure will result. Much can be done during pregnancy in the way of treatment to prevent miscarriages. I will here illustrate the position of this deformity by a diagram upon the board, by which you will see that, while it is a deformity belonging to the same class as the previous case, it is just the opposite in the direction of the flexion: the one being forward and the other backward. We will now endeavor to restore this organ to its normal relationship by carrying the fundus upward and forward, and sustaining it there by means of a pessary. By comparing the two cases you will see at a glance in the first case, forward flexion of the body and cervix, and in this case retroflexion of the body alone, the cervix remaining in its normal position.

CASE III.—This patient is a lady in middle life; she has had five children and seven miscarriages. She comes to us because of these frequent miscarriages, and also because she suffers from a very distressing pelvic tenesmus, and an irregular and profuse menstruation.

In making my examination in this case, I find that the os uteri points towards the meatus urinarius, or, perhaps more correctly, the middle third of the urethra, the cervix being low down in the pelvis. I also find that the entire uterus is lying very low down in the pelvis; in fact, the fundus uteri is lower in the pelvis than the termination of the cervix, and between the cervix and the fundus there is a well-defined cul-de-sac. This shows that the body and cervix uteri are flexed upon each other; this is also, then, a case of retroflexion, but it is more than that, it is also a retroversion. Now you must understand that these two conditions may occur together. You will remember that in the second case there was simply a retroflexion, that is, the body was flexed backward, but the cervix was normal. Here in this case we find that the body is flexed upon the cervix, but at the same time the whole organ is lying further backward and downward in the pelvis than is normal, so that we have a combination of the two, a deformity and a displacement. This complication with flexion not infrequently occurs, and I may here call your attention to another complication of flexion which is not infrequently found, and that is anteflexion with a retroversion. I here represent upon the board an anteflexion of the uterus as it usually occurs. Now, suppose that I take that uterus, which is flexed forward, and carry the entire organ downward and backward into the position of retroversion? I would still have a deformity of the uterus, because the fundus is flexed forward upon the cervix, but the entire organ itself lies further backward and downward in the pelvis than normal, so that we have an anteflexion with a retroversion. It is well to be able to make out these complications, and to know that they may occur, because, if we should fail to appreciate these conditions we might be somewhat puzzled to know just what the condition was.

To return to the case now under observation, we will endeavor first to bring the cervix and body of the uterus on a line with each other; this we will do by elevating the fundus, or rather changing it from retroflexion to retroversion, we will then maintain this condition of the uterus, if possible, by means of a pessary which will support the body. After a time, we will be able, by treating it as a retroversion, to elevate that fundus still further and maintain it in position;, hoping, by so doing, that the atrophied walls of the uterus at the junction of the body and cervix may so improve in their nutrition and strength, that in time the uterus will be able to sustain itself in its normal relations.

If, after this, the patient should again become pregnant, we will watch her carefully, and sustain the uterus in position, until it is sufficiently developed to rise above the brim of the pelvis, and thereby be sustained, so that she may go on to her full term of gestation. If we can do this, and then watch her carefully after her confinement, and prevent the uterus from again becoming retroverted and retroflexed, we may succeed in curing her. But this is anticipating; for the present, it will suffice to try and relieve her present displacement and deformity.

Case IV.—Our next patient is a married lady, forty-five years of age; she has been married eighteen years, and has one child. She complains of backache, leucorrhœa, and pelvic tenesmus.

Now, in this case, we desire to know what is the cause of this tenesmus, which is aggravated by walking, standing, or defecation, and also this backache, which, she states, is relieved on lying down.

I will first try to find out the cause by physical exploration. Now, in passing the finger along the vaginal walls, first I come in contact with the posterior wall of the cervix, which is just the opposite to what it should be: I find the os pointing towards the symphysis pubes. Passing my finger further back, I find what appears to be the fundus lying in the hollow of the sacrum, so that the axis of the uterus will correspond with the middle strait of the pelvis.

Now, if I were to attempt to pass the sound, I should find it would pass directly backwards. We find, then, that this is a case of retroversion. In replacing the organ, I pass a sponge into the vagina (using the sponge-holder), and make pressure upwards, at the same time introducing a sponge anterior to the cervix in a similar manner, and making equal pressure, the patient being in Sims' position. This is the most simple and the easiest way of restoring the uterus to its normal position in this form of displacement.

Now, in this case, I might very readily make a mistake; my *examination* here was not sufficient to prove the diagnosis. The mere fact of finding the cervix forward, and observing in the hollow of the sacrum a mass which generally indicates the fundus uteri, might be entirely a mistake. Suppose I find the cervix pointing towards the symphysis, and I find a tumor posteriorly, which represents the fundus of the uterus. Now, I might have an anteflexion with this mass posteriorly, and which to the touch feels like the fundus, but which may be simply a fibroid or ovarian tumor crowding the fundus forward.

This is a condition of things not infrequently found, and, on making a careless examination, it is pronounced to be a retroversion. In order to overcome the possibility of any source of error, it is necessary to pass the sound, when, if it is an ordinary retroversion, the sound will pass directly backwards.

I remember one of these cases where I came very near making a serious error. I was called in consultation, and was told by the physician in charge that he believed he had a case of retroversion. I made an examination, and, to the touch, it was a perfect case of retroversion. I tried to pass the sound, but the uterus was somewhat tender, and I desisted. I was about to abandon it, thinking the case was so plain, when I remembered that I would not have the opportunity of seeing the patient for some time; I therefore pursued my investigations a little further, and succeeded in passing the sound up to the fundus without any great difficulty, and by this means I could lift the uterus away up beyond the mass I had previously felt, and could get my finger between the body of the uterus and this mass, which proved to be a small ovarian cyst, which was extremely dense, and which felt equally as solid as the fundus itself.

This shows that, if we desire to be accurate in our diagnosis, we must not be satisfied with the touch alone, but must use the sound in these cases.

Case V.—This patient is married, and is thirty-one years of age; has never been pregnant; she is troubled with dysmenorrhœa; further than this she is perfectly well. Now we must ascertain the cause of this sterility and dysmenorrhœa; the pain, she states, commences immediately at the beginning of the flow. This history is extremely brief, but so typical of this class of cases, and the physical signs coincide so well with the symptoms, that I will briefly put them together.

I will first represent upon the blackboard a section of the pelvis, including lines to represent the plane of the inlet and the outlet. I find the cervix pointing towards the introitus, and carrying the finger along the axis of the vagina, it comes directly in contact with the os externum, instead of the anterior wall of the cervix, as it should do. I find that this cervix occupies the position of complete retroversion. I pass my finger upwards in front of the cervix, and I find the fundus pointing towards the symphysis pubes, and the cervix looking in almost the same direction.

Now these physical signs, the forward flexion of the body of the uterus and cervix, coincide with the clinical history of sterility and dysmenorrhœa; they go together so generally that I need hardly discuss them separately. This patient has scanty menstruation. With the malformation of the uterus which we have here, the function of menstruation is very often irregular in quantity and duration, sometimes being scanty and at other times profuse. Early in the career of such cases it is often profuse, owing to the hyperæmic condition of the sexual organs; as they advance in life there is some change in the nutrition of the uterus which interferes with the development of the mucous membrane, and causes menstruation to become scanty, while in former years it was free. Now if we can straighten this uterus by throwing the cervix backward and raising the fundus, I have no doubt we will be enabled to relieve the symptoms which exist, but I have grave doubts as to relieving the sterility at this late date; the longer this abnormal condition exists the more doubtful ought we to be as to the possibility of overcoming the sterility. To overcome bad habits in these organs, it is desirable to take them in hand when young; the tendency at twenty years of age is to repair damages and defects of development, but at thirty it is not so to the same extent. So in this case we can hardly promise to relieve her of the sterility, but we can hope to relieve the dysmenorrhœa.

Case VI.—This patient is suffering from menorrhagia, and has been since the birth of her last child.

I now propose to explore the cavity of the uterus to ascertain the cause of the bleeding. Upon passing this curette into the uterus I find that there is retroversion of the organ; I find it also to be beyond the normal size. On the withdrawal of the instrument I here find this piece of fungous growth which I removed from the anterior wall of the uterus; although, in my manipulations with the curette, I detached from the walls of the uterus a much larger amount than I here show you, and which I have brought away for inspection to complete my diagnosis. On passing the curette over the surface of the uterus, I could distinctly feel that I was separating a large quantity of this material. The posterior wall appeared to be quite smooth, but on the anterior wall I detected that scraping sensation which is caused by this fungous material. This patient had albuminuria during her pregnancy and perhaps made an imperfect recovery; there is also at the present time a marked catarrhal condition of the cervix and dilatation of the canal, conditions which frequently accompany these growths of the endometrium.

Case VII.—The patient I here present to you is twenty years of age, she was married when eighteen, and comes to us suffering from menorrhagia which has troubled her many months. A week ago, during her menstruation, she states that she passed a large clot, since which time she has had a slight flow from the vagina. I will now make a physical exploration of the parts. You notice that as I pass in this probe it passes backwards, indicating a retroversion of the uterus, the physical signs of which I also obtained by the touch. On further examination I find it to be one of those cases of sterility resulting from displacement and corporeal endometritis, giving rise to those fungous or polypoid growths of the mucous membrane of the uterus; specimens of which I have often presented to you at my clinics. This is all sufficient to account for the sterility and menorrhagia.

The treatment is to remove the fungosities with the curette, and then restore the uterus to its normal position, and retain it there with a pessary. This may be all sufficient to relieve the endometritis, but, should that linger, the usual treatment for that affection should be employed.

ORIGINAL ARTICLES.

GALVANIZATION OF THE BRAIN, AND ITS VALUE IN THE TREATMENT OF CHOREA.[1]

By CHARLES L. DANA. M.D.,
OF NEW YORK.

The phenomena which result from passing a galvanic current through the healthy human brain, and through that of lower animals, are within certain limits quite well known. As regards the human brain, these effects may be classified under the heads of subjective phenomena, or those of which the patient is conscious, but which do not reveal themselves to the observer; and objective, or those which are apparent and can be noted.

The subjective phenomena, when galvanic currents of moderate or great intensity (5–40 Daniell's cells) are passed from brow to neck, are as follows:

(1) Pain, sensation of numbness and pressure.

(2) Malaise, faintness, nausea.

(3) Flashes of light, color-sensations, and dimness of vision. Auditory sensations (with powerful broken currents). Gustatory sensations (metallic taste, etc.).

(4) Dizziness, subjective and objective.

The flashes of light, metallic taste, and dizziness are most easily induced, and they are most prominent at making and breaking the current.

The objective phenomena are:

(1) Involuntary movements of eye (nystagmus, etc.).

(2) Movements of the head toward the anode on closure, toward the cathode on opening the circuits, with transverse currents. Disturbance of equilibrium.

(3) Convulsions (?). Very rare; not reported of late years.

(4) Unconsciousness. This I have produced in a girl aged eleven, by applying a current of Stöhrer's cells, with a very large anodal electrode covering both parietal bones. The condition was not that of syncope, as the face remained flushed, and heartbeat was strong and regular.

(5) Syncope—a psychical effect (?). Sleepiness.

(6) Salivation, vomiting.

(6) Lowering of temperature of surface (?).[1]

(7) Change in calibre of retinal vessels.[2]

(8) Change in the calibre of meningeal vessels.[3]

Besides the above there occur *After-effects:*

(1) Headache, head-pressure, dimness of vision, drowsiness.

In the diseased brain there follow, with more or less regularity, certain therapeutical results, such as:

Relief of brain exhaustion, melancholia, habitual headache, cerebral congestion, irritative diseases of central origin; changes in apoplectic conditions and in chronic, inflammatory, and degenerative diseases.

In the hypnotic state, when neuro-muscular excitability is increased, Charcot states that the movements of various voluntary muscles can be excited by acting upon the cranial surface over the motor centres.

In the lower animals, owing to the fact that stronger currents can be used, more marked objective symptoms can be brought out. These are:

(1) More pronounced movements of head, and of eyes; convulsions.

(2) Changes in the calibre of the meningeal (pia mater) arteries.

These vascular changes are as follows:

(*a*) With *ascending currents*, cathode to brow, anode to neck; in other words, with cathodal galvanization: dilatation of pial vessels, and increase in rapidity of flow of blood.

(*b*) With *descending currents* (anodal galvanization): generally a contraction of pial vessels, not always very marked.

(*c*) With *transverse currents:* dilatation of vessels on the side of the anode, contraction on the side of the cathode.

---

[2] Ibid. Bull. de Thér., xcv. p. 130; Gazette Méd., 2 s., xv. 38. 1878.

[3] All of the foregoing effects that are produced by direct excitation of the brain can also be produced reflexly by stimulation of afferent nerves—a significant fact.

As a result of direct electrical irritation of the exposed brain of animals, we get certain phenomena not observable when the cranial bones are interposed. These are:

I. Contraction of voluntary muscles by direct irritation. This can be done better, and the motor regions more accurately mapped out, the higher in the scale the animal is, as regards neuro-muscular mechanisms.[1]

II. Excitations of special and general sensations.

III. Disturbances of equilibrium; forced movements.

IV. Changes in various neuro-mechanisms of organic life are also observable; *e. g.*, in the beat of heart, the tone of arteries, the rhythm of respiration, movements of stomach, intestines, bladder, Fallopian tubes, spleen.

Change in temperature.

Changes in the activity of glands; *e. g.*, the salivary, intestinal, and hepatic.

Below is given a table showing the results obtained by a number of experiments:

Experimenter.[2]	Animal Used.	Mode of Application.	Result.
Legros and *Onimus.*	Dog.	+ Pole to brow } — " neck } = (10 cells.) Reverse =	Constriction. Dilatation.
Letourneau.	Dog.	— Brow } + Neck } = ascending.	On breaking: Pupil widened; retinal vessels narrowed.
	Man.	— Facial nerve } + Neck } = ascending. (10 cells.)	On breaking: Widening of pupil and narrowing of retinal vessels. On closure: Narrowing of retinal vessels.
		+ Facial nerve } — Neck } = 18 cells (Onimus).	On closure: Contraction of arteries. On breaking: same.
Fisher. *Löwenfeld.* *Erb*, *Nothnagel.* *Riegel*, and *Jolly.*			*Faradic* and *galvanic* currents applied on cranium or thigh affect changes in cranial circulation; generally of congestion. Mechanical peripheral irritations do the same. Contractions of muscle-groups do the same.
Löwenfeld.[3]	Rabbits.	— Brow } + Neck } = ascending or cathodal. + Brow } — Neck } = descending or anodal. Transverse: + one side, — other } =	Arteries widen; circulation hastened. Arteries narrowed, but less uniformly; circulation slowed. Arteries widened on anode (+); narrowed on cathode (—). This difference persists.

The vascular changes in ear and brain membranes do not run parallel.

From the above, it will be seen how potent the electrical current is in modifying the functional activity of the brain.

A question of great interest now presents itself, and that is, In what way does the galvanic current produce the phenomena which result when percutaneously applied to the brain? A number of facts and theories have been advanced:

I. One thing which is, I believe, established beyond question is that these currents effect some changes in the tone and calibre of the meningeal bloodvessels. It is further quite definitely established[1] that the cathode or ascending current causes these vessels to dilate (in lower animals). It seems very probable also that the anode (or descending current), passed from brow to neck, causes a constriction of the bloodvessels. It yet remains to be shown, however, that this change is either constant or very marked. Transverse currents in lower animals have been shown by Löwenfeld[2] to cause dilatation of vessels on the side of the anode, and contraction on the side of the cathode, as has been stated.

It is well known that mechanical and electrical irritations of sensory, or pressor, and depressor nerves, in various parts of the body, will likewise cause, reflexly, changes in the calibre of the cerebral vessels. For example, cerebral congestion can be produced by irritating the sciatic. It has been thought, therefore, that the vascular changes above described are also the reflex of sensory irritations.

---

[1] The anode is more irritating than the cathode Asz > Ksz (Hitzig) when applied to the convolutions.

[2] For bibliographical references see Löwenfeld's "Electrotherapie des Gehirns." München, 1881. Erb's "Handbuch."

[3] Op. cit.

[1] Vide Löwenfeld, op. cit.

[2] Vide op. cit.

It is much more probable, in my opinion, judging from experiments with anæsthetized patients and narcotized animals, that these vascular changes are produced by a direct action of the current. The evidence, however, seems to me conclusive that these contractions and dilatations of the bloodvessels furnish only one factor in producing the various phenomena resulting from cerebral galvanization.

II. The theory advanced by Althaus, that these phenomena are mostly reflex from the action of the current upon the trigeminus, has been disproved.

III. The galvanic current, when passed through a nerve, changes its irritability, this being lowered at the anode (positive pole), raised at the cathode (negative pole), (phenomena of electrotonus).

It is possible that similar changes in irritability are produced by polar galvanization of the nerve-centres. Hitzig found, indeed, that the cortical motor centres responded more readily to the anode than to the cathode—the reverse of that which is the case with peripheral nerves. It has been suggested that this is due to the chemical action of the anode, which increases the acidity of the gray matter.[1] However this may be, Hitzig's observation does not prove that the general effect of the positive pole is not to lower and that of the negative to raise the irritability of the cerebral tissues as a whole. Experiment shows that the physiological effects of applying the anode are milder than those of the cathode; also that the anode very probably contracts the pial vessels, and slows the circulation. Clinical observation also shows, with hardly an exception, that the effect of the anode therapeutically is more agreeable and quieting.

IV. The galvanic current, besides its effect upon the bloodvessels and upon nerve-irritability, doubtless produces some direct change in the metabolism of the nerve-tissue, hastening, delaying, or modifying it. Whether these metabolic effects vary at all with the poles is uncertain.

V. The current acts to some extent upon the ampullary terminations of the eighth nerve, and probably thereby will cause dizziness and vertigo.

I have spoken of polar effects, and of ascending and descending currents. It appears to me that we ought to abandon the latter term as regards the brain, and perhaps also the cord. In passing a current from brow to neck, it descends some fibres and vessels, and ascends others.

I have found that by strictly polar electrization on the human brain the same phenomena result as by using the so-called current method; that is to say, the anode is, like the descending current, more mild. The well-known fact, that transverse currents produce unpleasant effects more easily than longitudinal, is readily explained by supposing it to be a polar action. The two sides of the brain have their irritability changed; the rapidity of nervous conduction is also changed, thence interference of nerve impulses and thereby disturbance of function. The blood-supply on the two sides is also, according to Löwenfeld, unequally affected.

I believe we should gain by using the polar method and nomenclature in studying the effects of cerebral galvanization.

I am inclined to hope that I have devised a way by which more powerful effects can be gotten in the galvanization of the brain than by the ordinary methods. It consists in placing the foot upon a copper plate connected with the cathode, and placing the anode, a large curved sponge electrode seven inches by four, upon the head. It is known that with the peripheral nerves more powerful polar effects are gotten by having the poles far apart, and it appears to me that the same may be true as regards internal organs. Great caution should of course be used in applying these large currents, for even mild ones sometimes produce unpleasant after-effects.

I have said nothing about the question whether electricity really reaches and affects the brain, for that is settled by the investigations of Burckhardt, Rumpf, von Ziemssen, Erb, and others.

My conclusions regarding the percutaneous galvanization of the brain are:

1. That it is one of the most easily reached and easily affected of central organs.

2. That in ordinary galvanization the polar method and polar nomenclature should be used, since it is probably the pole and not the direction of the current which produces specific effects.

3. That the anodal galvanization of the brain probably lowers cerebral irritability, contracts the pial vessels, slows the circulation, and produces effects upon the nutrition of the brain.

4. That its action is chiefly a direct one, but is supplemented by reflex processes.

5. That possibly more powerful or special polar effects may be gotten by using widely separated electrodes.

We come now to the particular subject of cerebral galvanization in chorea minor. I believe ordinary chorea minor to be an irritative disease of some part of the gray matter of the voluntary motor tract. The irritation may be chiefly in the spinal cord, as seems to be the case sometimes in dogs; or it may be chiefly in the brain (*i. e.*, internal capsule, basal ganglia, or cortex), as is the case with the ordinary chorea of children and in the post-hemiplegic forms. The later developed or accessory portions of this motor tract are most affected; and these are parts most readily responding to electrical stimulation.

Chorea is not a disease which should be left to nature. It often, indeed generally, runs a cyclical course, but in the beginning the physician can never tell whether it will not cling to the child for months or years. Hence, the best therapeutical means should be promptly applied to its treatment. The reports as to the value of electricity in chorea have heretofore been most conflicting. The methods of applying electricity have also been varied and numerous. Benedikt, Remak, Onimus,[1] Beard and Rockwell,[2] Meyer,[3] Leube,[4] Jaccoud. von Ziemssen,[5] have applied galvanism to the spine, Meyer, Leube, and Jaccoud using strong currents, the others weak currents. Von Ziemssen, and Beard and Rockwell do not speak well of it. The others claim good results. Althaus commends central galvanization with faradization of the affected muscles. Beard and Rockwell recommend general faradization in preference to galvanization in most cases.[1] Rosenbach and Steifert[7] apply galvanism to the tender points along the spine. Hammond speaks unfavorably of electricity in chorea, and Russell Reynolds[2] said in 1874 that electricity was of no use in this disease. The whole makes a somewhat unfavorable showing for electricity, and I should never have attempted its use, had it not seemed to me that it had so far generally been applied irrationally.

---

[1] The gray matter of the cortex is neutral or acid; that of the white matter, alkaline. Acids go to the positive pole.

[5] "Cyclopædia of Practice of Medicine," vol. xiv. p. 468.

But, acting upon the hypothesis that anodal galvanization of the brain ought to prove sedative in functional spasmodic troubles of cerebral origin, I began some time ago to use this method in the treatment of chorea. It was not until recently, upon the appearance of the second volume of Erb's work,[3] that I learned that he and Berger[4] had been using anodal galvanization of the brain in chorea also. Neither of these authors, however, report detailed cases or give specific clinical facts upon which they base their conclusions. I, therefore, feel the more justified in presenting my results now.

I present here a record of eight cases, treated more or less systematically with galvanization of the brain.

Case I.—Dora S., aged ten. Parents healthy; third in a family of eight, and the only one who has had chorea. Is the brightest scholar in the family and fond of study. Never had rheumatism; had a previous attack of chorea three years ago. First seen *Jan. 17th.* Present attack began about a week before. Is somewhat anæmic: has a mitral regurgitant murmur; it is loud, systolic, heard best at apex, is transferred and can be heard behind. Choreic movements chiefly on left side. Ordered liq. potass. arsenit., ♏ vj, t. i. d.

20th. — No improvement; worse if anything. Galvanism: anode to right parietal region; five Stöhrer's cells. Continued arsenic.

25th.—Was better for a day or two; then relapsed. Galvanism and arsenic.

Feb. 18.—Had improved for a time; then relapsed. Galvanism and arsenic. Did not return. Subsequently learned that she had rapidly recovered after last treatment.

Case II.—Martha S., aged ten. Family history negative. Had had a previous attack one year ago. Never had had rheumatism. First seen *Jan. 8th.* Somewhat anæmic; no cardiac murmurs. Chorea began about a week ago; unilateral, left side. Ordered Fowler's solution, ♏ v, t. i. d.

15th.—Worse. Renewed arsenic, ♏ v. Applied galvanism, eight cells.

17th.—Better until to-day. Renewed above.

19th.—Same story. Renewed above.

22d.—Better. Applied galvanism only. Did not return.

Case III.—Margaret H., aged eight. Family history negative. Has had no rheumatism and no previous attack.

Jan. 16.—First seen. Anæmic and poorly nourished. No cardiac murmurs. Attacks began six days ago, mostly on right side. Treated her with cod-liver oil, iron, quinine, and Fowler's solution—♏ vij–viij.

29th.—About same. Galvanism, six cells, five minutes. Fowler's solution continued in ♏ ix doses.

Feb. 2.—Had been very much better for two days, then gradually grew worse. Renewed galvanism and arsenic.

16th.—Better for a few days, then worse. Galvanism.

18th.—Better for a day. Galvanism.

23d.—Better to-day. Galvanism. Did not return.

Case IV.—Lena S., aged fifteen. Family history negative. Had never had rheumatism; third attack of chorea.

Feb. 16.—First seen. No cardiac murmurs. Chorea very bad on left side; cannot use knife and fork; attacks began six or seven days ago. Applied galvanism, six cells.

18th.—Better; galvanism, three cells.

21st.—About same; improved for a day. Galvanism, three cells.

23d.—About same; gave Fowler's solution, ♏ vj, and galvanism, three cells.

28th.—About same; renewed above.

March 14.—Nearly well.

Case V.—Alfred S. aged nine. History negative. Had no rheumatism or cardiac disease. Had a left-side ataxic chorea, not well marked. Would sometimes stumble and fall; could not eat well with left hand. Treated from April 11th to May 12th. Steadily improved under arsenic and galvanism, but chiefly the former.

Case VI.—Sarah K., aged ten. Family healthy. Has had no rheumatism. Has had two previous attacks of chorea—one and two years ago respectively. Present attack came on two or three weeks ago. First seen *April 16th.* An active, healthy-looking girl. Has a mitral regurgitant murmur. Very severe chorea on right side. Cannot use the right hand to feed herself Very restless and irritable. Ordered Fowler's solution, ♏ vj.

23d.—No improvement. Ordered Fowler's solution, ♏ vij, and galvanism.

27th.—Better; renewed above.

30th.—Better; renewed above.

May 2.—Better; renewed above.

---

[1] Dr. Rockwell informs me that in his experience galvanization acts better in cases of chorea where the children are not very anæmic or ill-nourished. In this latter class he prefers to use general faradization.

I cannot consider that "central galvanization" as used by Dr. Rockwell is the same thing as the stabile anodal galvanization with large electrodes and gradually increased and decreased currents, described and used by myself.

[2] "Electro-therapie," Leipzig, 1882, R. H. Pierson, p. 184.

[3] "Clinical Uses of Electricity," p. 83.

[4] Handbuch der Elektrotherapie, Heft II., p. 568. Erb says "the recent chorea of children has been benefited very decidedly by electrical treatment, [anodal galvanization] and the disease materially shortened in many cases."

[5] Centralbl. f. Nervenheilkunde, No. 10, 1879, p. 220.

5th.—About same; renewed above.

9th.—Has been better, but is now worse, and is nearly as bad as ever. Has been taking arsenic.

9th–14th.—Gave daily galvanizations and continued arsenic. She steadily improved and is now practically well. The immediate improvement after the daily galvanizations began was notable.

Case VII.—Irene B., aged fourteen. Family healthy. Had rheumatism last January. Had one previous attack of chorea. First seen *April 16th.* Patient not well developed. Has mitral regurgitant murmur and left supra-orbital neuralgia. Chorea began a week ago; it is very severe on the left side chiefly. She cannot feed herself with left hand. Ordered iron, quinine, and arsenic.

18th.—No better. Galvanism, two cells. Continued other remedies.

23d.—Much better; can feed herself. Renewed above, and gave cod-liver oil.

25th.—Better; no galvanism.

27th.—Worse, since galvanism was stopped. Renewed it with other remedies.

May 2.—Galvanism.

8th.—Has been kept on medicine alone and no galvanism. No improvement.

8th–14th.—Received galvanism every day and nothing else, except part of the time valerianate of zinc, which she had taken before without result. Is now practically well.

Case VIII.—Bertha H., aged thirteen. Family healthy; is oldest of four children, and the only one affected with chorea. Never had rheumatism. First had chorea seven years ago when first sent to school; it was bilateral, but worse on left side. It has remained with her since, only disappearing mostly during fall and winter, reappearing in the spring. In spring of 1881 went to hospital, and remained there for one and one-third years. Could always feed herself and walk. Came out last fall well; continued so until about ten days ago, when arms and legs began to twitch, chiefly on left side; face not noticeably involved. First seen *May 7th.* General appearance good; is somewhat pale, quiet, well-grown. No cardiac murmur. Ordered Fowler's solution, ♏ viij, t. i. d.

9th.—No better. Fowler's solution, ♏ x.

16th.—If anything, is worse.

16th–23d.—Applied galvanism, 2–5 Stöhrer's, 6–8 Daniell's cells daily. No other treatment.

By *19th* was much better. On *23d* was well.

The first cases recorded showed me, as I believed, that galvanizations produced temporary improvement at least, when given only three times a week. The last cases convinced me that daily applications had a potent effect upon the disease.

The average duration of the disease in seven cases was thirty-four days; the eighth case, not a well-marked one, lasted about forty days. The average duration of treatment was twenty-five days. The average duration of the disease, according to See, is sixty-nine days; but this is too long for chorea as it occurs in New York. The average of about thirty cases, aside from the above, treated by me chiefly by arsenic was between six and eight weeks. It is not upon the statistics of duration, however, that I am led to believe in the efficacy of anodal electricity. I observed at first that patients would say that they felt better for the next twenty-four or thirty-six hours after the seance; then the old symptoms came back. This happened in such a number of instances that I could not believe it was coincidence. Again, some cases I treated with arsenic, with no result; I then added galvanism, and improvement at once began. In some instances, I used electricity alone, and with benefit. The electricity should be applied daily for at least ten days. If, after that, there is no improvement, it may be discontinued. When given only three times a week, it did not always effect good result. In those cases in which electricity was applied every day, I am inclined to think that arsenic or other specific medication is not needed.

What I claim for anodal galvanization is that it is a most valuable adjunct in the treatment of chorea; that given daily for a week or ten days with arsenic, and probably without, it will materially shorten the duration of the disease in most cases of chorea in children.[1]

The method of application is as follows: A large sponge-electrode of flexible brass, 4 by 2 inches, is thoroughly moistened with salt water. The hair of the patient is also thoroughly wetted, and the electrode applied over the side of the head, above the ear. In hemichorea it need only be applied over the side opposite to the one affected. The other electrode is placed in hand of the affected side. The electrode upon the scalp is made positive, and a stabile current of three to six Stöhrer's, four to eight Daniell's cells, is passed for from three to six minutes.

THREE CASES OF FOREIGN BODIES IN THE TRACHEA OR LARYNX; REMOVAL; RECOVERY.

Reported by H. R. WHARTON, M.D.,
SURGEON TO THE CHILDREN'S HOSPITAL; DEMONSTRATOR OF CLINICAL SURGERY IN THE UNIVERSITY OF PENNSYLVANIA, AND ASSISTANT SURGEON TO THE UNIVERSITY HOSPITAL.

Case I.—Edward McC., aged seventeen months, was brought to the Children's Hospital on November 30, 1881, with the following history: A few hours before admission, while playing with some beans, he put one into his mouth, and apparently swallowed it, but was almost instantly attacked with a violent paroxysm of coughing and decided respiratory embarrassment. When the child was first seen, he presented the following symptoms: Marked dyspnœa, paroxysmal cough, great restlessness, and lividity of the face.

Prof. Ashhurst, who was in the hospital at the time of the child's admission, considered the symptoms sufficiently urgent to justify the performance of tracheotomy. Ether was administered, and the operation was accordingly performed, and the trachea exposed below the isthmus of the thyroid; a branch of the thyroid plexus of veins was divided, and bled profusely, but was easily secured and ligated. The trachea was then opened, and as soon as the edges of the tracheal wound were retracted, a forcible expiration occurred, which expelled the foreign body from the wound. This proved on examination to be a small white bean. The respiratory difficulty instantly disappeared, but as the trachea was quite flexible, and as its calibre might be interfered with by the pressure of inflammatory products, a small silver tracheotomy tube was introduced, and retained in position by the ordinary means.

---

[1] Since writing the above, Nothnagel, in a clinical lecture on chorea, published in the *Allgemein wien. medicinische Zeitung*, recommends the use of galvanism by somewhat similar methods.

Dr. George W. Jacoby, of this city, informs me that three years ago, he and Dr. Rudisch used galvanization of the brain daily in a very considerable number of cases of chorea, but with unsatisfactory results. I cannot explain the difference between his experience and the contrary one of Rockwell, Erb, Berger, Nothnagel, and those just recorded above, except by assuming some difference in the technique of applying it.

The child reacted well, and presented no unfavorable symptoms; the tube was removed on the fourth day, and, at that time, the respiratory acts were carried on both through the wound and the mouth.

The further progress of the case was entirely satisfactory; with the exception of a slight attack of bronchitis, which rapidly responded to treatment, no unfavorable symptoms presented themselves, and the case was discharged from the hospital, with the wound healed, on December 14th.

Case II.—James K., aged nineteen months, was admitted to the University Hospital May 3, 1883, with the following history: Four days before admission, the child, who lived in the country, some forty miles from Philadelphia, was amusing himself by biting grains of the common gourd seed corn from the cob, and feeding them to the chickens. While so employed, he accidentally inhaled a portion of a grain, and was instantly seized with a violent attack of coughing. As his symptoms became gradually worse on the fourth day after the accident, his physician advised his parents to bring him to the hospital. When admitted, the symptoms of dyspnœa were so urgent that Prof. Ashhurst was hastily summoned, and decided to perform tracheotomy at once. The child was given a few whiffs of ether; but as the respiration was much embarrassed, the incision was rapidly made and the trachea exposed without any considerable hemorrhage. The trachea was then opened, and the edges of the tracheal wound held open by wire retractors; respiratory movement had entirely ceased, and the child's appearance had become most alarming.

Artificial respiration was resorted to, and kept up for some minutes, even after all hope of resuscitation seemed to have passed; but finally a voluntary expiration occurred, which brought a portion of a grain of corn into the wound, from which it was removed.

Respiration was now thoroughly established, and was performed satisfactorily while the tracheal wound was kept open, but as soon as the retractors were removed dyspnœa again occurred. A small silver trocheotomy tube was now introduced and held in position in the ordinary way; it was thus found that the respiratory difficulty had subsided, and the breathing was carried on quietly by this means.

The child presented no unfavorable symptoms after the operation, but the attempt to remove the tube on the tenth day was unsuccessful, as the child soon presented symptoms of dyspnœa which necessitated the hasty reintroduction of the tube. Numerous attempts were made, even under ether, to remove the tube permanently; but all were unsuccessful for a like reason and the child was discharged from the hospital at the parents' request, wearing the tracheal tube, on June 26, 1883.

The case was again seen on July 23d, when it was found that the tube could be removed for a longer interval without alarming symptoms supervening. The parents were instructed to present the case from time to time, when attempts would be made to discard the use of the tube, but the case has not been seen since the last-named date.

The two preceding cases are of interest, especially, from the fact that the operation was performed upon quite young patients, both being under two years of age, and recovery following in both instances.

The condition noted in Case II., namely, the difficulty in the inspiratory act, the edges of the tracheal wound being drawn together and thus preventing the admission of air, apparently due to the extremely flexible condition of the trachea, is one that I have never before noticed.

Whether this was due to the normal flexibility of the trachea in a child of this age, or to the inflammatory condition of the mucous membrane at the seat of operation which had been set up by the prolonged presence of the foreign body, and had extended to the other elements of the trachea, causing a general inflammatory softening I am unable to decide, but that it was due to the latter cause in a measure, I am disposed to think, for in Case I., where the age of the patient was even less, the difficulty did not exist, and the tube was only introduced as a precautionary measure, as stated above.

The permanent removal of the tube after tracheotomy, as was seen in Case II., is sometimes a matter of great difficulty, but can generally be accomplished if sufficient patience be exercised, the tube being withdrawn from the trachea from time to time, and the child allowed to breathe without its use for a gradually increasing period of time at each withdrawal. That its permanent removal need not be despaired of is shown by numerous cases in which, even after the tubes had been worn from periods varying from several months to years, their use was finally dispensed with.

The difficulty produced by the removal of the tube is to be explained by the healing of the external wound, as far as the tube will permit, and its adhesion to the trachea, which causes it to assume a valvular action during the inspiratory acts; and also by the liability of the operation of tracheotomy to cause undue irritability and disorderly action of the muscles of the glottis, interrupting their usual rhythm; this latter fact has been pointed out by Mr. Thomas Smith.[1]

Case III.—Ellen W., aged seven years, was brought to the Children's Hospital on Aug. 13, 1883, with the following history: On the previous night, while holding a pin in her mouth, she attempted to speak, when the pin suddenly disappeared, and she supposed she had swallowed it, until she was suddenly seized with a severe attack of coughing and pain, the latter she referred to the upper region of the larynx. When examined she presented no marked symptoms of dyspnœa, had a slight cough, and complained principally of pain and a sensation of sticking, which she located in the upper portion of the larynx. Upon digital examination, the point of a sharp body could be felt beneath the tissues a little to the right of the pomum Adami. As the child was very nervous and difficult to control, I decided to etherize her and endeavor to remove the foreign body through an external incision.

---

[1] Medico-Chir. Soc. Trans., vol. xl. viii.

Ether was administered, and I made an incision a little to the right of the median line of the neck, and the tissues were divided, layer by layer, until the laryngeal fascia was exposed. At this step in the operation the point of the pin could be seen firmly imbedded in the right ala of the thyroid cartilage, and was seized with forceps and drawn out until its head impinged upon the inner wall of the larynx; the point was now bent to a right angle to prevent its falling back into the cavity of the larynx and thus being lost sight of. The wound was now enlarged downwards, so that in case of hemorrhage after removal of the foreign body the trachea could be rapidly opened and a tube introduced.

The pin was now seized with forceps, and a tenotomy knife introduced through the cartilage, close by its side, and the foreign body withdrawn without difficulty, a few bubbles of air only escaping, the edges of the puncture coming together, and preventing the further escape of air from the wound.

The external wound was closed with sutures, and a wet dressing applied.

The child reacted well from the ether, and was carefully watched for symptoms of hemorrhage into the larynx, but no unfavorable symptoms presented themselves.

The case progressed favorably until the third day, when an abscess formed in the wound, which was relieved by removing several of the sutures. After this, the child's recovery was rapid and uninterrupted, no laryngeal or tracheal symptoms presenting themselves; and the wound being entirely healed, she was discharged from the hospital on Sept. 6, 1883.

In the preceding case, the symptoms referable to the presence of the foreign body were not alarming, and I have no doubt that it could have been removed *per vias naturales*.

But as the child was extremely nervous and difficult to control, and as I feared that a delay might be followed by some change in the position of the foreign body, I decided upon the external operation, which seemed to offer the most speedy means of removing the offending body.

Mr. Semon[1] reported, before the Clinical Society of London, a case in which he removed a pin from the larynx of a boy, aged thirteen years, by the internal operation—that is, with the laryngeal forceps. In this case, the pin had been impacted for thirteen months, and the point projected a short distance into the œsophagus; there were fixation of the crico-arytenoid on one side, paroxysmal cough, and some difficulty at times in deglutition, but, on the whole, the symptoms referable to the presence of the foreign body were much less than would have been expected. A complete recovery followed its removal.

1405 Locust Street, Philadelphia.

MEDICAL PROGRESS.

The Course of the Flexor Longus Digitorum Pedis.—Dr. Sinclair White points out a mistake, occurring in some of the anatomical text-books on this point.

Having examined a considerable number of limbs with regard to this point, he finds that in no instance does the tendon of the flexor longus digitorum pass beneath the sustentaculum tali, its course being downwards and forwards over the inner surface of the astragalus and internal lateral ligament of the ankle-joint, in most cases grooving the upper part of the inner margin of the sustentaculum, and, in a few, passing above and in front of that process without touching it or any part of the os calcis in its course.

A glance at the articulated bones of the leg and foot will be quite sufficient to convince anyone of this. It will be seen that the groove on the back of the internal melleolus in no way corresponds with the concavity of the arch of the os calcis, and that the tendon passing down the groove on the back of the malleolus, could not gain the under surface of the arch, except by crossing over the prominent inner margin of the sustentaculum tali, and the tendon of the flexor longus pollicis, which lies immediately underneath that process; but the tendon of the flexor longus pollicis is not crossed by that of the flexor longus digitorum until the anterior margin of the os calcis is reached, so that the latter tendon must be internal to it behind that point. Inspection, however, of the recently dissected parts is the best proof.—*Journal of Anatomy and Physiology*, October, 1883.

Dislocation of the Semilunar Cartilage of the Knee.—Although this injury is described in all surgical text-books, we yet believe it is one that is not infrequently overlooked, especially on its first occcurrence. A gentleman falls down, and is picked up complaining of severe pain in the knee, with partial or complete immobility of the joint, which speedily becomes swollen. There is great likelihood that in these circumstances the diagnosis of "severe sprain" will be made, and the real condition remain unnoticed. The failure to replace the dislocated cartilage at the time not only entails much suffering and interference with the function of the joint, but it very greatly lessens the probability of a complete recovery ever being accomplished. The cartilage may be reduced, but it fails to become firmly fixed in its place, and ever afterwards there is a liability for it to slip out again during the free movements of the joint. When this happens, acute pain, possibly a fall as well, and temporary lameness are occasioned. There is, therefore, every reason why the surgeon should endeavor to recognize this particular injury on its first occurrence, and, having recognized it, to treat it properly. The accident happens during some sudden wrench to the joint, not necessarily severe; immediately severe sickening pain arises, and the limb is fixed in the flexed position, although passive movement is possible. Synovitis quickly ensues. If the cartilage is displaced from between the bones, or marginally, it forms a projection just over the interval, between the femur and tibia; but in some instances it is dislocated inwards, so as to lie between the two condyles of the femur, and then is quite beyond reach. In such cases the diagnosis must rest alone upon the cause of the accident—some wrench or sudden movement—the acute pain and fixity of the joint in the flexed position. The symptoms are more severe than those caused by a simple sprain of the joint from such an amount of violence, while on the other hand, the slipping of a loose cartilage between the bones causes still more acute suffering, and the body itself can be felt at times. The first thing to do is to replace the cartilage by extreme extension immediately following upon full flexion of the joint. In some cases the cartilage slips into place with a distinct snap, and in all cases the power of movement is at once restored. It is then important for the patient to wear a firm support to the knee for some months, which shall render impossible such a wrench of the joint as shall displace the cartilage, and if this is persevered in the cartilage again becomes adherent to the tibia. It is believed that the internal meniscus is more frequently displaced than the outer.—*The Lancet*, October 27, 1883.

---

[1] British Medical Journal, April 21, 1883.

Rupture of an Aneurism into the Gall-bladder.—Chiari reports the case of a man, æt. 33 years, who, for a long time before his death, had suffered from attacks of cardiac pain. He died during a sudden and profuse intestinal hemorrhage. At the autopsy there was found in the transverse portion of the duodenum, in the upper surface, a round opening, two-fifths of an inch in diameter. This led into the gall-bladder, and further examination showed the ruptured sac of an aneurism of the cystic artery, which had burst into the gall-bladder. Besides this, there was also found, in the lower half of the gall-bladder, a second aneurism, involving the inferior cystic artery, and filled with thrombi. The stomach, intestines, and œsophagus were filled with coagulated and semifluid blood. This makes the fifth case on record in which the gall-bladder has been involved by an aneurism of the cystic artery.—*Centralbl. f. klin. Med.*, June 16, 1883.

Relations of the Dorsalis Pedis Artery to the Cuneiform Bones.—Mr. Author Hensman states that the usual course of the dorsalis pedis artery may be indicated by a line drawn from the front of the ankle, midway between the malleoli, to the back of the first interosseous space.

This line will be found to cross in succession the fore part of the astragalus, the scaphoid, the middle, and also a small portion of the internal cuneiform bones.

In contemplating these facts it appeared to him strange that anatomists, in their descriptions of this artery, should have made no mention of the *middle* cuneiform bone, as one of its most constant posterior relations. In all the descriptions he had read with the view of ascertaining this point, he found that the internal cuneiform bone is always either named or clearly implied, but, as far as he had learned, the middle cuneiform is never even noticed.

It will be seen on dissection that this artery usually takes a fairly straight course between the points named; sometimes, however, it curves outwards, as if pulled aside by its tarsal and metatarsal branches, and in these instances its relations are necessarily somewhat altered. But he found when the direction of the artery is quite normal that it invariably crosses the broad base of the middle cuneiform, and merely touches (but not always) the fore and outer part of the internal cuneiform, just where it grasps the inner articular facet on the base of the second metatarsal bone. There is usually a slight scooping out of the pointed end of the cuneiform bone at this spot, and the artery most commonly occupies this little valley before dipping into the first interosseus space on its way to the sole of the foot.

After its passage over the middle cuneiform its deep relations are not constant. It may rest on the internal cuneiform as just stated, or, being more externally placed, it may skirt the inner side of the base of the second matatarsal, close alongside its junction with the inner cuneiform, or, finally, it may take a mid-course between the two, thus overlying both bones.

It can therefore, he thinks, be easily shown that this vessel always crosses the middle cuneiform bone, that it sometimes entirely avoids the internal cuneiform, and, moreover, that when it touches this latter bone it is for a distance short in comparison to the length of its path across the middle cuneiform bone.—*Journal of Anatomy and Physiology*, October, 1883.

The State of the Sensitive Nerves in Strychnine Poisoning.—In a recent memoir on this subject, Professor Couty, of Rio de Janeiro, states that in his experiments strychnine intoxication does not cause an increased sensibility of the sensitive nerves, but a diminution of their excitability; a diminution which is increased in proportion as the action of the drug is prolonged. Prof. Couty's experiments were only made on the nerve-centres of the brain and spinal cord. The brain especially loses its excitability under the action of strychnine, while the experiments on the spinal cord, on the contrary, show that there is an exaggerated sensibility.—*Revue Scientifique*, Oct. 27, 1883.

A New Ptomaine.—M. Brieger has discovered a ptomaine which forms during the digestion of albuminoid matters, and their transformation into peptone. The digestive act should not be prolonged, as in that case the ptomaine disappears. In order to obtain it, the digested matter is treated with ethylic alcohol; the insoluble parts are then treated with amylic alcohol (pure). This amylic extract is very toxic, and by successive purifications we may obtain a substance which, in doses of $\frac{1}{20}$ of a grain (in the impure state), suffices to kill a frog. To kill a rabbit, a dose of grs. vij–xv is sufficient. These animals, poisoned by it, die in a sort of a coma and stupor with paraplegia.

Other substances, such as fibrine, caseine, muscular tissue, and liver and brain tissue, also furnish this peptone. It is probable that it also forms during normal digestion, and if, as Mr. Brieger states, this is true, it is of great importance, especially in legal medicine.—*Revue Scientifique*, October 13, 1883.

Total Absence of the Left Lobe of the Thyroid.—Mr. William J. Gow, Student, St. Bartholomew's Hospital, states that in dissecting a body lately, which was that of an old woman, apparently between sixty and seventy years old, it was found, on examining the front of the larynx, that the isthmus and left lobe of the thyroid gland were totally absent. The inferior and superior thyroid arteries on that side were exceedingly small, but each of them sent a slender branch to the place where the missing lobe should have been. The right lobe was not at all larger than usual, and showed no signs of ever having been united across the middle line, the borders being remarkably well defined. The remains of the thymus gland seemed larger than usual.—*Journal of Anatomy and Physiology*, October, 1883.

Risks Attending Catheterism in Cases of Long-standing Retention of Urine.—In commenting upon Sir Andrew Clark's remarks on catheter fever (see The Medical News, November 10th, p. 512), Sir Henry Thompson writes to *The Lancet* (October 27th) as follows:

The risk sometimes incurred by elderly men in commencing the use of the catheter, accurately appreciated by Sir A. Clark at the Clinical Society, and well described and commented on in your leading article, is a subject of great importance. It is, however, by no means unrecognized by surgeons, and has long been one of much interest to myself; so that I have made it a special topic for remark and caution in my clinical lectures.[1] I have so often observed the danger in certain cases associated with a resort to catheterism, although rendered absolutely necessary to relieve chronic retention of urine, that I have advised the greatest care and special management for them. But the dangerous and fatal results are rare as compared with the great number of elderly men who are compelled to depend for relief on the catheter, and who derive the greatest advantage and comfort from its daily use. For a case never becomes advanced and dangerous in regard of retained urine, unless the retention has been long overlooked or neglected, and when advice to empty the bladder in an early stage has unhappily not been given. If employed at that early stage, before the urinary organs have suffered damage from retention persisting perhaps through many months or even years, no fatal or dangerous "fever" will be met with. It is the *neglect of timely catheterism*, and not the employment of a catheter, which is the real occasion of the fatal issue, which now and then occurs under the circumstances described.

The first surgeon to point out the occurrence of this particular form of "fever" was Sir B. Brodie, in his lectures; and I beg you will allow me to cite an extract from my last edition, referring to his views, describing the symptoms, and indicating the method which I have adopted to diminish the risks which should mostly be expected, and always be provided for, when a pint or more of urine habitually remains in the bladder, despite the patient's efforts to relieve himself. The passage is as follows:

"I revert to a fact, already alluded to, which is one of considerable importance, that although the urine may have been quite clear before the catheter was employed, yet in some instances, after its habitual use has been continued for a short period, the secretion becomes cloudy, and the patient is feverish and unwell. A stage of constitutional derangement, more or less marked, has sometimes to be passed by those persons who, having long experienced difficulty, suddenly change from their usual mode of micturition to the artificial one. It requires some judgment, as I have already pointed out, to decide when this change should be made, but having made it, the phenomena described occur in a few exceptional instances; and this fact you should be aware of, and you should watch the result of the daily catheterism. Sir Benjamin Brodie was the first to remark it, and in his valuable lectures called attention to the circumstance that patients might even sometimes gradually succumb with symptoms of low or irritative fever a few weeks after beginning to use the catheter. Bearing this in mind, our mode of proceeding may be advantageously modified in relation to those patients whose amount of residual urine is large. It is then undesirable to empty the bladder completely on every occasion of catheterism during the first few days. If the patient has been in the habit of retaining perhaps a pint of urine, or even more, after he has made water, it is a serious change for the bladder to be suddenly and completely emptied two or three times a day; the organ soon becomes irritable, the urine is charged with pus, and the patient loses appetite, becomes feverish, and there is sometimes considerable danger to life. The rule under such circumstances is to proceed cautiously. Instead of removing the entire quantity, leave some urine behind; and thus a compromise is made between the exigencies arising in this condition of the bladder, and the usually absolute rule that it should be emptied. Draw off half or only two-thirds of a pint; you will thus relieve the organ partially, and in the course of a week or sooner you may gradually accomplish the entire emptying of the bladder, and all will probably go well. And it conduces greatly to success to permit no outdoor movement to such a patient, but confine him to his room, in a warm temperature, if the weather be cold, or even to his bed for a few days. The probationary period, while the use of the catheter has to be learned, and the onset of chronic cystitis with constitutional disturbance is to be feared, is more safely passed *if absolute rest and quiet* are accepted as necessary conditions by the patient. It is only within the last few years that I have pursued this course, and I cannot speak too highly of the results. Nevertheless, very rarely, notwithstanding every precaution, you will find a case in which during this process the tongue grows slowly more red, dry, and contracted; the powers of life gradually fail, the senses become impaired, and the patient sinks. You will always find in such cases, if an autopsy is made, old-standing pyelitis, with dilatation and marked degeneration of the renal structure, and you will know that in no circumstances could the patient have long survived" (p. 57).

The lesson to be learned—and it is an important one—is this. When the bladder of an elderly man fails to empty itself, let him learn to use a soft catheter without much delay: thus life with comfort may often be maintained to its natural term. Neglect the catheter until chronic disease of the organs is established, and a catastrophe may then be hastened by the use of the instrument. Scores of men whom I know in this town, between sixty and eighty years of age, still active, mature in mind, and more than ever serviceable to their fellows, owe their existence entirely to habitual catheterism.

The Future of Cerebral Surgery.—At the conclusion of his introductory address, delivered before the Royal Medical and Chirurgical Society, on October 23d, Dr. Ferrier made a most important observation, which cannot fail to prove of interest to all contemporary surgeons. He remarked that physicians would not be justified in advising surgical operations on the brain, and surgeons would refrain from active interference, until the principles and diagnosis of regional disease had been established with as near an approach to certainty as is possible, where all is hidden from the eye and hand. But, he continued, it is doubtful that any reason now remains why a surgeon, who fearlessly exposes the abdominal viscera, should not open the cranial cavity. Dr. Ferrier has seen complete recovery constantly follow some of the most formidable operations that have been performed on the brain and its coverings, in animals of the most delicate and almost human organization, when stringent antiseptic precautions had been taken. He cannot, therefore, but believe that similar results are capable of being achieved on man himself. Secondary inflammation can be absolutely prevented, and there is no risk to life from even extensive destruction of the cerebral hemispheres. In removing tumors or diseased cerebral tissue, no doubt healthy structures might be injured; but this would not necessarily cause mental disorder.

---

[1] Vide 7th edition, Lect. viii., chiefly devoted to the subject, especially the latter part, page 57.

The triumphs of abdominal surgery, due in a great measure to advances in clinical and pathological science, and the correct appreciation of the physiology of abdominal structures and organs, have been followed by a great activity in the department of thoracic surgery. Surgeons now have the high authority of Dr. Ferrier to encourage them in untried efforts for the cure of cerebral disease by operation.

It may be said that trephining is a very old, and yet still a not very satisfactory practice; but hitherto it has generally been performed for the relief of some result of injury when deeper and more serious damage exists, or for the cure of a local condition implying, of necessity, more or less general disease of the brain. Tapping the pleura and Cæsarean section are also very old operations, practised long before thoracic and abdominal surgery had reached their present extended stage of dovelopment. They have been supplemented or superseded by operations performed with more deliberation, and not so often under conditions of emergency.

Through the labors of Dr. Ferrier, the future surgeon will probably perform with success operations which will bear the same relation to simple trephining as ovariotomy and Porro's operation bear to repeated tapping of ovarian cysts and Cæsarean section.—*British Medical Journal*, October 27, 1883.

Intestino-uterine Fistulæ and Artificial Anus.—Dr. L. H. Petit has recently written an elaborate article on this subject. The communications of the utero-vaginal canal with the small intestine, he says, are very rare. He has collected the records of twenty-three cases of ileo-vaginal and sixteen of intestino-uterine fistula.

Petit shows that of these cases, 14 followed strangulation of the intestine by rupture of the uterus or vagina; 18 cases followed pelvic phlegmon, which caused adhesions between the intestine and the vagina or uterus; in 2 cases an extra-uterine fœtal cyst opened at the same time into the intestine and uterus; in 4 cases uterine carcinoma had invaded the small intestine in the descending colon; and 1 case was doubtful, in that it could not be determined what point of the utero-vaginal or intestinal canal had been injured.

From an anatomical point of view these cases may be divided into simple fistula, and artificial anus properly so-called. The former follow adhesions of a loop of the intestine to the uterus or vaginal wall, from cancer or inflammation, only a limited opening being made in the intestinal wall; the latter are caused by strangulation of an intestinal loop in a rupture of the uterus or vagina, the whole circumference of the intestine being opened.

The symptoms of the two varieties are different. In cases of fistulæ there are intestinal irritation, escape of fecal matter through the vagina, but at the same time there are normal operations from the bowels. In the case of artificial anus there are symptoms of internal strangulation and the feces are passed through the vagina entirely. Differences are also seen in the progress, termination, prognosis, and treatment. Fistulæ gradually grow smaller, the feces pass in less and less quantities through the abnormal opening, and the case gets well, in the majority of cases, either of itself or after treatment consisting of vaginal and rectal injections, cauterizations and appropriate care of the patient. Artificial anus, on the contrary, does not tend to spontaneous cure, and it is only after the most persistent treatment, and operation that any cases get well.

As a rule, the diagnosis is easily made. It must be found out (1) whether the point of communication is in the uterine or vaginal wall; (2) if the rectum itself is implicated, or a higher portion of the intestinal canal; (3) if the lower portion of the intestine is permeable; (4) if the case is one of simple fistula or artificial anus; and (5) whether the lesion is of puerperal, cancerous, or what other origin. In making the examination, certain errors must be guarded against. Demarquay mistook the orifice of an artificial anus for the cervix uteri; and Radfort, an ileo-vaginal for a recto-vaginal fistula.

The prognosis is grave, in the sense that the affections causing the abnormal communications often cause death; but after the communications are once made, and the patient tided over the primary effects, the general state rapidly ameliorates, and the secondary effect, though very troublesome, is not incompatible with life. The treatment of these simple fistulæ consists in proper care, injections, tamponing the vagina, and cauterization of the opening. In vaginal fistulæ, the edges may be freshened and the opening closed by sutures. In the treatment of vaginal anus, the closure of the opening is only possible when there is no intestinal prolapse, and no spur (éperon), and when the lower portion of the canal is permeable. In cases of prolapsus, it is necessary to make a section and try to close the opening when the edges of the artificial anus have sufficiently approached a normal state to insure a passage of fecal matters after occlusion of the orifice. When there is a spur the enterotome must be used. When the lower portion of the bowel is obliterated, it is necessary to make a large communication between the upper extremity of the intestine and the rectal cavity. When these measures have been taken, the abnormal orifice may be sutured, after having been fastened. Occlusion of the vulva has been tried, without success. Gastrotomy has been proposed, in order to break up adhesions which may exist, and unite the two extremities of the intestine, but has not been tried.

When a vesico-vaginal and a fecal fistula exist at the same time, it seems to be advantageous to operate on both at the same time. Accidental communications of the small intestine with the uterus or vagina, of cancerous origin, tend to grow larger. They generally supervene at an advanced stage of the disease, and death soon carries off the patient.—*Ann. de Gynec.*, July, 1883.

Tannate of Sodium in Chronic Nephritis.—Lewin first recommended tannate of sodium in nephritis, and Ribbert's experimental researches demonstrated its action in causing decreased elimination of albumen.

Briese has used it, in four cases in Mosler's clinic, prepared as follows: ℞. Solution of tannic acid, 2 parts to 100; add solution of bicarbonate of soda (9 to 5) ad react. alcalin. S. Dose, one tablespoonful every half hour.

This mixture was not equally well taken by the patients. In some cases it caused gastric disturbances and vomiting. The daily quantity of albumen eliminated by the urine was not diminished, the nephritis went on, and the patients grew worse daily, and it was apparent that the remedy was, in these cases at least, of no value whatever.—*Centralbl. f. klinisch. Med.*; September 1, 1883.

The Value of Vaccination.—M. Jules Ferry has issued a circular, ordering the revaccination of all scholars in French public schools. This order is explained by the fact that it has been ascertained that, in those schools in which revaccination has been carried out, no case of smallpox has been known to occur for a series of years, the reverse being the case in many schools in which revaccination has not been carried out.—*British Med. Journal*, October 27, 1883.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

Communications are invited from all parts of the world. Original articles contributed exclusively to The Medical News will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

Subscription Price, including Postage,

Per Annum, in Advance, ... $5.00.

Single Copies, ... 10 cents.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

Address, HENRY C. LEA'S SON & CO.,
Nos. 706 & 708 Sansom Street,
Philadelphia, Pa.

SATURDAY, NOVEMBER 17, 1883.

CICATRICIAL STRICTURE OF THE ŒSOPHAGUS: ITS CAUSATION AND MANAGEMENT.

In the *Journal of the American Medical Association*, for October 27, 1883, Dr. H. F. Campbell calls attention to not less than twelve cases of cicatricial stricture of the œsophagus due to swallowing strong solutions of lye, as well as to eight additional instances of ingestion of the same caustic fluid, of which four proved promptly fatal from œdema of the glottis, in three no bad result followed, and in one serious injury ensued. As all of these cases occurred within a circle of twenty miles from Dr. Campbell's residence, Augusta, Georgia, it is obvious that accidents of this nature are far more common than one would have supposed; and its explanation is to be found in the fact that solutions of "concentrated lye," which appear to be largely used in washing, scouring, and other cleansing processes, are carelessly left in exposed situations, and are accidentally swallowed by infants and children, who constituted at least nineteen of the cases alluded to, their ages having varied from eighteen months to six years.

With a view to remedy the growing frequency of these accidents and the fatality resulting from them, Dr. Campbell urges that the sale of "Continental Concentrated Lye," and "The Star Ball Potash," which seem to be the most dangerous agents of their class, be interdicted by legislative enactment, or that the manufacturers be compelled to stamp upon the packages containing the articles the word "poison," and, for the unlettered, the recognized warning against danger—the death-head and cross-bones. In justice to the manufacturers, it should be stated that these articles are intended for making soap, and not as labor-saving expedients for lazy mothers and servants; but as they will doubtless continue to be diverted from their proper application, it might suggest itself to the dealers also to label their goods, in the event of legislative action on the subject, "Lazy mothers are warned that solutions of these substances should not be kept, lest they be drunk by children, and death ensue."

Turning to the primary object of the paper, namely, the nature and treatment of stricture of the œsophagus resulting from chemical injury, we are pleased to find that the author of the paper insists upon the frequent, if not invariable, coexistence of spasm of the muscular fibres of the gullet with the organic lesion, through which the latter may be rendered impermeable not only to food but to the passage of instruments. It is well known to surgeons that comparatively few cases of cicatricial stricture prevent fluid ingesta, and it is equally well known that the contact of solid food or of instruments in such cases is quite sufficient to close the constriction completely. These attacks of tonic spasm not only mislead the practitioner, but, if frequent and long continued, result in the death of the patient from inanition. It is under these circumstances that cutting operations are not uncommonly resorted to, and, improperly so, since, under ether, it will be found that, in the majority of instances, the spasm will yield to proper instruments carefully introduced, their effect being to progressively lessen the spasm with each insertion, at the same time that they induce absorption of the new material, especially if it be recently formed. Hence in these cases gradual dilatation should be instituted as early as possible, and be persevered in until the easy deglutition of solids renders the resort to bougies and probangs less frequent.

Cases are, however, met with, in which the patient is on the verge of starvation. The coarctation is impermeable to instruments, and is rapidly becoming, or has become, so even to fluid food. In such examples Dr. Campbell avers that no cutting operation should be practised for the object of nutrition until after the failure of rectal alimentation, which he considers a far more valuable measure for permanently supporting the patient than the experience of other surgeons would warrant. While in cases of complete or almost complete occlusion, we are disposed to endorse his views as to the impropriety of internal œsophagotomy and œsophagostomy, we are far from willing to admit that gastrostomy is not applicable to the class of cases under consideration. In not a few instances, indeed, it is a precious resource to prolong life. More than this, by placing the parts at rest, dilatation may subsequently be resorted to with a prospect of success, when the gastric fistule may be closed. Had the operation been performed in some of the little patients that were permitted to die, a certain proportion would, in all probability, have been alive to-day. In a valuable article contributed to the American Journal of the Medical Sciences, for April, 1883, Mr. Morell Mackenzie refers to twelve gastrostomies for cicatricial stricture, in which the trouble had existed, on an average, for five months before the operation, and in which life was prolonged, on an average, for five months and a half. Le Fort has shown in the *Gazette des Hôpitaux*, No. 90, 1883, that five patients were living, respectively, at the end of four months and a half, eight, twenty, twenty-four, and thirty-six months, and that five died, respectively, at the end of seven, seven, eight, fifteen, and eighteen months after the establishment of the fistule, results which surely indicate that the operation is perfectly justifiable.

The final histories of eleven of the cases quoted by Dr. Campbell, of which, however, only four occurred in his own practice, show that five that had no treatment died, on an average, in a little more than six months, and that of the six that were subjected to gradual dilatation, and in which the measure was begun early, the longest period after ingesting the lye having been three months, four were more or less complete successes, one died at the expiration of eighteen months, the treatment not having been systematic, and one was living, mainly on fluids, at the end of sixteen months. All of the patients, except a woman, thirty-four years of age, were young children, a class of subjects difficult to manage on account of the fear of pain and the disinclination of parents to distress the child if anything whatever can be swallowed, to which may be added, in not a few instances, the timidity evinced by the average general practitioner in passing instruments.

MODEL ABATTOIRS.

Within recent years there has been a much-needed improvement in the manner of slaughtering cattle, in the construction and management of slaughter-houses, and in the methods of final disposal of the waste products of the business. This progress, however, has been chiefly identified with the abattoir system, private establishments for the most part still adhering to the old and defective methods. The difficulties in the way of regulating the construction and management of private establishments, so as to make them fully conform to a proper standard, and the obstacles encountered in instituting and maintaining systematic and scientific inspections, have been so great that reforms in this direction have made little or no progress.

In the light of this experience, efforts have been made to discourage the continuance of private establishments, and in their place to substitute the public abattoir system, which recommends itself as the only plan that has thus far met all sanitary requirements with respect to the lairage of animals, construction of buildings, management of the business, utilization of refuse, and which makes a daily inspection of all the details practicable. It is only by the adoption of this system, organized and regulated under the strictest sanitary supervision, that the public can feel confident that their interests are properly protected.

A very important movement in behalf of slaughter-house reform has been inaugurated in London under the name of the London Model Abattoirs Society. The objects of the Society, as stated at a recent meeting by the President, Dr. B. Ward Richardson, F.R.S., are the following: To establish in London a model slaughter-house, from designs of which others might be constructed; to advocate the erection of public abattoirs; to illustrate and teach the most rapid, skilled, and humane methods of slaughtering animals; to improve the method for the dressing of carcasses of animals, so that the flesh might enter the market in the purest condition; to insist on the importance of those engaged in slaughter-houses having proper conveniences for washing and cleansing themselves; to bring into use the completest means of removing offal, blood, and other organic substances, so that they might be moved with expedition; and to institute a systematic and scientific inspection.

Dr. Richardson is right in insisting on the necessity of replacing the private by the public slaughter-house or abattoir, on grounds of humanity, cleanliness, health, and economy. No better means could be selected for encouraging and giving force to this new movement than that adopted by the Society. Every one who is familiar with the present system is fully convinced of the grave character of its deficiencies. The lairage of animals is likely to be unsuitable and filthy; the slaughter-houses defective in construction and appointment, and therefore slovenly and dirty; blood-pits and storage receptacles neglected and foul; the slaughterers themselves unclean, and so likewise the storage department for the meat. The animals are made to suffer unnecessarily while waiting to be killed, are often cruelly and unsatisfactorily slaughtered, and the carcasses dressed and stored in an unwholesome manner. Without constant inspection, which is not possible under existing circumstances, these improper practices continue, and the meat is placed upon the market without ascertaining whether it is healthy or diseased. The facilities for removing the refuse matter are equally unsatisfactory, and for this reason, this material is not disposed of with sufficient promptness to avoid a nuisance upon the premises.

To get rid of these evils, which so generally prevail in all cities, the abattoir system must be endorsed, encouraged, and legislated upon if necessary. A number of our cities have already established public abattoirs, notwithstanding the opposition by parties interested in the survival of the old plan. The experiment has been most satisfactory, and deserves to be extended. A movement such as that inaugurated by the London Society would do much towards cultivating a better appreciation of the subject, and in hastening the general adoption of a system which has so much to commend it.

JAMES MARION SIMS, M.D.

The death of Dr. J. Marion Sims carries profound grief to the American profession. Not only in this country, but abroad, in whatever land true medicine lives, his departure will be mourned, for his fame and the influence of his teaching were almost world-wide. Sitting in the darkness of this sudden and great sorrow, it is natural to consider the work that he did in his busy life.

As there are epochs in the history of medicine with which famous names are associated, so there are famous names belonging to the special departments of medicine, names of those who have founded or greatly advanced those special departments. As the circulation of the blood suggests the name of Harvey, or pathological anatomy that of Morgagni, or obstetric anæsthesia that of Simpson, as vaccination always brings up the name of Jenner, or auscultation that of Laennec, so does gynecology—a department of medicine recent in origin—suggest that of Marion Sims; patient, brave, of restless activity; triumphant, noble man. He was a bold pioneer, opening new pathways; original, and with creative genius, he discovered for himself, and made his discoveries a gift to the profession. Even when unconsciously repeating what had been done before him, he greatly enriched the discovery, and carried the advance far beyond any predecessor. No matter what may be the great glory of those who have followed his footsteps, the best of them feel that they would never have accomplished what they have, had he not shown the way.

It is needless to say that before he faithfully worked out a method, the curing of genito-urinary fistulæ in the female was a rare exception, and now, thanks to his patient, self-denying labors, it is the rule. The best method of making uterine examinations he discovered and taught. He has done more than any man of his generation to teach not only the diagnosis, but also the most important surgical therapeutics of uterine diseases. Going to New York after many a hard lesson, after working out many a difficult problem unaided in his Southern home, and thus made strong in self-reliance, he gave an impetus to the study of diseases of women which must be felt long after his body mingles with kindred earth. The Woman's Hospital of New York, which owes its foundation to him, has been a school of the most valuable instruction to the profession; and that hospital has led to the establishment of similar institutions in various parts of the country, blessing those who are relieved in them, and blessing the profession, to whom they have been great centres of light. His treatise upon *Uterine Surgery* is one of the master-pieces of medical literature of the century. It has been translated into several foreign languages, and is found wherever there are educated physicians.

It would require much space to give even a list of the instruments Dr. Sims has invented for the diagnosis or treatment of uterine diseases. Many of these are found in the consulting rooms of all gynecologists, and in all hospitals where diseases of women are treated. If to-day all the publications of his pen and all the instruments of his device were destroyed, a great blank in gynecological science and art would be made, a blank that would remain for years.

He was a man constantly trying to add to his knowledge in his special department, and how cheerful and helpful to all who sought his advice! Of great personal magnetism, he was an inspiration to all brought in contact with him. But his inspiring power was stronger, wider than this; it was far-reaching, long-lasting, so that men who never saw him felt his influence, and were quickened through all their lives by his example and printed words; hearts as well as heads acknowledged his power.

Marion Sims, in many respects the greatest gynecologist of the century, has passed away, but he has left an undying fame.

SYPHILITIC PHTHISIS.

Although much has been said and written upon the subject of syphilitic phthisis, we are inclined to believe that many physicians have not a clear conception of what constitutes it. Dr. A. Sokolowsky has contributed a paper to the *Deutsche medicinische Wochenschrift*, for September 12, which points out with more than usual clearness the differences between this and the ordinary forms of phthisis.

There are two ways in which syphilitic disease manifests itself in the lungs, each of which is characterized by distinct clinical features:

1. In an otherwise favorable general condition,

and without other noticeable symptoms of syphilis, there appears in a circumscribed spot in the lung, more frequently in the right, a syphilitic neoplasm. In this limited area there are found the signs of consolidation and even of destruction of the lung, accompanied by slight cough, scanty expectoration, and rather disproportionate dyspnœa. On the other hand, the decided fever, perspiration, and diarrhœa of phthisis are altogether wanting. If, now, such a case, properly recognized, be treated with mercurials, complete recovery is possible. The cough disappears, the strength returns, and the local signs may entirely yield. The cases falling under this category are not, however, numerous.

2. In a second class of cases, including a decided majority, syphilitic processes set up in the lung in more advanced stages of syphilis, accompanied also by simultaneous, easily recognizable syphilitic lesions in other organs, as the larynx, liver, and aorta. This form corresponds very closely in certain of its clinical aspects with advanced phthisis. There are here also cough, emaciation, diarrhœa, and albuminuria. On the other hand, it is characterized by the total absence of fever. These very feeble, emaciated persons presenting the physical signs of destructive disease of the lungs and larynx have not fever, and if, from time to time, a slight rise of temperature occurs, it is never above 101.3° F., and exhibits not the slightest similarity to the hectic fever of phthisis. In strong contrast to this is the high degree of emaciation and debility, the pale, waxy, yellowish face being rather that of a patient with some malignant disease than that of a phthisical case. In like manner, night-sweats are either totally absent, or they are very trifling. Finally, the expectoration of blood is comparatively rare, at least very much more so than in common phthisis, while the dyspnœa is altogether out of proportion to the local disease.

In contrast to the cases of the first category, those of the second group, while they may be greatly improved by anti-syphilitic treatment—mercury and the iodide of potassium—never recover, the local lesions being almost unchanged, even while the general condition improves. Sooner or later, the patient perishes, with cavities in his lungs, extensive ulceration of the larynx, involving especially the true and false vocal cords, while the posterior wall is comparatively free, and with amyloid kidneys, liver, and spleen.

Such a sharply drawn picture as this should not be difficult to recognize, and, if correct, must be of material assistance in diagnosticating cases of syphilitic phthisis. We fear that syphilitic histories in cases of phthisis are too often overlooked in our examinations, and we believe that closer scrutiny and more accurate diagnosis might give more satisfactory therapeutic results.

COMA CARCINOMATOSUM.

Jaksch has recently reported (*Wiener med. Wochenschr.*, 1883, No. 17) the case of a woman who died after an illness of four months, in which gastric symptoms and emaciation were conspicuous. Seventy-four hours before death, she fell into a condition of coma accompanied by a peculiar dyspnœa and very deep, moderately frequent respirations. During the whole time the urine contained abundantly of diacetone and acetone. The autopsy revealed extensive carcinoma of the stomach, with numerous miliary metastases in other organs. Jaksch is disposed to consider these symptoms due to a poisoning of the blood by the acetone and diacetone, the well-known cause of coma in diabetes.

In order accurately to ascertain the whole truth and the exact views of the profession of the State of New York in reference to the Code controversy, the Central Organization of the New York State Medical Association, has just issued a proof-pamphlet of seventy-two pages, containing the names of all members of the profession in the State, classified by Counties, and then in accordance with their views on the Code question, as obtained by direct replies to inquiries, or from information obtained from the Secretaries of County Societies or others. It is intended to send this pamphlet for revision to each member of the profession whose address can be obtained, with the request to correct any error which may appear in connection with his name.

According to the most accurate information now at hand, there are 5219 physicians in the State, classified as follows:

Committed to the National Code, .	2,424.
" " New Code, . .	943.
" " having no Code, .	210.
Unclassified, ...	31.
Uncommitted, ...	1,611.

It is believed that the time has arrived for every member of the profession in the State of New York to declare himself for or against the National Code, and it is earnestly desired that those who are still uncommitted will speedily reach a decision, so that the views of the whole profession of the State may be obtained as to whether it wishes to retain its fraternal relations with the American Medical Association, and the regular profession of the United States, or to disfranchise itself therefrom by abolishing the National Code and adopting a new Code of Ethics not in harmony with it, or by abrogating all Codes.

SOCIETY PROCEEDINGS.

OBSTETRICAL SOCIETY OF PHILADELPHIA.

Stated Meeting, November 1, 1883.

The President, R. A. Cleemann, M.D., in the Chair.

Dr. B. F. Baer related the following cases, the clinical histories of which present some points which he thinks are instructive and worthy of discussion. They are somewhat unusual in character, and it is remarkable that they all occurred within a period of thirteen days.

FORCEPS LABOR, FIFTH POSITION.

On October 17th, I was requested by Dr. —— to visit his patient, Mrs. H., who had been in labor thirty-six hours, prepared to perform craniotomy. She was a primipara, 43 years of age.

I found the patient nervous and exhausted, the soft parts dry and rigid, the os only partially dilated and the membranes ruptured many hours. The head, a large one, was in the cavity of the pelvis, and, whilst not impacted, it was nearly so. The larger portion of the head was posterior and to the left, the smaller portion, anterior and to the right. The fœtal heart-sounds were heard in the left lumbar region and nowhere else. I therefore diagnosticated a left occipito-posterior, or fifth position of Baudelocque.

I placed a vectis, and endeavored to assist rotation forwards, but failed to make any impression. I next adjusted, with some difficulty, Simpson's forceps, and by traction during uterine action, with gentle efforts at rotation, allowing the forceps to turn as the occiput rotated anteriorly, that process was finally accomplished in about two hours of hard work. I now removed the blades, and after finding that the head could not be otherwise delivered, I readjusted the instrument and assisted in extension of the head, delivering a living child said to have weighed twelve pounds. There was no laceration of the perineum. Both mother and child have done well. The case is interesting because of the age of the primiparous patient, and in the position of the occiput, which is rare.

ARM PRESENTATION; PODALIC VERSION.

On October 23d, Dr. —— requested me to see a patient with him, a girl sixteen years of age—a primipara at full term—in labor about twenty-four hours, and trunk presenting.

In general appearance she resembled more a child of twelve than a girl of sixteen. The external genitals and vagina were small and undeveloped. The abdomen was greatly distended, globular, and fluctuating. Palpation was of only negative diagnostic value, probably on account of the large quantity of amniotic fluid. But I thought I detected the head in one iliac fossa, and the breech in the other. Auscultation revealed the fœtal heart-sounds, feebly heard in the right iliac region. The upper portion of the vagina was distended by a large, protruding, "bag-of-waters," and the os uteri was fully dilated. I could only slightly touch the presenting part, which was entirely above the superior strait. I detected what I thought to be a limb, and from what I had learned previously by inspection, palpation and auscultation of the abdomen, I believed it to be an arm. I then dilated the orifice of the vagina preparatory to passing my hand, should that be found necessary, after rupture of the membranes, which I now did, and found a shoulder presenting and an arm on the verge of passing the os. This I arrested, and made version by the feet. I preferred this to version by the vertex, because I deemed it easier and less dangerous to both mother and child to effect delivery in that manner, than to apply the forceps in this special case. The child was alive, but feeble. The body passed through the narrow vagina very slowly, and only after pressure on the fundus of the uterus, until the head reached the floor of the pelvis. Here, by assistance, the occiput rotated forwards and the head was arrested. Flexion of the head could not be made to occur by supra-pubic pressure, and by pressure upon the nape of the neck, whilst a finger or two acted upon the anterior surface of the head through the rectum. I then quickly adjusted the forceps, and carrying the handles forward with the body of the fœtus, made flexion and delivered a living child. There was not the slightest laceration of the perineum.

The uterus did not contract well; and although ergot was administered, and time given for the organ to recover its tonicity (thorough kneading being used meanwhile), when the placenta was expelled a smart post-partum hemorrhage followed. This was easily controlled by the application of pure vinegar to the cavity of the uterus, injected by means of the long-nozzled uterine syringe, which holds about half an ounce. I prefer this method of introducing the vinegar to any other, for the reason that it is more easily and thoroughly applied. I carry the nozzle, guided by the index-finger, as in the introduction of the sound, into the uterine cavity, and project the vinegar, without force, over the surface. This can be repeated if necessary, which is seldom. Too much praise cannot be accorded Prof. Penrose for his earnest advocacy of the use of vinegar in the treatment of post-partum hemorrhage, the result of uterine inertia. In my experience, it has never failed to secure firm and continuous contraction, when properly applied. It is simple, antiseptic, and harmless.

ARM PESENTATION; PODALIC VERSION.

October 29th Dr. —— sent for me, stating that he had a case of shoulder presentation, that the membranes were ruptured, and the os only partially dilated. He had attempted to make version by the feet, and had brought down an arm in mistake for a foot. I found a primipara, æt. 22 years, illegitimately pregnant, at full term, feverish and excited. A large, fat right arm occupied the vagina, and the shoulder was jammed into and projecting through the os, which was firmly contracted around it. It was a dorso-posterior position, and the head was in the right iliac fossa. All the liquor amnii had been drained away, and the uterus was closed tightly around the child, which was apparently dead.

We administered ether, and I at once began an effort to bring down a foot, deciding that version by the vertex here could not be made, because the arm could not be returned to the uterine cavity, and, even if the arm had not been down, I feel sure that the bipolar force would not have been great enough to have brought that head to the superior strait. But to get through the narrow vagina and rigid os, which were filled already by the arm and shoulder, was one problem, and another, apparently greater one, was the turning of the large child in a contracted uterus. An attempt was, however, not only justifiable, but obligatory, for the sake of the child, of whose death we were not sure. Then, embryotomy, in a case of this character, would, I believe, have been attended with greater danger to the mother than version. I gradually inserted my hand and carried it into the uterine cavity, and with it I tried again to replace the arm, but failed. My hand was now so benumbed that almost all sensibility was lost. However, I finally reached the feet, selected the uppermost or left one, and began my efforts at version, assisting all my internal manipulations, of course, by placing the external hand on the abdomen, and acting with it on the opposite pole of the child. When I made traction on the leg, the arm advanced further into the vagina, and it now seemed that I should certainly be compelled to give it up, the difficulties appeared so great. But patience and perseverance are cardinal virtues here, and by exercising them to my utmost capacity, I succeeded in getting the foot and leg into the vagina, where I secured them with a fillet. I now gave this to Dr. ——, and whilst he made traction upon it, I pushed upon the shoulder, and succeeded finally in revolving the child on its long axis, causing the arm to ascend and the leg to occupy its place in the vagina. The remainder of the delivery was that of a difficult breech case, where traction on the child and pressure upon the fundus of the uterus are imperative. The child was dead. The mother reacted well, and has not presented an untoward symptom. There was slight laceration in the sulci on either side of the vagina, not through the cutaneous surface, and not enough to require sutures.

BREECH PRESENTATION.

Twenty-four hours later, on October 30th, my friend Dr. Wm. L. Taylor requested me to see with him Mrs. X., a primipara, thirty-five years of age, who had been in labor twenty-four hours, the breech presenting in the left sacro-posterior position. The membranes had ruptured twelve hours previously, the os was rigid, and only slightly dilated, and the breech was impacted in the superior strait, which seemed to be narrow. The patient was short of stature, fat, and had a small vagina. It was thought that the child was dead, but of this we were not sure.

Was there any use in waiting longer for nature to effect delivery? We decided that there was not, and, I believe, correctly. An attempt at traction was made by acting on the thigh, but it was futile. I passed my hand with great difficulty into the cavity of the uterus, which closely surrounded the child, and endeavored to reach a foot, but found that the legs were extended; and it was only after I had advanced my hand absolutely to the fundus of the uterus that I secured the desired member. The uterine cavity was now so rigid and full that it appeared impossible to flex the leg, and extend the thigh. But here perseverance again succeeded, and the leg was brought into the vagina. Delivery was finally consummated by the greatest effort. The child was dead, and from appearances had been so for some hours, as Dr. Taylor had suspected. The mother recovered, as after an ordinary labor.

PUERPERAL CONVULSIONS.

A few days before, October 21, there entered my service at the Maternity Hospital a girl, eighteen years of age, illegitimately pregnant, and near term. She presented a depressed appearance, and was pale and puffy from œdema. Her urine was examined at once, and found to contain a large quantity of albumen and some casts. Her labia minoræ were so œdematous that she walked with difficulty.

She was placed upon a treatment consisting of Basham's mixture, digitalis, laxatives, and warm baths, with good food. On the 20th, the nymphæ were so greatly distended that I feared obstruction to delivery, which was about to take place; I therefore made about a dozen small punctures over their surfaces. This was followed by a very free discharge of serum, so that in the evening the labia were reduced more than one-half. During the night, labor occurred, and she was delivered naturally at seven A.M. on the 21st, having been attended by my assistant, Dr. J. P. Pyle. There were no symptoms during the labor nor immediately after it to attract attention, but before leaving her, he administered thirty grains of the bromide of potassium as a safeguard.

At 9 o'clock he was hurriedly called, and found her just recovering from a convulsion. He at once sent for me, and began the administration of chloroform. But before I reached her, at 10 o'clock, she had had two more seizures, and just as I entered the room she went into another, which was one of the most terrific convulsions I have ever witnessed. I immediately opened a vein and allowed about sixteen ounces of blood to flow. I will confess that I did not want to take blood from this patient, because she was in such an apparently low condition. The bleeding did not seem to have the slightest effect, for very soon after it she had another convulsion fully as severe as the one preceding. Since the first attack there had been given, per rectum, twenty grains of the hydrate of chloral and forty grains of the bromide of potassium, and, per os, one-fourth of a grain of elaterium. But the convulsions continued to recur, unless the patient was kept constantly under chloroform, and coma was deepening with each attack. I now injected, hypodermatically, three-fourths of a grain of the sulphate of morphia. This was at 11.30 A.M. She did not have another convulsion, although no more chloroform was administered until 2 P.M. At this time she had a slight one, and at 2.30 another much more severe, when I repeated the dose of three-fourths of a grain of morphia. After this she had no more convulsions. The dose of elaterium was now repeated, and the kidneys stimulated by large doses of saline diuretics, administered by the rectum. The bowels moved freely and repeatedly soon after the last dose of elaterium was given, and the kidneys responded promptly; but the urine became nearly solid, when the test for albumen was applied, and casts were so numerous, and of such a character, that an unfavorable prognosis was pronounced by the competent microscopist who made the examination. The patient, however, came gradually out of the profound coma, but did not recover consciousness until nearly three days had elapsed, becoming at times wildly delirious and maniacal. As soon as she could swallow, I resumed the administration of Basham's mixture and digitalis, and on the next day added quinine and ergot, the latter especially to restore tone to the capillaries, and thus assist in improving the condition of the brain. Milk and beef tea were given largely. The patient will leave the hospital to-morrow, although her urine still contains albumen in considerable quantity.

If uræmia is ever the cause of eclampsia (which is not settled), this case presented the kidney state which is usually found in cases said to be of that origin.

Since it is *à propos*, I will relate a case which was probably not of uræmic origin, because the urine did not indicate the slightest disease of the kidneys.

PUERPERAL CONVULSIONS.

My friend, Dr. J. B. Deaver, asked me to assist him in the delivery and treatment of a case of convulsions. The patient was eighteen years of age—a primipara, and unmarried. The occiput was posterior and in the hollow of the sacrum. The first convulsion occurred after the head had passed the superior strait, and it was a very severe one. Dr. Deaver immediately bled, and very freely. Another convulsion occurred soon after the bleeding, although chloroform was administered and chloral given by the mouth. When I reached her, she had had three attacks, and was profoundly under the influence of the anæsthetic, and, of course, could not be convulsed in that state. I adjusted the forceps and delivered, with the occiput posterior, being unable to rotate it anteriorly. The anæsthetic was now removed, and not long after another violent convulsion occurred. I now injected two-thirds of a grain of morphia under the skin. She did not have another seizure, and made an uninterrupted recovery. As stated above, there was not the slightest evidence of disease of the kidneys, either before or after labor. The cause here was reflex—the patient being predisposed by a depressed mental condition, etc.

The first indication to be met in the treatment of puerperal eclampsia should be to control the convulsions. I do not think it will be gainsaid that the prognosis becomes less favorable with each recurrence. I believe that morphia, administered hypodermatically in a large dose, and repeated, if necessary, is one of the most efficient, if not the most efficient, means which we possess for that purpose. In the next case which I am called to treat I shall give one grain. I will bleed, if I think that it is indicated, and shall use chloroform; but I will certainly give the morphia. I will then attend to elimination through the bowels, kidneys, and skin. Dr. Clark, of Oswego, N. Y., first brought the morphia treatment before the profession, in a fearless and excellent paper, published in the *American Journal of Obstetrics* for January, 1880, which is worthy of study.

Dr. Elliott Richardson thought the extent of dilatation of the cervix a very important point in considering the advisability of version in shoulder presentations. When the fœtus is in a transverse position it cannot descend, and as the cervix dilates it slips upward on the neck and chest of the child, and thus puts the vagina in a condition of longitudinal tension and consequently of narrowing. Any sudden or extreme attempt at dilatation of the vagina, when in this condition, involves a great risk of laceration. In Dr. Baer's case the narrowness of the os uteri was a favorable circumstance for podalic version.

There is a wide difference in the treatment of puerperal convulsions, as practised in this country and in Germany. Carl Braun strongly discountenances bleeding, and recommends chloroform with the administration of benzoic and citric acids to assist the action of the kidneys. He considers that the prime object is to put the body at rest.

Dr. W. T. Taylor thought that, in Case 2, if the method of Dr. Wright, of Cincinnati, for the correction of the shoulder presentation by converting it into a vertex had been tried, the difficulties and dangers of a version by the feet might have been avoided.

He does not think bleeding should ever be omitted in the treatment of puerperal convulsions in plethoric patients. Bleed freely and give chloral in large doses by the rectum. He thinks the use of opium should be preceded by bleeding.

Dr. Alfred Whelen has tried one-quarter grain of nitrate of pilocarpine hypodermatically after bleeding; the result being successful. The use of the pilocarpine did not seem to be followed by serous effusion. In one case in which no treatment of any kind had been used, an autopsy showed all the serous cavities filled with effusion. He thought the arterial tension, consequent on the convulsion, was the cause of the exudation.

Dr. R. A. Cleemann had tried all plans, and none of them were certainly successful; every method would fail at times, and any method will be followed by recovery. He thinks bleeding should be tried in every case to remove the vascular tension which is the great source of danger.

Dr. B. Trautmann had under his care a primipara, plethoric, who was suffering from puerperal convulsions; she was bled, a large dose of calomel was given, chloral was administered, and pilocarpine was injected, but all without effect: the patient died. In another case the urine contained fifty per cent. of albumen with casts, and no convulsion occurred. What is the relation between albuminuria and convulsions? Is the origin of the convulsion in the nervous system, and the albuminuria a result?

Dr. H. F. Beates.—The presence of urea in the blood being generally considered a prime factor, most of the forms of treatment have reference to its elimination. Bleeding should be very free to act in that manner, and if it is prompt and free, it will be followed by improvement; pilocarpine acts as an eliminator of urea, by the skin, thus relieving the kidneys and the system. He had treated two cases by this method, and both had recovered.

Dr. Philip M. Schieat had recently under his care, a primipara, aged 25 years; she had convulsions for four hours; chloral and bromide of potassium had been given freely, but with no effect; a hypodermatic injection of three-quarters of a grain of morphia sulphate was followed by quick relief; she was very plethoric, but there was no need for bleeding after the use of the morphia.

Dr. Baer, in Case 2, had considered version by the vertex, but thought that he could deliver more quickly and with less danger to both child and mother by means of podalic version. He considered elimination a false principle in the treatment of puerperal convulsions. First stop the convulsions; eliminate afterwards if there be any necessity for it. How much elimination can be effected by drawing twenty or even forty ounces of blood? The majority of these patients need all of the blood they have; they have none to spare. There is a neurasthenia at the bottom of these attacks. The patients are generally nervous and depressed from circumstances connected with their physical and social condition. Dr. Penrose, in his lectures at the University, taught bleed—bleed—every case that was bled sufficiently, got well; every case that was not bled died. Dr. Carson's lecture followed immediately after that of Dr. Penrose, and he was as bitterly opposed to bleeding as Dr. Penrose was enthusiastic in its advocacy. He has been afraid of pilocarpine, because its action, once established, cannot be controlled; he thinks, however, that the effusions observed have been caused by the convulsions, and not by the remedy. Morphia, used hypodermatically, is the remedy upon which he puts dependence; it will control the convulsion. Any medicine administered by the mouth or rectum must be of slow and uncertain action, because of the slowness of absorption from the alimentary tract.

Dr. Beates reported a case of

DIPHTHERITIC PARALYSIS

in a child of eight months. The muscles of the neck were affected, and resulted in extreme flexibility of the neck, the head rolling all about. Death resulted apparently from paralysis of the phrenic nerve.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, October 12, 1883.

The President, Dr. William J. Morton, in the Chair.

Dr. Leonard Weber read a paper on

THE NEUROTIC ORIGIN OF PROGRESSIVE ARTHRITIS DEFORMANS.

Having briefly recapitulated the symptomatology and etiology of arthritis deformans, the reader proceeded to develop his personal views concerning the nature of the disease in question. He said that among the comparatively large number of cases of arthritis deformans he had seen in the course of the last twenty years, he could not but recognize sorrow and grief, fright, irritation and exhaustion of nerve-centres by sexual indulgence and a dissolute life as leading factors, just as potent in producing the disease as rheumatic influences, if not more so. Again, remembering the symmetrical appearance and progress of the disease in most cases, no more plausible explanation seemed possible than the supposition of causes located in the central nervous system. The neuralgic and trophoneurotic symptoms also supported this view, though it was not to be forgotten that in a spine stiff and deformed by arthritis, there might easily occur changes of innervation, producing neuralgias and trophoneurotic changes secondary in character.

Finally, the negative results he had had in treating polyarthritis deformans after the usual anti-rheumatic method, with iodides, colchicum, etc., and, on the other hand, the very positive results obtained in similar cases by the galvanic treatment of the central nervous system, combined with a generous diet and the persistent administration of cod-liver oil and iron, led him to believe in the neurotic origin of the disease in many cases. It was through the repeated failure of the old method that he first became convinced of the erroneousness of the conventional opinion of the rheumatic or gouty origin of this formidable malady. Up to the present, no autopsies had been made with reference to the condition of the nerve-centres in this disease, and it would be a fit subject for future research to find the changes in the cord, presumably in the anterior horns, which might induce certain forms of arthritis deformans.

With regard to the main features of the disease, he had this to say, as a rule, it began and developed very slowly, without any other symptoms, at first, but pains in one or more joints, which came and went either spontaneously or after exertion. Not infrequently the patient complained at this early stage of an unusually tired feeling in the joints. The pains were neuralgic in character, circumscribed or diffused through the limb. In the peripheral form, the joints of both hands and feet; in the central variety, the hip, knee, and spine were the parts affected. In the course of time a great deal of stiffness and discomfort was experienced. The joints became enlarged, and became unshapely by the proliferation of hard, osseous protuberances on the outer surface of the swollen epiphyses, and creaking or cracking in moving or palpitating the joints was perceptible to the patient as well as to the physician. The adjacent soft parts, particularly the muscles, showed in a comparatively early stage of the disease a degree of atrophy not at all commensurate with their passive condition alone, but much more likely due to peculiar nutritive changes of neurotic or myotic origin.

In the peripheral form the disease affected the joints almost always symmetrically; in the central form, the advance was irregular. In one case he had seen it remain stationary in the hip-joint for many years, but attacking some joints of the fingers and toes at last. In another case, a female patient about thirty-five years of age, the upper part of the body only was affected. He has now a case under observation where nearly all the joints of the body were badly affected when he first saw the patient, who had been a helpless cripple for many months. The disorganization of the shoulder, knee, and particularly the hip-joint, leads often to a considerable shortening.

In one of his cases still under observation, the shortening of the lower limb amounted to nearly three inches.

In the spinal vertebræ ankylosis was more quickly developed by the disease than in other parts of the body. One of his patients could neither bend nor turn her head when he first saw her, the entire spine being stiff, but there were no symptoms of compression or even remarkable irritation of the cord. The disease was slowly but steadily progressing; while it might remain stationary for a length of time, exacerbations were sure to follow. Fever or other great constitutional disturbances he had not noticed in its course. In a female patient, æt. 37, he found the urine to have a specific gravity of 1026, containing some sugar and phosphates in abundance. Her mother had diabetes, and was a sufferer from arthritis deformans at the same time.

The following cases were selected from his records as illustrative of the points he wished to bring out.

Case I.—Mrs. M., æt. 47, American; no syphilitic or hereditary taint, but sister is reported to be a sufferer from chronic rheumatism. Married early in life; went on the stage, and, as a somewhat prominent actress, led an active and varied life, experienced many changes of fortune, travelled a good deal, and never hesitated to expose herself to wind and weather, yet always enjoyed good health until two and a half years ago, when, after a premonitory period of worry and depression of spirits caused by the loss of the last piece of property she owned, she experienced pains in both wrists and elbow-joints, followed by swelling and distortion of the same. Hands and feet soon followed, and when I saw her first, on Feb. 27, 1883, she had not a joint that did not creak or crack or was not out of shape, except those of the clavicle and the lower jaw. The knees and spinal vertebræ were in the worst condition and the most painful. Standing or walking, even with support, was out of the question. Her urine contained phosphorus; no albumen. Sleep and general nutrition bad; bowels irregular; no treatment had so far done any good, but the disease had made rapid and steady progress. Ordered to take of propylamine (trimethylamine) ʒj, aq. ℥viij, oleosacch. cibi ʒij, a tablespoonful ter in die before, and two pills of ferr. sulph. and potass. carbon. after, each meal; good food, and a tablespoonful of cod-liver oil three or four times a day. Galvanism to spine and the cervical ganglia of the sympathetic three times a week. The local and general improvement has been so satisfactory that she is now able to get up and around with the help of a cane, and to do light work with her hands. The pain and swelling and distortion of joints are much less; sleep and nutrition greatly improved.

Case II.—Mrs. K., æt. 34, German; married twice, had two still-births and two abortions; second husband had syphilis, and died of phthisis. Patient presents no signs of either disease; no hereditary influences. In 1877–78, severe attacks of bronchitis that troubled her the whole winter, but eventually got well without any apparent damage to the lungs. After some years of trouble, anxiety, exposure, and want, a deformans broke out two years ago, with pain and swelling of small joints of hands and feet, soon spreading to one knee, shoulder, and hip-joint. The disease was preceded by severe headaches, from which she suffers yet occasionally, but less violently. Some of the joints present a gelatinous feel, and several nodules of the above description can be felt beneath the integuments of her arms. No pain on pressure over sternum, clavicle, or tibia. Neither specific nor anti-rheumatic treatment, so-called, was of any service, but the disease has been very tardy in its progress, and the disfigurements of the joints are not to be compared to those of Case I. She has always been able to walk, though not without pain, and from time to time has been confined to her room. Appetite and general nutrition not good. The treatment described in Case I. was commenced in January, 1883, and carried out pretty regularly up to the present time, except as to the application of electricity. The result thus far has been satisfactory; further progress of the disease has been stopped; pain, swelling, and disabilities of locomotion are much less.

Case III.—Mrs. K., æt. 35, American, married, multipara. Father in good health; mother suffering from diabetes and arthritis deformans. Patient well built and nourished; living in good circumstances; has been for some years very unhappy in domestic relations, and been often deprived of rest and sleep, and been otherwise maltreated. After a series of premonitory symptoms, such as hemicrania and neuralgia in the upper extremities, she showed the first symptoms of the disease in the joints of fingers, wrists, and shoulders about a year ago. Her urine contains phosphates (largely) and a little sugar. The affection has made no great progress as yet, and the treatment has not been carried out well enough to be of great service, owing to the irregular attendance on the part of the patient.

Case IV.—Mrs. H., æt. 55, multipara; no hereditary taint; no apparent cause beside a good deal of anxiety and grief on account of the persistent ill-behavior of her only son. First symptoms in small joints of fingers and toes, five years ago. So far she has not experienced any great inconvenience from her affliction, but as often as she makes up her mind to take the propylamine mixture and cod-liver oil for some time, great relief follows as to pain and swelling.

Case V.—Mrs. S., æt. 65, German, married, multipara; no hereditary taint, but a good deal of exposure to rheumatic influences in her younger days. First attack in her right hip-joint, fifteen years ago, which led, in the course of time, to a shortening of nearly three inches, and now to complete ankylosis. No other suffering until recently, when several small joints of her hands and feet became affected, and she had to take to her bed. Various sorts of cures were applied, to no purpose; for the last three months she has taken propylamine and the compound syrup of the hypophosphites, with the result that she is able to be about again, and that no other joints have been attacked.

Case VI.—Mr. G., æt. 60, Austrian, clergyman, single; of good constitution, and no hereditary taint. He served as a missionary in his prime; travelled extensively in South and Central America. He was, of course, exposed to the severe effects of unhealthy climates, and suffered many hardships besides. He had several attacks of rheumatism, of which he got well, but eight years ago it settled in his right hip and left knee; and when I first saw him, five years since, he was in constant agony, confined to his bed for many months, and the above joints presented all the symptoms of advanced arthritis deformans. Some of the joints of his hands and feet had also become recently affected. His urine contained albumen in considerable quantities; there were amblyopia—the ophthalmological examination showing the affection of the retina often found in Bright's disease—and atheroma.

By the use of the iodides and other remedies, he was but little relieved; but two seasons at the hot springs of Virginia removed the severe recent affections of the joints, relieved his kidney trouble, and considerably improved his eyesight. The old affections of hip and knee remained as before, but ceased to give him much trouble, so that he was able to be about and attend to his clerical duties.

Dr. E. C. Wendt, in opening the discussion, said that he had seen a number of cases of arthritis deformans, mostly in hospital practice, all of which had, under the usual plan of treatment, gone on from bad to worse. He had also seen one of Dr. Weber's cases, in which a marvellous result had been obtained, in a comparatively short time, by an entirely different plan of treatment. He thought the value of Dr. Weber's interesting paper lay mainly in the therapeutic suggestions which it contained. If other observers corroborated the ideas here advanced, a decidedly progressive step would have been taken. He thought it was important to elucidate the causation of the disease: mere symptomatic treatment was quite irrational.

Dr. Dana remarked that the few cases seen by him had not illustrated the neurotic origin of the disease. In New York, he was of the opinion that the disease was rarely met with in private practice. He had seen only a few cases in hospital and dispensary service; this was even true in the Marine Hospital for Sailors, where rheumatism abounded. He recollected having seen one aggravated case: the patient was an old woman, some seventy years of age, who had suffered from the disease for sixteen or seventeen years. It began in the vertebral column, and gradually involved the hips, knees, and toes. She was so helpless, that in order to evacuate her bowels it was necessary to place her in the horizontal position over a pail. The patient had Bright's disease and died of apoplexy. Upon post-mortem examination, deposits of urates were found in the joints of the great toes. The patient was poor and surrounded by all the conditions favorable to the development of the disease.

Dr. Dana said he had seen some women of a neurasthenic type, women who had suffered from functional nervous disturbances, who developed a kind of inflammatory swelling of the fingers, so that in one case the hands became almost useless. He did not know but that later on in life these cases might develop into arthritis deformans; and, if so, they would illustrate the theory advanced in the paper. In considering neurotic inflammations of joints, Dr. Dana thought the relation of the trophic nerves to them, if there are any trophic nerves, should not be lost sight of. Never, so far as he knew, have we found any articular disease following functional nervous trouble. The nervous difficulty must be organic. In no experiment upon animals, except where an organic lesion of the spinal cord has been produced, have we been able to produce arthropathies.

Dr. Wendt did not know that the author's paper contained any evidence that the disease was developed from an organic lesion of the spinal cord. If there had been such grave central disease of the spinal cord, improvement could not have been so rapid. He thought the neurotic condition was not the ultimate, but an intervening cause. If we would go back still further into the history of these cases, he thought we would find that there was first a disturbance of nutrition, after which the neurotic condition developed.

Dr. Burrall wished that he could add something to our knowledge of this subject. The disease was one we were continually meeting. It seemed to him to be an arthritis resulting from trophic changes. In two cases which he could now call to mind, these changes resulted from worry. One case had gouty trouble. There was no uric acid found in the urine of patients suffering from arthritis deformans. As far as therapeutics were concerned, he knew of only two remedies. The two remedies he would hope to derive beneficial results from the use of, were arsenic, which is a nerve-tonic, and eupatorium perfoliatum (boneset).

The President felt like adding a word in regard to the practical part of the paper. He had not seen many cases of arthritis deformans in private practice; he could only recall five. It was probable that most cases were seen by the general practitioner. In the first four he had met with unsatisfactory results; but in the last, becoming convinced of the fruitlessness of the anti-rheumatic plan of treatment, he had administered cod-liver oil, iron, and static electrization, with great benefit to the patient. He was of the opinion that the disease occurred most frequently in the so-called neurasthenic.

It was interesting to note that the first advocate of the neurotic origin of the disease was an American, Dr. J. K. Mitchell, the father of Dr. S. Weir Mitchell, of Philadelphia. At a very early date, 1834, Dr. Mitchell announced it as his theory, that acute, subacute, and chronic rheumatism were diseases of the spinal cord. The neurotic theory of the origin of the disease in certain subacute forms was a very attractive one. He was prepared to admit, as an argument in its favor, that the ordinary anti-rheumatic treatment fails to relieve the patient. In the next place, there is a well-understood relationship between the disease in question and well-recognized nervous ailments. We have only to call to mind the arthropathies of the myelitis of traumatic neuritis and of certain hemiplegias, to find a defensible relationship to the changes in the joints characteristic of arthritis deformans.

Dr. Dana remarked that, as interesting as it might be to claim the theory of the neurotic origin of arthritis deformans for America, it was difficult to see how the information afforded by the President's remarks made it clear that such really was the case. The author of the paper had laid special stress upon the idea that arthritis deformans was an essentially different disease from acute or chronic rheumatism. Hence Dr. Mitchell could not be credited with the origin of this theory, as his claims concerned only acute and chronic rheumatism.

The President did not think that Dr. Mitchell's claims were thus narrowly restricted. It was doubtless true, however, that these claims should not have covered all forms of rheumatism as known at his day.

Dr. Durrall incidentally called the attention of the members of the Society to the fact that there was at the present time a case of Charcot's disease in the wards of the Presbyterian Hospital of this city. Dr. Charcot claims that Dr. Mitchell was the first to associate joint disease with the central nervous system.

Dr. Weber, in closing the discussion, said that he was glad to have learned, from the remarks which had been made, that it was well to have brought the subject before the Society, and that he had come forward none too soon with his views upon the subject.

NEW INVENTIONS.

A NEW AIR COMPRESSOR FOR THE ATOMIZER.

By CARL SEILER, M.D.,

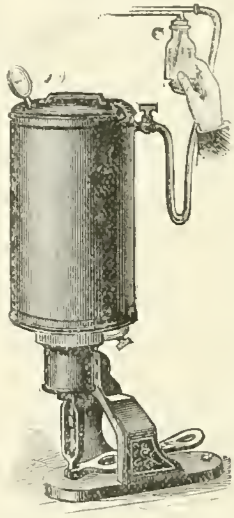
INSTRUCTOR OF LARYNGOLOGY AND LECTURER ON DISEASES OF THE THROAT AND NOSE AT THE UNIVERSITY OF PENNSYLVANIA.

The use of atomized liquids in the treatment of diseases of the upper air-passages has become of late almost universal, and has in a great measure supplanted the older methods of applying remedies to the mucus membrane of the throat and nose; and in modern surgery the carbolic acid spray plays an important part. This atomization, or spray, as it is commonly called, is produced by forcing a current of air, or steam, through a tube, which, in passing out from the small opening at the end, rushes past the opening of another tube, the end of which is below the level of the liquid to be atomized. In doing so the current exhausts the air in the second tube, thus causing a rise of the liquid until it appears at the opening, when it is carried along with the current of air in a finely subdivided state; or else the tube is fastened air-tight into a vessel containing the liquid and the air is forced by another tube partly into the bottle and partly into the upper end of the tube. The pressure of the air within the vessel causes the liquid to ascend, and, coming in contact with the air-current, is carried out of the contracted end of the tube in the form of a spray.

The air-current should be a continuous one, and it is therefore necessary to compress the air in some convenient chamber, whence it flows through the atomizing tube. This is accomplished in a variety of ways, the most common of which is the well-known double-bulb atomizing hand-ball, made of rubber, or the force may be obtained from a small steam boiler, as is the case in the steam atomizer.

The hand-ball has the great disadvantage that the operator has both hands employed, one in holding the tube and the other in working the ball, so that he cannot direct the spray in the desired direction, nor control the motion of the tongue of the patient; and further, that the long-continued use becomes very fatiguing to the hand working the ball. The steam atomizer, besides being very complicated and easily deranged, cannot be used to throw the spray downward into the larynx nor upward into the naso-pharyngeal cavity.

Having experienced these difficulties for many years in my practice, I was grateful when, three years ago, I obtained from Mr. J. Elliott Shaw a Burgess air compressor, which ever since has given me great satisfaction. This apparatus, which is easily worked, compact in form, and light in weight, is in its general form shown in the cut. It consists of a small air-pump worked by a treadle and surmounted by an air-chamber. The pump cylinder is made on an arched stand, and contains a piston having a valve opening upward. The piston is connected to the treadle by a forked connecting rod, and is moved by a slight and easy motion of the foot. The upper end of the pump cylinder is closed, with the exception of a valve aperture opening into a small or sub-air chamber, which is securely attached to the large air reservoir made of heavy tin, and which is nine inches in diameter and fourteen inches high; connection is made between the sub-air chamber and the reservoir by a small brass tube, the air being admitted or confined by a stop-cock. Near the top of the reservoir there is another stop-cock, to which is attached a flexible rubber tube leading to the atomizer. In the upper end near the edge of the reservoir is secured a small spring pressure gauge, indicating by the movement of its hand on the dial the pressure to the square inch of the air contained in the apparatus —from one to twenty pounds. The whole instrument stands thirty-two inches high and weighs sixteen pounds.



Thus from this description it will be seen that we can compress the air to any desired pressure under twenty pounds, and draw it off from the reservoir as it is needed for making applications to the throat or nose with the atomizer, replenishing the air by a little pumping when the pressure gets too low; and I have found that when filled at a pressure of from ten to twelve pounds there is enough air to give a spray, with a good atomizer, for ten minutes, or to make application to three or four patients in succession without pumping. When used for the carbolic acid spray, a gentle movement of the treadle will keep up the current at the desired pressure for an indefinite length of time, and in this respect the apparatus is superior to the steam atomizer, for in it the water in the boiler becomes exhausted very soon and must be replenished, causing an interruption of the spray for several minutes.

OBITUARY.

James Marion Sims, M.D.

It is with feelings of profound sadness that we announce the death of Dr. J. Marion Sims, which took place, suddenly and unexpectedly, on Tuesday morning last, November 13th, at his residence in Madison Avenue, New York. His health had been somewhat delicate for some time past, indeed, ever since the severe attack of pleuro-pneumonia two years ago, which came very near carrying him off; but no one could have supposed from his appearance that his life's end was so close at hand. He had been busily engaged for some days past in making his preparations to sail for Europe next Saturday to spend the winter abroad, and it was only the evening before he died that he made some professional calls. In the early morning he awoke, and after writing a few lines and taking a drink of water, he lay down and, apparently, was soon asleep. He breathed heavily, however, and his wife presently perceived that there was something wrong about him, and before she could summon their son, Dr. Harry Marion Sims, life was extinct. An autopsy showed the immediate cause of death to have been a degeneration of the muscular fibres of the coronary artery, with sudden obstruction of the circulation.

The demise of this great and good man will fall like a pall upon the heart of the American medical profession, of which he was so great an ornament, which he enriched so much by his labors and his genius, and by which he was so universally beloved and venerated for his many noble qualities. His loss will be deeply felt and will excite widespread sympathy. When such a person dies the world is conscious of having lost a man. When the history of American medicine shall be written, one of its brightest pages will be the account of Dr. Sims, a name of world-wide fame, as enduring as the hills and valleys of South Carolina, his native State.

Born on January 25, 1813, in Lancaster District, he received his English and classical education in the South Carolina College, at Charleston, and then studied medicine, graduating from the Medical College of the Palmetto State in 1832, and from the Jefferson Medical College in 1835. Thus equipped with a more than ordinary amount of knowledge, and impelled by a lofty ambition to excel in his profession, he selected Montgomery, Alabama, as his future home, and it was there, in the midst of genial and appreciative friends, in a delightful cotton region, blessed with a charming climate, and enlivened by the song of the mocking bird, that he laid the foundation of his future fame and usefulness.

Meeting with several cases of vesico-vaginal fistula, which had repeatedly and in vain appealed for relief to other practitioners, it occurred to Dr. Sims that an operation might be devised, by which a permanent cure of this distressing affection might be effected. For this purpose he opened a private hospital with a capacity of sixteen beds, conducted solely at his own expense. His patients were all young colored slaves, all primiparæ, who, as they were of no use to their owners, willingly placed themselves under his charge. He had, strange to say, originally no fancy for obstetric and gynecological practice. His practice was of a general nature, largely, however, partaking of surgery.

The first two or three cases of vesico-vaginal fistula that came under his observation were summarily dismissed, because, from all he had seen and read upon the subject, he considered the affection as utterly incurable. A third case, brought to him soon after the last, would have shared a similar fate, had it not been for a circumstance that changed the whole tenor of his life, by inspiring him with the thought which thus enabled him to lay the foundation of gynecology, of which he will, in all time to come, be regarded as the scientific father. A lady fell from her pony, and striking the sacrum, dislocated her uterus, causing intense agony. Called almost immediately after the accident, he placed her upon her knees, so as to elevate the pelvis, and depress the head and chest, and he found, to his surprise as well as joy, that the organ at once returned to its normal position. New light had burst upon his vision in reference to the operation for vesico-vaginal fistula; atmospheric pressure, with the slight aid of his fingers, had done the work, and he was not slow to take advantage of what proved to be a most important discovery. He now set about inventing new instruments, new needles, and new sutures, for the more secure closure of these horrid and disgusting fistulæ. Sims's speculum is used in every part of the civilized world, and silver sutures enjoy an equally great popularity, although they are not indispensably necessary to the success of such operations.

He now had often half a dozen cases of vesico-vaginal fistulæ under treatment in his little hospital at one time. In a letter, written November 6, 1882, he says: "When I began this work I was thirty-three years old, full of life, energy, endurance, and enthusiasm. I was so sure that I could cure every case in a few months that I proposed to the masters of the unfortunate young women to keep them at my own expense if they would clothe them and pay their taxes, and promised not to do anything that could endanger their lives or render their condition worse. As they were entirely profitless to their owners, I easily got control of them, and they were only too happy to come with the hope of getting rid of their disgusting infirmities. Keeping so many patients at my own expense for four years impoverished me, and, what rendered matters worse, my own health gave way. Convinced that I could not obtain relief in the South, I was compelled, in 1850, to go North. When I reached New York, I weighed only ninety pounds, and my disease harrassed me until 1856. I may mention the fact that when I began my experiments, my professional brethren in Montgomery were all ready to come and help me, for they thought with me that I was on the eve of a great discovery; but, when they saw only failure after failure, they became tired of it, and in the third and fourth years I could get hardly any one to help me. During the last year my principal assistants were the patients; and they had always eagerly looked forward to the time of having their operations repeated, often contending with each other who should be next. All the operations were performed without an anæsthetic. Indeed, I had been at work a year before the introduction of ether."

Thus, at length, in 1849, after many trials and failures, Sims triumphed over all obstacles and placed his method upon a scientific and enduring basis. Upon one of his patients he performed not less than thirty operations, before he finally succeeded in effecting a complete riddance of her loathsome infirmity. It is difficult to say which most to admire in this case, whether the fortitude of the poor sufferer, or the patience, perseverance, and skill of the great surgeon. It affords an example of sublime devotion, of which history records but few instances. Dr. Sims published the first account of his operation in The American Journal of the Medical Sciences, for January, 1852. It was prepared while he was confined to his bed, at a time when he was considered hopelessly ill. It speedily attracted universal attention.

In 1853, Sims removed to New York, where, during the following year, he founded the Woman's Hospital, the first institution of the kind on this continent, exclusively devoted to the treatment of the diseases of women.

In this undertaking he was aided by the powerful influence of Mott, Francis, Stevens, Griscom, and other celebrities, as well as by a number of the most respectable ladies of New York. If Sims had done nothing else, the energy and determination displayed in placing this institution in a proper working condition would be sufficient to entitle him to the gratitude of the public, and to establish his claims as a wise philanthropist. During his early connection with it, it afforded him an opportunity of introducing his peculiar operative procedures, and the profession and the public an opportunity of forming a true estimate of their value.

In 1861, Dr. Sims visited Europe, and during his sojourn in Paris was invited to perform his operations in the principal hospitals of that city, the great surgeons, men of world-wide renown, sitting as pupils at the feet of the American Gamaliel to be enlightened respecting a procedure which was completely to revolutionize the treatment of the surgical diseases of women.

The following year he took his family abroad with a view of educating his children; and availing himself of the reputation won during his first visit, he soon obtained a large and lucrative practice, patients flocking to him from all parts of the Continent, Great Britain, and even the United States. During his absence, extending into 1868, the French, Spanish, Portuguese, Italian, and Belgian governments vied with each other in investing him with their decorations. Napoleon III. made him a Knight of the Legion of Honor, and the Belgian Government conferred on him the order of Leopold I., while many of the most prominent medical societies enrolled him among their members. During the Franco-Prussian war Dr. Sims rendered important services at the head of the Anglo-American Ambulance Corps, for which he and his assistants received the thanks of the French Government.

At the meeting of the American Medical Association in Louisville in 1875, he was elected President of that body, and delivered his inaugural address the following year at the meeting of the Association in Philadelphia.

Dr. Sims has found time to contribute numerous articles to the periodical press, and to publish monographs on "Silver Sutures in Surgery," "Uterine Surgery," "Ovariotomy," "Intra-uterine Fibroid Tumors," "Trismus Nascentium," and "The Microscope in the Sterile Condition."

Of late years, owing chiefly to ill-health, his life was a nomadic one, most of his time being spent in Europe, where he was always sure of a warm welcome, greeted by crowds of wealthy patients, including not a few of the nobility. In 1880 he had a violent attack of pneumonia, from the effects of which he was very long in recovering.

Dr. Sims was one of the most generous and hospitable of men; with genial, winsome manners, with a mind of keen perceptions, well-stored with varied information. He was a fond and loving husband; a fond and loving father.

NEWS ITEMS.

Yellow Fever in Mexico and on the Border.—The Consul at Guaymas, Mexico, in a letter to the State Department dated October 23d, says that the yellow fever is slowly diminishing at that place, only twenty-one deaths during the month to date, and but two new cases in past twenty-four hours. It is also abating at Hermosillo, only one death in the past twenty-four hours. He stated that the ports of La Paz and Mazatlan are now free from the scourge, and that clean bills of health are given to vessels clearing from those ports.

The Deputy Collector of Customs at Yuma, A. T., in a letter to Surgeon-General Hamilton, dated November 2d, says that, in his opinion, next season will be the dangerous one for that coast, as the germs of the disease were brought in by persons contracting it in Sonora and dying in Arizona. He also says that two distinct fevers coexisted in Sonora at the same time—the epidemic form being the specific yellow fever. He adds that the disease was very successfully treated by the use of an emetic composed of an infusion of the inner bark of the mesquit tree and a little common salt—"in each case the fever subsided rapidly and the patient was restored in a few hours."

Daily reports up to the 31st of October from Sanitary Inspectors W. F. Price, at Yuma, and W. E. Chesley, at Benson, A. T., show that no cases of yellow fever entered those places by rail, nor were there any arrivals from infected points in Mexico.

Assistant Surgeon Main reports, under date of Oct. 31, from Brownsville, Texas, the continued good health of that place and of Matamoras, Mexico. He says, however, that, owing to a tornado at Altala, in Mexico, the death-rate from yellow fever was greatly increased in that place, and gives the total number of deaths from the scourge to have been 1981, and in the adjacent villages not less than 3000. He adds that the above is no exaggeration, as the treatment of the sick was *nil*. In Mazatlan the mortality is given—deaths in the city, 1821; in its vicinity, 4000. At Acapulco, no definite account of the mortality could be obtained, but the fever was regarded as an endemic disease at first, and not until the death-rate became alarming were any sanitary measures inaugurated for arresting the disease. As this city is one of the principal sea-coast ports of the Pacific whose commerce is chiefly with the city of Mexico, a source of great danger to the interior may result from yellow fever epidemics at this place.

Yellow Fever at Havana.—Sanitary Inspector D. M. Burgess, in a report to Surgeon-General Hamilton, dated November 1, says that there were five hundred and seventy-six deaths at Havana during the month of October, of these, eighty-six were from yellow fever, twelve of whom died in the Military Hospital, and the remainder (seventy-four) were private individuals or from merchant vessels. Dr. Burgess inspected the following named vessels bound to U. S. ports up to November 3: Span. bk. "Resuelta," for New Orleans, October 30—had one case of yellow fever on board while in port—was disinfected; Span. bg. "Victoria," for New Orleans, also had case of yellow fever on board while in port and was disinfected; Am. schr. "Christiana," for Key West, at a suspicious wharf; Am. str. "Hutchinson," for New Orleans, in open bay; Am. schr. "Sea Gull," for Key West, at a suspicious wharf; Am. str. "Santiago," for New York, in open bay; Am. str. "City of Washington," for New York, in open bay. Total number of deaths from yellow fever during the week, twenty.

Report on the Cholera in Egypt and Syria.—The U. S. Consul at Beirout, Syria, in a communication to the State Department, dated September 20, 1883, furnishes the following report relative to the cholera in Egypt and Syria:

On the twenty-fourth of last June a case of cholera occurred in Damietta, a city of the Delta, the hygienic conditions of which were exceptionally bad, even for an Oriental city. The disease spread rapidly throughout this town, and during the few weeks of its duration swept away about one fifteenth of the population. After the disease had prevailed for some time, a cordon was established around the city in which cholera had appeared. Notwithstanding this precaution, the disease spread to Cairo and the valley of the Nile above the capital.

While Alexandria was as yet free from cholera, a quarantine of ten days was established at Beirout against arrivals from Egypt. Arrivals were, however, permitted, and the Lazaretto, which has barely capacity for four hundred occupants, had at one time as many as fourteen hundred refugees. The Lazaretto of Beirout was established at a time when the city was small and enclosed within walls. It is a plateau projecting into the sea to the east of the old town and about a mile distant from it.

Being swept by the west wind, which blows from the old town, it was not especially liable to objection as a quarantine station against the plague, which was a disease rather contagious, and which could be measurably guarded against by household quarantine. But since the extension of Beirout, many houses have been built near it, and the abattoirs of the city are within a few hundred yards of it. It has therefore ceased to be a suitable station for a Lazaretto, being in effect a quarter of the city.

The arrangements of this Lazaretto are even worse than its situation. A few various buildings and a narrow camping ground are all the facilities for accommodating refugees.

The sanitary precautions were almost wholly neglected, and for a considerable time there was no resident physician. The different arrivals mingled with one another, with little attempt at isolation. I mean that passengers arriving at separate dates were able to mix with each other in the quarantine. As a specimen of the system adopted, there was a seller of iced drinks, who stood at the door of the Lazaretto, and sold his beverages to those inside and outside the walls. The cups were passed in, drained by the thirsty prisoners and then passed out again, to be used by the guards and outsiders, who thronged the outer rooms. On the third of August a soldier of the guard was taken with cholera, and at first sent in a public carriage to the military hospital in the town, but the doctor in charge declined to admit him. He was then taken to the hospital of the Sisters of Charity, where he was likewise refused admission. He was then taken back to the quarantine station, and died there. On the 5th of August, a girl, about a half a mile distant from the Lazaretto died of cholera. On the 7th of August, a woman in a remote quarter of the town was taken with cholera and died, and who it was said had washed the clothes of a man from the quarantine who did not have cholera.

Subsequently to these cases three deaths from cholera were reported by the quarantine officers. The last death occurred on the 14th of August. On the 10th of August an order from the Sublime Porte came for the establishment of a military cordon around Beirout. Against the cordon the American, British, German, Russian, Italian, and Spanish Consuls protested, telegraphing to their respective legations at Constantinople, as well as to the Governors-General of Syria and Lebanon, in identical messages, basing their protest on experiences during former epidemics, and the universal remonstrance of the medical men of Beirout, the municipal sanitary and foreign doctors, including American and French, that the cordon was useless, impossible, and dangerous. Previous to this time an order was issued for the discontinuance of the reception at Beirout of refugees from Egypt. In fact the cordon was inefficient, a number of persons passing through the cordon by paying a small fee. Such was the absurdity of the measure and its palpable deficiency, together with the actual suffering which it caused to the people by cutting off their supply of food and interrupting their business, while nevertheless the public health was exceptionally good, that after five days it was abandoned. On the 6th of September the last batch of refugees was discharged from the Lazaretto, and the city was declared free from cholera, and clean bills of health were given to vessels.

A review of this visitation opens up two inquiries: 1st. How did it happen that the first three deaths were persons not arriving from Egypt, and only one an inmate of the Lazaretto? 2d. Why did four deaths in the Lazaretto take place without any spread of the infection? Medical, as well as non-medical, men are divided in opinion on the question. Some believe that the disease, both within and without the Lazaretto, was not Asiatic cholera, but sporadic *cholera morbus*. It is popularly believed that one of the cases outside was one of poisoning by a jealous husband. Certainly it is unparalleled that a crowded, ill-nourished, and ill-housed body of refugees in the Lazaretto should be exposed to the infection and escape with so small a percentage of seizures.

Two explanations may be given on the basis that the disease was genuine cholera: 1st. That its character was so far modified by unknown causes that it has largely lost its infectious properties. 2d. That the bivouac without shelter of so large a number of inmates was unfavorable to the development of cholera germs. Certainly the present epidemic in Egypt lacks the virulence and universality of former epidemics.

It is also worth while to mention that soon after the outbreak of the cholera in Egypt, a considerable number of sailing vessels began to come to the port of Beirout, where they were quarantined for fifteen to twenty days. The place of anchorage designated by the quarantine officials for the said vessels was very close to the town. From these vessels, I am creditably informed, the sailors were in the habit of slipping ashore during Ramadan at night and returning to their vessels before daylight.

The month of Ramadan commenced on the sixth of July, and ended August the fourth, during which the Moslems in the East, do not eat or drink anything from daydreak until sunset, but dissipate by eating and drinking during the night, which usually brings on much sickness.

Thus it seems a miracle that the cholera did not spread in Beirout. It is right, however, to give credit to the local authorities, who took every possible measure to render the sanitary condition of the town as good as it can ever be, by cleaning the streets most thoroughly, spreading large quantities of lime and other disinfecting matter, and watering all the public places twice a day, to cool the hot temperature of the locality. These sanitary precautions were, in the opinion of many, the principal reasons that the cholera did not spread in Beirout, granting that the above-mentioned cases were genuine cholera. Further, I may mention that soon after the cholera appeared in Egypt, about one-half of the population of Beirout left the city and fled to Mount Lebanon, where the cholera has never spread during former epidemics, and where people feel perfectly safe from this dreadful disease.

REPORT OF SURGEON-GENERAL WALES. — In his annual report, Surgeon-General Wales, of the Navy, recommends that the medical departments of the great naval powers be invited to a conference, with a view to the adoption of a uniform nomenclature, classification, and tabulation of diseases, and of a system of interchange of periodical reports of the movement of disease from which international reports of sanitary conditions all over the world may be published at stated intervals.

The Surgeon-General advances the opinion that the present naval hospital system no longer fulfils the requirements of modern sanitary science. He recommends that the establishments at Chelsea, Brooklyn, and Philadelphia be sold, and that station hospitals be built at convenient points for the accommodation of acute cases only. It is intended that chronic cases, and those likely to be of long continuance, are to be sent to a general hospital at a central point.

The Dartmouth (N. H.) Medical College.—The largest class ever graduated from Dartmouth Medical College received their diplomas last Tuesday. The degree of M.D. was conferred upon forty graduates. A prize for the best examination in therapeutics was awarded to L. F. Wentworth, of Bridgewater, Mass.

Louis Thuillier.—The plate commemorative of the services and death of Louis Thuillier has been placed in the Normal School in Paris. It bears the following inscription, in letters of gold:

Louis Thuillier
Mort pour la Science.
Alexandrie, 1883.

The remains of Thuillier will soon be removed to Paris, the expenses of the removal being borne by the French Government. The Municipal Council of Paris has decided that the name of Louis Thuillier shall be given to one of the streets of the Latin quarter.

Medical Women for India.—A meeting was recently held in London for the purpose of considering the subject of medical women for India. Surgeon-General Hunter, M.D., F.R.C.P., presided. Mr. Kittredge, of Bombay, gave a detailed account of the efforts that had been made for the creation of a guarantee fund, by means of which competent female medical practitioners induced to visit India, might be assured a comfortable living. They had been enabled by the liberality of native gentlemen to secure already a guarantee fund amounting to between 40,000 and 50,000 rupees. Mr. Cama had given a donation of £12,000 for the erection of a hospital for women and children at Bombay. The Government had granted permission for women to dispense medicine; and, further, the authorities of the Calcutta University had conceded to females the right of training at the medical college and of qualifying for the degree of M.D. Apart from the great suffering which existed for want of medical women in India, this movement deserved support because of the impetus it would give to the moral and social improvement of native women.

Chicago Meat.—For years the character of meat sold in the markets of Chicago has not been above suspicion. Chicago canned beef has also been the subject of a well-founded distrust on the part of consumers. This suspicion and distrust arose from the fact that animals known to be suffering with disease, such as hog cholera, cancer and splenic fever in cows, and foot-rot in sheep, were shipped to the stock-yards in this city, and slaughtered either by unscrupulous local dealers or by packers. There was great profit in the practice. This rascally trade is to be broken up. For some time the health department have had one inspector located at the stock-yards. Since September 1st, he has condemned and sent to rendering establishments, eighty-five head of cattle. At the present time, two inspectors are located there, and their inspection is severe. This inspection will undoubtedly be maintained, and there need be no further fear of the quality of meat offered for sale in Chicago. In connection with the inspection of cattle, it may be said that this inspection benefits other cities as well as Chicago. Inspector Lamb notified the Chicago health commissioners last month that three car-loads of cattle, containing twenty head affected with cancer, had been sent to a firm in Grand Rapids, Michigan. Notice of their approach was immediately sent to the health authorities there. It might be said, in passing, that Grand Rapids is not a good place in which to dispose of diseased meat, the health authorities being uncommonly watchful and successful in the prosecution of guilty parties.

In connection with the above, it is worthy of notice that the Commissioner of Agriculture, Mr. George B. Loring, has issued a very important circular, in which he has called, at Chicago, on November 15th and 16th, a conference of representatives of all bodies interested in the animal industries of the United States. At this convention it is proposed to discuss the subject of contagious diseases among our domestic animals, under the following heads: (1) The extent to which they prevail in this country; (2) the methods of their introduction and spread; (3) the methods by which they may be eradicated or isolated; (4) the efficiency of existing legislation.—*Sanitary News*, November 1, 1883.

Tin in "Tinned" Foods.—Tinned meats, soups, vegetables, and more especially fruits, are all, without exception, contaminated by metals; such is the irresistible conclusion of recent scientific investigation. In 1878, Mr. Albert E. Menke communicated to the *Chemical News* results of analyses of a tin of lobster, one of apples, and another of pineapple; the latter contained tin dissolved in the juice equal to 1.3 grain per pound, the lobster and apples a much smaller quantity. Mr. Hehner, in 1880, communicated to the *Analyst* the results of a prolonged and thorough investigation of the subject. He found tin in tinned French asparagus, American asparagus, peas, tomatoes, peaches, pineapples, white cherries, red cherries, marmalade, corned beef (five different brands), ox-cheek, ox-tongue (three kinds), collared head, tripe, oysters, sardines preserved in oil, salmon, lobsters, shrimps, curried fowl (two kinds), boiled rabbit, boiled mutton, roast chicken, roast turkey, soup, and in three brands of condensed milk. The amount of tin found does not appear large—*e. g.*, in the milk one-tenth of a grain per pound, in one of the soups half a grain per pound, and in a pound tin of preserved oysters seven-tenths of a grain per pound. On a later research, Mr. Wynter Blyth has found far larger quantities. In a recent report to the Vestry of St. Marylebone, detailing the examination of twenty-three samples of tinned apricots, tomatoes, pineapples, and cranberries, the amounts found calculated as stannous hydrate range from 1.9 grain to 14.3 grains per pound, the mean amount being 5.2 grains. The juice and fruit in some instances had a metallic taste. Several of the tins showed signs of corrosion.

The older school of toxicologists, as represented by Orfila, considered pure tin vessels innocuous; if accidents occurred, they were ascribed with confidence to the admixture of lead in the alloy, or to arsenic. The arsenic theory ceased to be held when it was found that arsenic was present in so small a quantity that an adult would have to spend more than forty years drinking and eating from tin vessels before he imbibed a poisonous dose; and even the explanation of lead so often accompanying the tin has not of late been considered sufficient, but the question is of some moment whether tin in itself, present in a soluble form contaminating food, may not act injuriously. All know the toxic action of the chloride of tin on the one hand, and the inactivity of stannic oxide on the other: it is evident that in tinned foods we have to do with neither, but with some form of stannous hydrate. The little that is known of the action of stannous hydrate may be summed up in a few lines. Doses of about .174 gramme per kilogramme of body weight cause in guinea-pigs death with signs of intestinal irritation; but with doses smaller than .17 to .2 gramme the effects are uncertain, and the animals generally recover. Hence, supposing man to be affected in the same proportion, he would have to take from three to four drachms, or consume at a meal ten pounds of the most contaminated of Mr. Wynter Blyth's tinned fruits.

But it is not a question of immediate lethality, it is rather one for inquiry as to the action of small repeated doses continued for a long time. In the summer season, some families who go yachting, fishing, or travelling in remote parts often carry a considerable supply of "tinned" provisions, and must take, in the aggregate, physiologically active doses of stannous hydrate, possibly producing some slight dyspepsia or intestinal irritation. From time to time, indeed, serious symptoms are witnessed after eating tinned meats; but the exact cause of such illness has never been in any thorough way investigated. It must also be remembered that certain sugars now in the market contain tin in the proportion of about half a grain to the pound—no very great quantity in itself, but the small fractions of the metal found in this and that article of food in daily use may mount up until an active dose is taken. Physicians and medical men generally will do well to inquire closely into the diet of their patients suffering from obscure gastric affections; and it is hoped that, in the mean time, experiments may be made by competent men on the action of stannous hydrates.—*Med. Times and Gazette*, October 27, 1883.

Tracheocele.—M. Détis reports a case of tracheocele affecting a man æt. twenty-nine years, who, with the exception of an attack of rheumatism, had been in previous good health. After a severe attack of coughing, during an attack of bronchitis, he suddenly noticed a small tumor, about the size of a hazelnut, just above the sternum. Within three days' time it increased to the size of a pigeon's egg, and interfered with respiration and deglutition. It then remained stationary for three weeks, when it burst suddenly, discharging pus and blood, and then became reduced in size. After that it grew again slowly for a time, but was smaller and softer than before. It alternately grew larger and diminished with expiration and inspiration. Détis treated it by compression by a kind of truss, and after six weeks it was cured; but the patient became subject to chronic asthma, which required constantly increasing doses of morphia for its relief.

The reporter has been able to find records of twelve other cases, and from these and his own he draws the following conclusions: 1. Tracheocele may be caused by bodily exertion of any kind. 2. Its principal symptoms are enlargement, or expansion, during expiration, diappearance under compression, and an indistinct, muffled, and squeaky voice. 3. The prognosis is favorable. 4. The treatment is purely local, and consists in constant compression.—*Centralbl. f. Chirurgie*, July 7, 1883.

Health in Michigan.—Reports to the State Board of Health, for the week ending November 3, 1883, indicate that inflammation of the bowels has considerably increased, and that measles, intermittent fever, and remittent fever have decreased in area of prevalence.

Compared with the average for the month of October in the preceding six years typho-malarial fever, remittent fever, and diphtheria were considerably less prevalent, and consumption, intermittent fever, diarrhœa, and whooping-cough were less prevalent in October, 1883.

Including reports by regular observers and others, diphtheria was reported present during the week ending November 3, and since, at twenty places; and scarlet fever at twenty-five places.

Obituary Record.—Dr. E. H. Trudel, President of the Montreal School of Medicine and Surgery, and Professor of Obstetrics, died on the 5th inst., aged 63. He had practised in Montreal since 1844, and for many years had been one of the most prominent physicians of the Province.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM NOVEMBER 5 TO NOVEMBER 12, 1883.

Bache, Dallas, *Major and Surgeon.*—Par. 1, S. O. 238, A. G.O., October 18, 1883, assigning him to duty at Willet's Point, New York, revoked.—*Par. 2, S. O. 252, A. G. O.*, November 3, 1883.

Sternberg, George M., *Major and Surgeon.*—Leave of absence granted October 4, 1883, extended one month.—*Par. 4, S.O. 255, A. G. O.*, November 7, 1883.

Vickery, R. S., *Major and Surgeon.*—Assigned to duty at Fort Townsend, W. T.—*Par. 3, S. O. 149, Department of the Columbia*, October 29, 1883.

Wolverton, William D., *Major and Surgeon.*—Granted leave of absence for one month.—*Par. 6, S. O. 201, Department of the East*, October 24, 1883.

Merrill, J. C., *Captain and Assistant Surgeon.*—Granted leave of absence for one month.—*Par. 7, S. O. 201, Department of the East*, October 24, 1883.

Patzki, J. H., *Captain and Assistant Surgeon.*—Granted leave of absence for three months, on Surgeon's certificate of disability.—*Par. 6, S. O. 254, A. G. O.*, November 6, 1883.

Owen, W. O., *First Lieutenant and Assistant Surgeon.*—Relieved from duty at Vancouver Barracks, W. T., and assigned to duty at Fort Stevens, Oregon.—*Par. 2, S. O. 148, Department of the Columbia*, October 26, 1883.

Wilson, George F., *First Lieutenant and Assistant Surgeon.*—Assigned to temporary duty at Fort Townsend, W. T.—*Par. 2, S. O. 149, Department of Columbia*, October 29, 1883.

OFFICIAL.

WAR DEPARTMENT, SURGEON-GENERAL'S OFFICE,
WASHINGTON, D. C., October 24, 1883.

Surgeon-General Charles Henry Crane.

With profound sorrow, the death of Brigadier-General Charles Henry Crane, Surgeon-General, U. S. A., which occurred at his residence in Washington, D. C., October 10, 1883, is announced to the officers of the Medical Department of the Army.

General Crane, son of the late Colonel I. B. Crane, 1st. U. S. Artillery, was born at Newport, R. I., July 19, 1825, and received his early education at Maple Grove Academy, Middletown, Conn. He entered Yale College in 1840, graduating in 1844, with the degree of Bachelor of Arts. The degree of Master of Arts was conferred upon him by the same Institution in 1847.

He graduated in medicine at the Medical Department of Harvard University in August, 1847.

Having been approved by an Army Medical Examining Board, December 11, 1847, as a candidate for the position of Assistant Surgeon, U. S. Army, he was immediately placed under contract as an Acting Assistant Surgeon, and accompanied a detachment of troops to Mexico, arriving at "Camp Washington," near Vera Cruz, February 20, 1848. He was commissioned Assistant Surgeon, U. S. Army, February 14, 1848. From February 20, to July, 1848, he served with the "Army of Invasion" in Mexico.

On returning from Mexico, early in August, 1848, he reported for duty at Fort Columbus, New York Harbor, and was assigned to duty with the 2d U. S. Artillery. October 8, 1848, he accompanied two companies of the 2d U. S. Artillery to Fort Monroe, Va. He was then ordered to Florida with troops, arriving at Fort Pickens, Pensacola, Fla., November 16, 1848. From this date until August 10, 1851, he served at Key West Barracks, St. Joseph's Island, Forts Pickens, Brooke, Fraser, Casey, and Myers, and with expeditionary forces in the field. On being relieved from duty in Florida, and at the termination of a leave of absence, he reported for duty December 18, 1851, and on January 13, 1852, sailed from New York in the steamer "Falcon," with recruits for California. He arrived at Benicia, Cal., February 28, 1852, and was assigned to temporary duty at Benicia Barracks. From June 16, until September 1, 1852, he was engaged in field service against hostile Indians near Merced River, Cal. From September 23, until November 10, 1852, he was again in the field with an expedition in the Sacramento Valley, Cal. November 10, 1852, he arrived at Fort Jones, Cal., where he remained on duty until July 15, 1853.

From October 31, 1853, until March, 1856, he was on duty at Fort Lane, Oregon. During these years he was actively engaged in Post duty and with military expeditions against Indians, prominent among which was that against the Rogue River Indians in 1856, where he rendered distinguished service.

On August 7, 1856, he was ordered to Fort Yamhill, Oregon, where he served until relieved from duty on the Pacific Coast in December, 1856.

Reporting for duty in New York, he served for a short time with the Medical Purveyor, U. S. Army. From May 1, 1857, until September 20, 1859, he was one of the members of an Army Medical Examining Board convened to meet in New York City. Being relieved from this duty, he remained in New York, acting at times as Medical Purveyor.

September 20, 1859, General Crane accompanied Lieutenant-General Scott to San Juan Island, on his diplomatic visit, returning to New York December 12, 1859, and continuing on duty as Attending Surgeon at Headquarters of the Army, and on special duty until February 28, 1862.

He was promoted Major and Surgeon May 21, 1861.

On February 28, 1862, he was assigned to duty as Medical Director, Department of Key West, Fla. On June 30, 1862, he was transferred to Hilton Head, S. C., and assigned to duty as Medical Director, Department of the South. July 31 to August, 1863, he is reported as awaiting orders at Washington, D. C., and on duty connected with Prisoners of War.

September, 1863, he was placed on duty in the Surgeon-General's Office, Washington, D. C. July 28, 1866, he was appointed Assistant Surgeon-General, U.S. Army, with the rank of Colonel, and upon the retirement of General Barnes, was appointed Surgeon-General, July 3, 1882.

March 13, 1865, General Crane received the brevets of Lieutenant Colonel, Colonel, and Brigadier-General, for faithful and meritorious services during the War of the Rebellion.

In the death of Surgeon-General Crane the Medical Department of the Army sustains a serious loss. Still in the vigor of life, and with a resonable prospect of several years of active service in the position to which he had been but recently promoted, it has pleased an inscrutable wisdom to remove him from our midst.

His record, honorable and spotless, lives after him; a source of pride and satisfaction to his friends, a model worthy of imitation by all.

The larger portion of his official life was engaged in administrative duty, for which he had always manifested a peculiar fitness.

Selected to assist in the arduous and important duties devolving upon this Office during the latter years of the War of the Rebellion, his sound judgment, delicate sense of justice and right, deliberate action, and firm decision, soon won for him an enviable reputation, and materially assisted in raising the Medical Corps of the Army to the high degree of discipline and efficiency which has characterized it in the past and present.

In the literary and scientific work of the office he manifested untiring interest; to his watchful care, encouragement and aid, are largely due the successful progress and completion of undertakings which have gained for the Medical Corps the admiring recognition of the world.

Thoroughly acquainted by early experience with the requirements of his Department, assiduously attentive to the routine of business, even in its details, punctilious in regard to the rights of all, and earnest in his endeavors to promote harmony and a healthy *esprit du corps*, General Crane labored patiently, faithfully, and effectively for the best interest of his charge.

In his private life he was conspicuous for his firm, devoted friendships; for his kindly interest in, and sympathy with, the joys and griefs of those about him; for his habitual attention to the courtesies which adorn life. Unselfish and generous to a fault, his many deeds of kindness and charity were done quietly and without ostentation.

He needs no higher tribute to his worth as a man than the widespread sorrow which his loss has occasioned, and the respect for his memory which will long be cherished by all who knew him.

General Crane, at the time of his death, was one of the Commissioners of the Soldier's Home, a Visitor to the Government Hospital for the Insane, and to the Columbia Hospital for Women.

After appropriate funeral services at his late residence in this city on October 11, 1883, his remains were removed to Shelter Island, N. Y., for interment.

D. L. Huntington,
Acting Surgeon-General, U. S. Army.

NOTES AND QUERIES.

COLLEGE DIPLOMAS.

To the Editor of The Medical News.

Sir: I would like a brief space in your journal to state a few facts in reply to an article (The Medical News, Sept. 22, 1883) referring to one of the graduates of the Medico-Chirurgical College, thereby reflecting on said College. Rev. R. V. Danne, on applying for the senior course, presented two authenticated certificates from the University of Melbourne, Australia, testifying to his having attended two full courses in medicine at that institution, also a certificate to that effect from Mr Spencer, American Consul in Australia. Under no other circumstances could he or any one be admitted to the senior class in the Medico-Chirurgical College, which maintains a three years' course. Mr. Danne passed a satisfactory examination and received his diploma. If the faculty were deceived, it was in the face of apparently most "conclusive evidence." As the article further states, our standard *is* high, and it is our intention to adhere to our announced principles, and in every detail to labor for the elevation of the medical profession.

Very respectfully,
Wm. S. Stewart, M. D.,
Dean.

Medico-Chirurgical College, Philadelphia,
Nov. 14, 1883.

The Medical News *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the News *should be addressed to No. 1004 Walnut Street, Philadelphia.*

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. XLIII. SATURDAY, NOVEMBER 24, 1883. NO. 21.

ORIGINAL ARTICLES.

A CONDENSED TABULAR REPORT OF 178 CASES OF HEMORRHAGIC MALARIAL FEVER,

WITH SPECIAL REFERENCE TO THE INFLUENCE OF QUININE IN THE TREATMENT OF THE DISEASE.

BY E. D. McDANIEL, A.M., M.D., LL.D.
OF CAMDEN, ALA.
EX-PRESIDENT OF THE ALABAMA STATE MEDICAL ASSOCIATION, ETC.

IN the issue of THE MEDICAL NEWS of 21st July last, I presented a "Tabular Report of 24 Cases of Hemorrhagic Malarial Fever" that had come under my observation. The analysis of these cases led me to the following conclusions:

1st. That the black race is less susceptible of the disease than the white man is, but is not *exempt*.

2d. That the susceptibility of the sexes is about equal—the greater number of cases occurring among males being due to greater exposure.

3d. That no particular age is protected, inherently.

4th. That quinine is not only not the only effective and reliable remedy as is now widely taught, believed, and practised, but that it is, on the contrary, an uncertain, and even a dangerous agent in this disease, and often seems to determine an unfavorable result.

Of these conclusions, the 1st, the 2d, and the 3d have not been contested, and I therefore regard them as accepted and dismiss them from consideration. But the 4th, which is incomparably the most important to the medical profession, to patients, to society, to the human race, is controverted. I expected this, indeed, it was one of the purposes of my report to call general attention to this important point, to challenge the routine and dangerous employment of the cinchona salts, now so extensively adopted in the treatment of hemorrhagic malarial fever, and to induce many physicians to devote more close attention to the subject, to make careful observations and minute reports of the different modes of treating the disease and of the results. That this purpose now promises to be accomplished, is indicated by a report of 33 cases made in the issue of THE MEDICAL NEWS for August 1st, by my eminent friend Dr. R. D. Webb, of Livingston, Ala., and by reports since sent me by some of the most accomplished and successful practitioners of Alabama, embracing men of opposite views and of diverse practice as regards the matter in dispute.

The question of the benefit or hurt done by quinine, in any of the doses or modes of administration now employed in hemorrhagic malarial fever, as indicated by its influence on the rates of recovery or of death, these rates being compared with the rates of recovery or of death in the same disease, under other modes of treatment, with like environments, adjuvants, or accessories, is, therefore, now singly and fairly before us; and the coöperative investigations, observations, and reports now being made promise a satisfactory answer. There is no doubt that the fever under consideration, like other diseases, varies at different times and places, by being more pernicious or less pernicious, and that the physicians who treat it, like other physicians, vary, by being some more judicious, and others less judicious, in applying any mode of treatment. The reports of the same men, or of different men with the same views, or with different views, may also be expected to vary reasonably, according to time, place, and circumstances. But large aggregates will not fail to give fair averages, and a correct analysis of accumulated and various reports may safely be trusted to reveal the true influence of quinine on the death-rate in hemorrhagic malarial fever. Indeed, the greater the variety and diversity of circumstances and contingencies, and the more numerous the perturbing and modifying influences under which facts are observed, the more authoritative will be the generalization derived therefrom; and if the general voice of observations made by various styles of reliable men, and under the widest reasonable range of surroundings, complications, coincidences, and antagonisms, proclaims, in loud, clear, unmistakable tone, the law, that quinine in hemorrhagic malarial fever is "a savor of life unto life," or, contrariwise, that it is "a savior of death unto death," how supreme and authoritative must that law be to be thus plainly thundered forth from the midst of sources of so much apparent uncertainty and confusion? The voice of Nature is the voice of God.

The object of this paper is simply to *reach* and *establish facts*. It is not intended to ascertain or to explain how quinine hurts, or how it benefits, in the fever now under consideration, but merely whether it hurts or benefits. This is the practical matter before us. The *mode of action* of quinine is altogether a different thing, and will be in order only after the *action itself* shall have been definitely ascertained.

Having said what seemed to me necessary for the clear understanding of what is to follow, I now present a table of 178 cases of hemorrhagic malarial fever, made up of

25 cases seen by myself, 24 of which were before reported.
33 reported by Dr. Webb, of Livingston, Ala.
22 reported by Dr. Saml. Perry, of Marion, Ala.
46 reported by Dr. Jackson, of Summerfield.
11 reported by Dr. Webb, of Greene Co., Ala.
41 reported by Dr. Minor, of Greene Co., Ala.

Of the six reporters, Drs. R. D. Webb, Samuel Perry, and H. Y. Webb are understood to be of those who regard quinine in the disease with favor, while Drs. P. B. Minor, R. D. Jackson, and myself are of one mind in opposition to quinine.

Synopsis of 178 Cases of Hemorrhagic Malarial Fever, showing the Influence of Quinine on the Death-rate.

Reporter.	No. of Cases.	Recovered.	Died.	Quinine Taken.	Quinine not Taken.	Recovered with quinine.	Recovered without quinine.	Died with quinine.	Died without quinine.
Dr. P. B. Minor,	41	32	9	8	33	2	30	6	3
Dr. H. Y. Webb,	11	6	5	10	1	6	0	4	1
Dr. R. D. Jackson,	46	38	8	2	44	0	38	2	6
Dr. Saml. Perry,	22	13	9	20	2	11	2	9	0
Dr. E. D. McDaniel,	18 7	13 1	5 6	12 7	6 0	7 1	6 0	5 6	0 0
Dr. R. D. Webb,	24 9	21 2	3 7	23 3	1 6	21 2	0 0	2 1	1 6
Total,	178	126	52	85	93	50	76	35	17

Of these 178 cases:
- 126, or 71 per cent., recovered;
- 52, or 29 per cent., died;
- 85, or 48 per cent., took quinine;
- 93, or 52 per cent., did not take quinine.

Of the 85 cases with quinine:
- 50, or 59 per cent., recovered;
- 35, or 41 per cent., died.

Of the 93 cases without quinine:
- 76, or 82 per cent., recovered;
- 16, or 18 per cent., died.

Thus the death-rate in the cases with quinine is 23 per cent. heavier than in those without quinine, an excess greater than the entire death-rate in the cases without quinine. Taking these rates as a basis, if the whole 178 cases had been treated with quinine, there would have been lost 21 lives more than actually were lost under the divided treatment, and 41 more than would have been lost had all been treated without quinine. And on the same basis, if the whole 178 cases had been treated without quinine, there would have been saved 20 lives more than were saved under the divided treatment, and 41 more than would have been saved if quinine had been used in all.

A STATEMENT OF 41 CASES OF HEMORRHAGIC MALARIAL FEVER,

OCCURRING BETWEEN THE YEARS 1865 AND 1883, INCLUSIVE.

BY P. B. MINOR, M.D.,

OF FORKLAND, ALA.

THE accompanying tabulated statement is offered only as a record of facts, and from which the profession can draw its own inferences. The author has so frequently seen the hemorrhage from the kidneys reproduced by the administration of quinine, and all the bad symptoms aggravated thereby, that he has long since abandoned its use *in toto* in this disease. It is hard for the practitioner of the South to look upon any disease of malarial origin and not fly to the old stand-by—quinine—for its relief; but this is undoubtedly a disease in which (in the words of Dr. E. D. McDaniel, of Ala.) "quinine is at best a very uncertain and dangerous remedy, except in very discreet hands."

"By its fruits shall the tree be known." Let those of the profession who have had a large experience with this disease come forward and state the results, with and without the quinine treatment.

		Color.		Sex.		Result.		Quinine.		Attack.			Recovered.		Died.	
Case.	Approximate Age.	White.	Black.	Male.	Female.	Recovered.	Died.	Taken.	Not taken.	Primary.	Secondary.	Relapsed.	With quinine.	Without quinine.	With quinine.	Without quinine.

HISTORICAL NOTES ON SYPHILIS.

BY R. L. MACDONNELL, M.D.,

OF MONTREAL, CANADA.

IT is generally thought that syphilis made its appearance in Europe in 1494. Guaiacum and mercury were soon employed for its cure. The former was first recommended as a specific by Glanfield at the beginning of the sixteenth century. The Chevalier Ulric de Hutton, a German poet and man of letters, spoke of it in high terms in his essay on the Lues Venerea, the earliest printed work upon the subject, published in 1533.

Sir Ulric was a contemporary and opponent of Erasmus, and an enthusiastic Lutheran. He may fairly be said to have written from experience, for he died of the disease. Jerome Frascator devoted the greater part of the third volume of his poem[1] on syphilis to the praises of *lignum sanctum*, now called guaiac. This extraordinary work saw the light in 1530 at Verona; it is remarkable for the chaste and classical elegance of its language, worthy of the best days of Imperial Rome.

Guaiacum was prescribed by the best, and, more than that, the most fashionable physicians of the day, such as Nicolas Massa, who was also a famous anatomist, and Musa Brassavola,[2] who was decorated with the title of archiater by four popes, and with that of consulting physician by Charles V., Francis I., and Henry VIII. of England. This eminent practitioner thought highly also of the use of sarsaparilla and china root in syphilis and was the author of a book upon these subjects.[3]

The fashion changed and mercury was soon found a much more efficacious remedy. Berenger de Carpi, the anatomist, was the first to recognize its value, and by him it was used in the form of an ointment. This very successful mode of treating the disease was kept secret by Carpi, who by this practice amassed a large fortune, and contrived at his death to leave enormous legacies to his friends. When graciously invited to practise at the court of Spain, he returned an insolent answer to the king, and one of the popes he treated in the same contemptuous manner.

Berenger, or Berengarius, as according to the fashion of the time, he was called, was reported to have dissected one hundred human bodies, and to have been the discoverer of the vermiform appendix. Against him, at one time, was brought the charge of having vivisected two Spanish criminals for the purpose of examining the peristaltic actions of their intestines, and Eloy quaintly tells us that he selected Spaniards "plutot que d'autres parcequ' il haïssoit leur nation." The anatomists of that day, notably Vesalius, were often accused of human vivisection.

Mercurial ointments had been in use before Berenger's day, but not for syphilis. Old Guy de Chauliac, who wrote early in the fourteenth century, described an ointment in which one-tenth per cent. of mercury was present. Inunction was thus practised for many years before the internal administration of mercury was thought safe. Fumigation, too, was much in vogue. The credit of introducing this plan of treatment is due to the poet Frascator, though Aloysius Lobera, a Spaniard, who was physician to the Emperor Charles V., was the first to strongly advocate its use, and to give precise directions as to the best method of carrying it out. He regarded mercurial fumigation as an admirable procedure in all inveterate cases of syphilis, in persons of a robust habit of body; but prohibited it altogether in cases of weak or hectic patients, or such as were subject to cough, asthma, or dropsy.

It appears to have been the custom to prescribe for syphilitic patients, in addition to inunction, a prolonged diaphoresis and a very low diet. On the continent the patient was placed in a cave, oven, or dungeon, and Wiseman says that it was the custom in England to use a tub for this purpose. Extraordinary abstinence was enjoined during the continuance of the inunction. Hence the expression *tub-fast* used by Shakspere. Timon (Act IV. Sc. iii.) says to Timandra

> "Season the slaves
> For tubs and baths; bring down rose-cheeked youth
> To the tub-fast and the diet."

In the foot-note to this passage in Johnson & Steven's edition of the poet's works the following quotations from old plays are given

> "—you had better match a ruin'd bawd
> One ten times cur'd by sweating and the tub."
> Jaspar Maines, 1639.

Again, in the *Family of Love* (1608), a doctor says:

> "O for one of the hoops of my Cornelius' tub, I shall burst myself with laughing else."

In *Monsieur d' Olive* (1606)

> "Our embassage is into France, there may be employment for thee: Hast thou a tub."

Paracelsus, shameless charlatan though he was, was the first to teach the profession that mercury could be given by the mouth. Not only for mercury, but for a number of our most valuable remedies, to wit, antimony, sulphur, nitre, laudanum, and iron, are we indebted to this mighty impostor Philippus Aurelius Theophrastus Bombastes Paracelsus ab Hohenheim.

The prevailing belief in the humoral theory of disease, hampered for centuries the usefulness of this most useful remedy. Salivation and salvation meant the same thing in those days. Disastrous results were soon observed. As early as 1550, or earlier, there were cases recorded, notably by Massa,[1] of metallic mercury being found in the bones of persons who had died of syphilitic disease.

---

[1] It was dedicated to Cardinal Bembo: "Ce fut à lui qu'il dedia son Poëme intitulé. Syphilis, c'est a dire, du mal vénérien; & Bembo, apres l'avoir lu, entrouva la versification si riche & si belle, qu'il envoya á Sannozar, celebré Poëte Latin et Italien. Cetui cé fut'equ!ement satisfait de la lecture de cet onvrage, il avona mëme au Cardinal Hyppolite de Médicis et à Jean Baptiste de Mantone dit le Mantuan, qu'il estimoit plus ce poëme que celui qu'il avoit compose "de Partu Virginis" et auquel il avoit travaillé pendant vingt an. En effet la piece entitutée Syphilis est un onvrage daus le qout des georgiques de Virgil, dont la versification est riche et nombreuse, les images vives et les pensées noble."
Eloy—Dictionnaire Historique de la Medicine.

[2] There were two Brassavolas, eminent physicians in the sixteenth century. The other, whose Christian name was Jerome, was in high practice at Rome. He published a treatise on the nourishment of the body by means of enemata. The opinions expressed he confirmed by actual experiment. It was also proved by him that certain drugs could be administered in this manner, particularly cinchona in fevers.—Eloy, 1778.

[3] De Radicibus Chinæ usu Tractatus cum quæstionibus de Ligno Sancto. Venetiis, 1566.

[1] "Non semel in sepulchris argentum vivum in mortuorum capitibus inveni."

Treatment based upon this theory was first opposed by Pechlin in 1696, and later by Checoyneau, of Montpelier. Milder measures were the result of their teaching; but a great change took place after Van Swieten introduced into the Austrian army the use of his famous solution of corrosive sublimate. Gradually, up to the present day, the treatment of syphilis has become less heroic and more effectual.

The first treatise written in English on the subject is that of Clowes, "A Brief and Necessary Treatise Touching the Cure of the Disease now usually called the Lues Venerea." This work was first printed in 1585. Clowes was a surgeon of St. Bartholomew's and of Christ's Hospital. He had himself cured at the former institution alone upwards of a thousand patients, or above two hundred annually, in the course of five years. He used mercurial frictions and the occasional exhibition of turpeth mineral (a sulphate of mercury), or mercurius diaphoreticus, of which he speaks in terms of high commendation. Clowes was also the author of an important treatise on "burnings made with gunpowder, and wounds made with gunshot, halberd, pike, lance, etc." This latter work must have had a ready sale, for it was published in 1588, the Spanish Armada year.

Clowes' military experiences were gained in the low countries, whither he had been sent by good Queen Bess to help the wounded of the army of the Earl of Leicester.

Those were the days when syphilis was indeed syphilis;[1] and the possession of a nose was a warranty of a high moral character. The noseless became an important element in the community. Later on, in 1761, was published an essay entitled "A Plan for the Extirpation of the Venereal Disease." The author proposed that all the inhabitants of the world should simultaneously be mercurialized. To defray the cost of this large undertaking, a tax of one guinea on noses was to be levied; for, he says, "I hope that there are at least a fourth of the inhabitants of the island that have this ornamental feature actually remaining."

The business of repairing damages to these facial appendages was a trade in itself. Families took it up together, and the art descended from father to son. There lived in Sicily, in 1442, a family by the name of Branca, who were specially gifted in this somewhat unusual method of gaining a livelihood. They used skin-flaps from the arm. At the commencement of the sixteenth century a family named Vianco, in Calabria, followed the same profession.

Tagliacozzi, in 1597, Professor of Surgery in the University of Bologna, was the first to describe accurately and to practise publicly the operation since known by his name. Although he had many imitators, the practice fell into disrepute, and many began to doubt that it had ever been performed; latterly it has been revived, and successful cases have been recorded. The operation of rhinoplasty by the translation of a flap from the forehead originated in India amongst the native operators, and was brought before the notice of European surgeons in 1794.

In the seventeenth century, syphilis was a common cause of death. In the mortality returns of London, lues venerea is put down as the cause of 97 deaths in 1675; of 114 deaths in 1680; and of 104 deaths in 1694. Read Sydenham and Astruc, if you would like to know what the malady of France was in those days.

Many of the most noted characters in history were victims to its onslaughts. The enemies of Cardinal Wolsey, in 1539, accused him publicly of being diseased, and of "knowing himself to have the foul contagious disease, etc., he came daily to your highness (Henry VIII.), rowning in your ear, and blowing upon your most noble grace with his perilous and infectious breath."

Syphilis, by its common name, occurs frequently in Shakspere. Poor Dame Quickly ended her days in "'the spital,'' probably Bartholomew's, the nearest to Eastcheap, of malady of France. And the bard shows a remarkably familiar knowledge even of the secondary and tertiary symptoms, many of which are named in this following passage from Timon of Athens (Act IV. Scene III.):

> "Consumptions sow
> In *hollow bones of man:* strike their *sharp shins*,
> And mar men's spurring. Crack *the lawyer's voice*,
> That he may never more false title plead,
> Nor sound his quillets shrilly: *hoare* the flamen
> That scolds against the quality of flesh,
> And not believes himself: *down with the nose*,
> *Down with it flat; take the bridge quite away*
> Of him, that his particular to foresee,
> Smells from the general weal: make *curl'd pate ruffians*
>   *bald*;[1]
> And let the unscarr'd braggarts of the war
> Derive some pain from you: Plague all;
> That your activity may defeat and quell
> The source of all erection."

MEDICAL PROGRESS.

Action of Corrosive Sublimate on the Bacteria of Diphtheria.—Dr. Kaulich, following out the results of Koch's studies as to the action of corrosive sublimate on bacteria, administers this substance internally and applies it externally. As a topical application he uses the following: Corrosive sublimate 1 part, water 1000 parts. In children upon whom tracheotomy has been performed, the trachea is washed out with the same solution, while inhalations of corrosive sublimate gr. $\frac{1}{20}$, water f℥ xxx. Kaulich also prescribes, for children, gr. ⅙–⅓ of sublimate in gum water, slightly alcoholized. He also uses as a spray for inhalation concentrated lactic acid, grs. jss–ij, distilled water fʒj. This is used every three or four hours. For the swelling of the ganglia of the neck he uses the following as a liniment: Spirits of turpentine and chloroform āā fʒss, oil fʒiij.—*Journal de Méd. de Paris*, Oct. 27, 1883.

Lingual Cysts.—In his *Thèse* on this subject, M. Géhe makes four divisions or varieties of lingual cysts—serous, mucous, hydatid, and dermoid.

Pathology.—Serous cysts are generally situated on the under surface and at the base of the tongue. They contain clear, transparent fluid, and are lined on their inner surface with pavement epithelium. The mucous cysts are situated wherever the mucous glands are found

---

[1] The loss of hair in syphilis was not observed until 1536.

—at the tip and sides of the tongue and between the tonsils. They contain a ropy fluid, in which may be found cholesterin crystals. Hydatid cysts—cysticerci, echinococci, etc.—may develop at any part of the tongue. The dermoid cysts, which are seldom found, are situated in the middle line of the organ.

Etiology.—As regards dermoid cysts, Géhe accepts the theory which explains their formation by a pushing forward of the blastoderm through the bronchial fissure. Serous cysts take their origin from erectile vascular tumors, or from the so-called Bochdalek's glands, in the same manner as retention cysts. Mucous cysts are of inflammatory origin, and are caused by inflammation of the mucous crypts and partial obliteration of the gland ducts.

Symptoms.—The symptoms depend very much on the situation and structure of the cysts. Severe symptoms may sometimes arise from inflammation of the sac alone. Only hydatid cysts grow to any considerable size; the others generally remain small, and interfere only with speech and mastication. The course of these cysts is always chronic.

The diagnosis is not difficult, since the cysts can be readily examined. The treatment is the same for all cysts of the tongue, and consists in transfixing by a silk thread, which is left in place and causes suppuration, or puncturing, with or without a subsequent injection of an irritating fluid, or in partial or total extirpation. The last is least likely to cause trouble, and is radical. —*Centralbl. f. Chirurgie*, June 23, 1883.

NERVO-TABES.—At the meeting of the Académie des Sciences, on October 15, 1883, M. Vulpian presented a communication from DR. DÉJERINE regarding an affection, the symptomatology of which bears a close resemblance to progressive locomotor ataxia, but in which the lesions are not similar, at least so far as their situation is concerned, to those found in tabes dorsalis.

The works on the subject of progressive locomotor ataxia, which have appeared in the past few years, have shown that in almost all cases the affection is characterized, in its pathological anatomy, by atrophy with sclerosis of the posterior fibres and the posterior nerve roots of the cord. There are, however, certain cases in which no lesion of the cord can be found at the autopsy, although the symptomatology, of the disease had been complete, and on this account certain pathologists have expressed doubts as to the correctness of the pathological examinations in these cases.

M. Déjerine now communicates the report of two cases in which the majority of the symptoms were those of locomotor ataxia, running through all its stages, but from which the post-mortem evidences of that disease were absent. On the contrary, there was found in these cases a sclerous atrophy of the peripheral sensory nerves, this atrophy gradually becoming less as the nerves were followed toward the cord, so that the cord itself, as above stated, showed no lesion. M. Vulpian remarked that he regarded it as of much importance to science that these observations had been reported, and that there are doubtless many such cases at present in which the lesion is confined to the peripheral nerves. M. Déjerine proposes to give this affection the name nervo-tabes, as contradistinguished from medullary tabes or progressive locomotor ataxia. —*Revue Scientifique*, October 27, 1883.

TREATMENT OF SECONDARY SYMPTOMS OF SYPHILIS. —M. GOUGUENHEIM has recently (*Bulletin de la Societe de Thérapeutique*, August, 1883) given the results of the iodide and mercurial treatment in the secondary stages of syphilis.

In 1882, from April to November, 220 patients, with primary and secondary affections, were treated by the iodide in doses ranging from fifteen grains to thirty grains. In some rare cases as much as ʒj, ʒjss, and even ʒij were given. Of the above number, 144 were cured, 44 left too soon to form an opinion, 22 were treated with mercury, *i. e.*, with liq. Van Swieten or protochloride of mercury, in pills, or by injections of peptone mercury. Of the 144 who left cured, the average stay in the hospital was 33 days. In 1881, 350 cases were treated by the mercuric method, with liquor Van Swieten, in doses of gr. ¼. 198 cases went out cured, whose average was 33 days; 68 went out improved; 84 were lost sight of by leaving too soon. The results from these statistics are equal.

From January to April, 1882, 88 cases were treated by Van Swieten's solution, in doses of grs. ss; 59 were cured; 14 left better; 15 lost sight of; average stay of those cured, 25 days. From June to November, 1883, 53 were submitted to peptone mercuric injections, in doses of gr. $\frac{1}{5}$–$\frac{1}{4}$; 20 were cured; 2 improved; 18 lost sight of; 11 were placed under iodide treatment in consequence of threatened dangerous mercurialism. For the 20 cured, the average stay was 23 days. According to this, we see the larger doses bring about a cure in much less time, 23 days instead of 33; but 11 became so affected with the mercury as to necessitate the substitution of the iodide for it.

Forty-eight were subjected to the expectant treatment, ℥ss of solution of salt being ordered, three times a day, to satisfy the patients. Out of this number, 16 were cured; 8 made better; 13 placed under iodide after the breaking out of serious symptoms; 11 were lost sight of. The 16 cured stayed only 18 days. This last number is startling at first sight, but it must be remembered that for evident reasons only the mildest cases were allowed to remain without proper treatment, and therefore must not be reckoned amongst proper statistics.

It is clear that the iodide, in doses of 15 grains to ʒss, effects a cure in about the same time as the Van Swieten's solution, when given in doses of gr. ¼, but the preference must be given to the sublimate when administered in large doses, the more so if the hypodermic injection be employed.

Comparison of the action of each with regard to special symptoms. We must find out if this inferiority in the iodide has not some compensation in other respects.

Primary Sore. If the iodide be given during this stage, the chances are there will be no secondaries. One seems as efficacious as the other.

Syphilides—erosive, papular-erosive, and hypertrophic—of the vulva and anus. Without cutaneous manifestation it is treated by local application of arg. nit., every third day. Internally, iodide or mercury is given.

Syphilides—vulvar and anal; roseola. The hydrargyrum here has a superiority, especially if injected hypodermically.

The more obstinate cutaneous syphilides, papular, squamous, palmar psoriasis, also plantar, and lichen. The superiority still rests with the mercury.

Syphilides, buccal and pharyngeal. Here we find a difference in favor of the iodide. Mercury has even aggravated such cases, and prevented a cure. Such syphilides in the mouth assume a yellowish aspect, become painful, and exhale a fetid odor, in spite of all local applications; whereas, if the local treatment is accompanied by administration of the iodide, a cure quickly ensues. This is a very important fact to know, and is very generally ignored. Here the iodide takes precedence of any other known mode of treatment.

Manifestations on the larynx. In these cases we must make a distinction between isolated papules and diffuse and hypertrophic manifestations. In the simple papular eruption of the larynx, mercury is as efficacious as iodine. It is, however, very different if we have to do with the diffuse appearance of inflammation, perhaps upon the epiglottis, which becomes thickened and implicates the vocal cords, the arytenoid region, etc., to such a degree as to threaten suffocation and asphyxia. Mercury, in such cases, is worse than useless—it is dangerous. The iodide, on the contrary, always gives the best possible results if given in large doses of ʒss, ʒj, and even ʒijss, in the 24 hours.

Insomnia, cephalalgia, diffused pains, osseous pains, arthralgia, myosalgia. Here the mercury and iodine are equally specific.

Ulcerating and secreting cutaneous syphilides very rarely seen, aggravated by mercury. Cured easily by the iodide.

Iritis cured by iodine, and by dropping atropia into the eye.

Visceral syphilides, such as pulmonary disease, with phthisical signs, cured by iodide.

Sometimes it (the iodide) produced a loss of appetite and stomach derangement. There is at times gastralgia. Mercury may produce gastralgia, in distinct pains and diarrhœa. Iodide should be given at a meal, very diluted. The hypodermic obtains the most rapid results, but is attended with difficulties not easily overcome. The iodide can produce intoxication or iodism, consisting of coryza, conjunctivitis, pharyngitis, acne, and other eruptions.

With regard to mercury. With the 31 cases treated by peptone mercury, 11 were the subjects of intoxication, such as salivation and loosening of the teeth.

Iodide is easier for administration, and the security far greater. The dangers from iodism are far less than those from salivation.

Contraindications against both drugs: chronic gastric affections contraindicate the use of either, and it is advisable to use hypodermic injections of mercury. The state of the stomach and throat will be a powerful agent in the selection of our medicines, and in all cases where the throat element is prominent we shall do well to choose the iodide. The condition of the skin may contraindicate the use of the iodide, and, where cutaneous eruptions exist, mercury will be preferable, although the iodide has been known to act beneficially in such cases.—*Midland Med. Miscellany*, Nov. 1, 1883.

CELLULOSE AS A DRESSING FOR WOUNDS.—DR. FISCHER, of Trieste, proposes the employment of cellulose as a dressing for wounds. Before it is applied, the cellulose is impregnated with water or some medicated solution; it is then covered with an impermeable substance, such as rubber cloth. This method of dressing is particularly applicable to wounds the cicatrization of which is favored by moist heat.

Fischer claims the following advantages for this method: 1. On account of its perfect purity, it is preventive of septic conditions. 2. It is extremely light, and will have none of the bad effects sometimes occurring with heavy dressings. 3. It causes neither erythema nor erysipelas in the vicinity of the wound. 4. The heat and humidity are preserved for twenty-four hours or more. 5. It does not adhere to granulating surfaces. 6. It can be perfectly adapted to any surface upon which it is desired to apply it. 7. It is cheaper than other substances used for dressing wounds.—*Journ. de Méd. de Paris*, October 13, 1883.

IODOFORM IN CHRONIC CYSTITIS.—DR. DAVID PRINCE, of Jacksonville, Ill., in an article on this subject, says that, reasoning from the knowledge of the action of iodoform upon other irritable surfaces, it seemed probable that the effect might be equally good on the bladder. For the most satisfactory effect it seemed desirable that the vehicle itself should be free from irritating properties. Starch was thought, from its unirritating nature, to meet the requirements, and the result justified the anticipation. ʒj grs. xv of iodoform, ground with ʒiss of starch and moistened with ℥viij by weight of water, of which about ℥iij by weight were injected, acted like a charm on the first trial. A soft catheter was introduced, through which the urine remaining unexpelled was discharged, after which the iodoform mixture was injected and allowed to remain.

In the treatment of a case of several years' duration, in a young woman, the recovery is rapidly progressing. In this case, there had come a stricture of the urethra, probably through reflex spasmodic action, and in introducing the dilator for enlarging the urethra, it was punctured, the dilator passing into the vagina. The dilator was withdrawn and passed in the right direction and the stretching was then effected, as if no accident had happened. The iodoform injection was next made. The rent appeared to heal by first intention, as there was never any symptom of its presence. There has since been no resistance to the introduction of the catheter, through which the mixture is daily injected. In the case of a gentleman who had suffered greatly for several years, there was no pain after the first introduction. He thought after four days' treatment that the capacity of his bladder had been doubled.

It is suggested that the treatment of moderate strictures of the urethra, accompanied by vesical inflammation, may be advantageously managed by a precursory treatment with iodoform and starch, after which the treatment by electrolysis and the mechanical means for dilatation may be employed. It is anticipated, from this experience, that the treatment may be employed for gonorrhœa.

The employment of pencils or bougies of iodoform in gelatine has been very satisfactory, but their retention cannot be prolonged beyond the first act of micturition. In the employment of the proposed injection, it may be expected that the iodoform will not be completely expelled by the first passage of urine, on account of the adhesion of the heavy crystals of iodoform to the mucous membrane.—*St. Louis Med. and Surg. Journ.*, Nov. 1883.

THE EXCISION OF INDURATED CHANCRE.—BUMM is disposed to deny any special therapeutic value to this procedure, not because he regards chancre as a symptom of general syphilitic infection, but on practical grounds. After the expiration of the first three or four weeks succeeding a suspicious connection, when the chances are still very favorable, it is difficult or even impossible to form a clear opinion as to the character of a local affection. It generally happens that the majority of patients present themselves for treatment with well-marked induration and glandular affections, and after the most favorable time for this treatment has gone by. —*Centralbl. f. klin. Med.*, Oct. 20, 1883.

EXTIRPATION OF A CANCEROUS VAGINA FOR CARCINOMA.—SCHROEDER reports the extirpation of a vagina for carcinomatous ulceration involving the greater part of the vagina. Instead of operating by the ordinary method, by dissection from above downwards, Schröder made a circular incision anterior to the orifice of the vagina; then isolating the canal by a blunt instrument carried towards the cervix, which he removed with the lower segment. He found that this method greatly facilitated the operation. It was not found necessary to apply any sutures. There were no untoward accidents and the recovery was rapid. In another case of partial extirpation of the vagina, he found it more advantageous to dissect from below upward.—*Berlin. klin. Woch.*, August 27, 1883.

THE MEDICAL NEWS.
A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,
PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

Address, HENRY C. LEA'S SON & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA, PA.

SATURDAY, NOVEMBER 24, 1883.

IS RESECTION OF THE CARCINOMATOUS PYLORUS A JUSTIFIABLE OPERATION?

WHEN Péan, in April, 1879, resected the pylorus for carcinoma, the procedure was denounced as a vivisection on the human subject, and the same view was entertained, outside of Germany, of Rydygier's operation practised eighteen months later. The third pylorectomy, however, in the hands of Billroth, was regarded as a great surgical triumph; and with the report of each successive case, the operator has attempted to justify his action, holding, in the event of failure, that it was not resorted to sufficiently early. In order that our readers may draw their own conclusions as to the propriety of the procedure, we present them with an analysis of the facts derived from a careful study of all the cases that have fallen under our notice. The latest reports are those of the single cases of Mikulicz and Heinecke, and the seventh case of Billroth, from the pen of Von Hacker, published in recent numbers of the *Wiener medizinische Wochenschrift*, and the two cases of Molitor, recorded by Gutsch in the *Archiv für klinische Chirurgie*, Heft 3, Bd. xxix., 1883.

Pylorectomy has been performed for carcinoma 36 times, the operators having been Billroth in 7 cases, Bardenheuer in 3 cases, Molitor in 2 cases, and Péan, Rydygier, Nicolaysen, Wölfler, Berns, Jurié, Czerny, Lücke, Kitajewsky, Weinlechner, Gussenbauer, Von Langenbeck, Hahn, Caselli, Southam, Fort, Krönlein, Tillmanns, Richter, of San Francisco, Sydney Jones, Superno, Bigi, Mikulicz, and Heinecke, respectively, in 1 case. Of the 36, 27, or 75 per cent., died, and 9, or 25 per cent., recovered.

The cause of death in 25 of the cases was collapse in 17, peritonitis in 4, collapse and partial peritonitis in 2, and inanition in 2. The majority perished within a few hours—one, indeed, on the table, 18 having died within twenty-four hours, 2 on the second day, 2 on the third day, 1 on the fifth day, and 3 on the eighth day. Of the 9 recoveries, only one month had elapsed after the operation in the 2 cases of Mikulicz and Heinecke; and nearly three months and a half had expired in Billroth's last case; 1 of Billroth's patients was doing well at the end of nine months, and 1 at the expiration of eighteen months, as reported by himself at p. 86, *Verhandlungen der Deutschen Gesellschaft für Chirurgie, Elfter Congress*, Berlin, 1882; Czerny's 1 case was living at the expiration of ten months; Wölfler's 1 case at the end of two years and a half, but a carcinomatous nodule made its appearance in the outer cicatrice in rather more than one year, which was removed by Billroth eleven months subsequently, when it was found to involve the outer surface of the peritoneum, but to have no connection with the stomach, which was in good condition; 1 of Billroth's died of recurrence in the peritoneum and retroperitoneal glands in scarcely four months; and 1 of Molitor's subjects perished in eleven months and a half of carcinoma of the rectum and pelvis, without any evidence of local recurrence, although a post-mortem examination could not be obtained.

A point of great prognostic interest is that recovery occurred in every case, 4 in number, in which the tumor is noted as having been colloid carcinoma, 3 patients being alive, respectively, at the end of one month, ten months, and thirty months, while one died of continuous recurrence in less than four months. In 7 of the recoveries, of which the notes are before us, we find that there were no complications whatever in the cases of Wölfler and Molitor, and in one case of Billroth's; that three noncarcinomatous glands were removed by Billroth in the case that was living at the end of nine months; that Billroth removed one infected gland and two nodules from the gastrocolic ligament in the case that survived nearly four months; that he removed three glands in the case that was living at the end of nearly three months and a half; that Mikulicz enucleated one gland from behind the stomach; and that Czerny, in his case that was living at the expiration of ten months, enucleated two small glands from the omentum, which slipped from his fingers and were left behind. It is not improbable that they may have become attached to the peritoneum, in which event they will act as fresh centres of infection..

In 31 of the 36 cases we are enabled to refer to the original articles in reference to the question of complications. In 8, or 25.80 per cent., there were neither adhesions nor glandular involvement, while these features were present in 23, or 74.19 per cent., the infected glands being most common in the great omentum and surrounding the pancreas, and the adhesions being most frequent to the pancreas. Adhesions were met with in 13 cases, carcinomatous glands in 13 instances, and secondary nodules in the mesocolon or omentum in 3 cases.

The time required to complete the operation varied from one hour and a quarter to five hours; only four were executed in less than two hours; and the average was two hours and forty minutes. Even in the simple or uncomplicated cases, the average was only two minutes shorter.

We have learned from the foregoing facts that pylorectomy has killed 75 per cent. of the subjects that have been selected for the operation. When the case is not complicated by adhesions or glandular involvement, the deaths number one-half. The most frequent cause of the fatal issue is shock, collapse, or failure of the heart's action, which is probably due to the prolonged influence of the anæsthetic, to the pernicious effects of the spray, and, it may be, to irritation of the stomach and solar plexus, since, in several cases, there was an almost complete cessation of the pulse on incising the organ. We have, moreover, learned that adhesions, or secondary nodules, or glandular contamination, or all of these conditions, may be looked for in 74.19 of the cases, and it is interesting to note that Gussenbauer and Von Winiwarter have shown, from an examination of the records of the Pathological Institute of Vienna, that adhesions were present in 68.26 per cent., and that the glands were involved in 59 per cent., of 542 carcinomata of the pylorus. We have seen, further, that the successes demonstrate the possibility of the operation, but, gauged by the generally accepted criterion of permanent success—namely, well-being at the expiration of three years—the recoveries fail to show a final cure. Adding to the 27 deaths the 3 cases of recurrence, 83.33 per cent. of the operations have not been productive of permanent good. Deducting from the entire number the two recoveries which were reported at the expiration of one month, and the one which was well at the end of nearly four months, but including among the failures the three cases of return of the disease, and granting to the advocates of pylorectomy as cures the three cases in which the patients remain well, respectively, for nine, ten, and eighteen months, without recurrence, 33 operations show 91.66 per cent. of failures against 8.33 per cent. of successes. This assumed success is, however, more than counterbalanced by the frightful mortality of the procedure, through which it may be truly said that pylorectomy shortens instead of prolongs life.

The advocates of the operation urge that it is usually performed too late, or at a time when the patient's health is so deteriorated that he cannot withstand the shock. This objection is only partially true. The 8 simple cases were attended with a mortality of 50 per cent., and, as we shall see presently, the 4 resections for cicatricial stricture were also followed by an equally fatal result. Hence, we are disposed to attribute the death-rate as much to the severity of the operation and the long time required to perform it, as to the condition of the subject at the time it was practised.

In view of the incurable nature of carcinoma, pylorectomy, even if attended with a death-rate of 50 per cent., is justifiable in our opinion, in proper cases, that is to say, when the pylorus alone is involved, when the tumor is small and not complicated by adhesions or glandular involvement, particularly if it be of the colloid variety, and when the condition of the patient will enable him to bear the severe shock. Were these conditions always, or frequently present, the surgeon should not hesitate to afford the patient his only chance. The diagnosis, however, in the early stages of the disease is most obscure, and there is no possible mode of determining the questions of the nature of the growth and of complications. In several of the cases an apparently mobile tumor was found to be firmly attached to the pancreas or other organs; and in one case, recorded by Billroth, in which a mobile tumor and other symptoms clearly pointed to carcinomatous stenosis, the disease proved to be a lymphoma behind the pylorus. Billroth, indeed, states explicitly that only one case out of every fifty or sixty is fit for resection. In addition to the cases in which he finished the operation, he had, up to June, 1882, opened the belly twenty times, and abandoned further precedure on account of complications. All of these cases fortunately recovered from the exploratory incision, as did also the five of Rydygier, the three of Bardenheuer, and the single cases of Czerny and Rupprecht, the patient of Verneuil having perished. In examples of this description, the obstacles to removal will be found, as a rule, to be adhesion of the pylorus to the pancreas and implication of the chain of glands in front of the bodies of the vertebræ and behind the stomach. If to these incomplete operations be added the four cases of gastroenterostomy, one case of gastrostomy, and 1 case of duodenostomy, which were resorted to to prevent starvation when the pylorus could not be removed, we have 72 cases in which pylorectomy has been finished or abandoned, with the result of prolonging life in 4, or 5.5 per cent. on an average, for seventeen months.

Although the technique of the operation is almost perfect, the obstacles to the proper insertion of the sutures, and to fashioning the wound of the stomach to that of the duodenum are not easily surmounted by the surgeon who has to deal with his first case. If to these difficulties be added the adhesions met with in so large a proportion of the cases, along with the shock which of necessity must attend so prolonged an operation, it is obvious that pylorectomy must be excluded from general surgery. Indeed, in view of its great mortality, of recurrence in one-half of the cases that had survived long enough to determine this point, and of the doubts as to the final termination of the remaining cases which were living at the date of the last reports, it is questionable whether it should be repeated by those who have had the most experience with it.

The pylorus has also been resected for stenosis arising from ordinary causes 4 times. In 3 cases it was removed for stenosis from ulcer, the operators having been Rydygier, Lauenstein, and Van Kleef. The patient of Rydygier was in good condition seven months subsequently, and advanced five months in pregnancy. The case of Lauenstein perished from gangrene of the transverse colon on the seventh day. The patient of Van Kleef was living at the expiration of six months. In the fourth example, Billroth operated for obstruction due to the swallowing of caustic soda, and death ensued on the sixth day from peritonitis, the contents of the stomach having escaped into the peritoneal cavity from the giving away of six of the stitches. The mortality of the operation for stenosis is, therefore, 50 per cent. If these cases be added to those of resection for carcinoma, we find that 40 pylorectomies have resulted in 29 deaths and 11 recoveries, the percentage of the former being 72.5, and of the latter, 27.5.

With a view to complete the surgery of gastric resections, we may be permitted to recall the attention of our readers to the successful removal of a portion of the stomach for chondroid fibroma, by Cavazzini, and to the case of extirpation of a portion of the anterior wall of the greater curvature for carcinoma, by Koehler, which died of collapse in six hours.

ACTINOMYCOSIS—"SWELL-HEAD."

At the request of the Chicago Commissioner of Health, Oscar C. DeWolf, M.D., an investigation of the bovine disease popularly known as "swell-head" or "lumpy jaw" has been recently instituted by Dr. W. T. Belfield.

A brief summary of the facts developed during the investigation must be of interest to the profession in general, apart from its particular value to the sanitarian. A large number of cattle affected with "swell-head" from all parts of the West, have arrived in Chicago, but owing to the enforcement of stringent regulations by the Inspector of Cattle at the Union Stock Yards, the proportion has been greatly decreased. Five animals were examined by Dr. Belfield. Four of them were in poor condition; their hides were roughened and their bodies presented varying degrees of emaciation. In these animals the disease had attained its greatest severity. The fifth animal was in good order and the symptoms of the disease were less plainly marked.

Macroscopic examination revealed a globular tumor, varying in size from that of an orange to a musk melon, situated in the facial region in each affected animal. Three of these tumors were firmly attached to the superior maxilla, one to the inferior maxilla, while the fifth was located below the orbit. The tumors connected with the jaw-bones were hard, resisting, and gave to the touch the sensation of cartilage. Different points upon the periphery were soft and semi-fluctuating. The surface of each tumor was ulcerated and covered with thick pus. The tumor below the orbit was soft and fluctuating.

Upon section, the greater portion of each tumor was found to be composed of a hard white substance, resembling fibro-cartilage, firmly attached to the periosteum. The boundary-line between the tumor and true osseous tissue could not always be discovered. The osseous tissue was swollen, softened, honeycombed with cells, and filled with thick pus. The soft, fluctuating points were found to be cavities filled with pus. In the pus were found numerous small yellow bodies, resembling yellow miliary tubercles, about the size of a pin's head.

Microscopic examination showed the mass of the swellings to be composed of firm, connective tissue, and the miliary bodies to be groups of microscopic plants, called actinomyces, which belong to the class of radiating fungi.

From this examination, the diagnosis of actinomycosis was made.

To the best of our knowledge, this constitutes the first recognition of actinomycosis in America. The disease itself has been known for a long period of time under such names as "swell-head," "lumpy-jaw," sarcoma, cancer, and tuberculosis.

Bollinger, Royal Professor of Veterinary Surgery in Munich, discovered the actinomyces in a case of "swell-head" in 1877, and suggested the name of the disease. His researches were abundantly confirmed by the results of other investigators. Ponfick and Johm proved the causative relation existing between actinomyces and the disease "swell-head." The fungi were separated from the tumor, cultivated, and injected into the veins and abdominal cavities of different animals. These experiments resulted in the production of a disease identical in all its characters with the original affection.

The habitat of the actinomyces has not as yet been discovered. A plausible theory is that the plants have their origin in the cereals, and it is supported by the facts that actinomycosis occurs only in graminivorous animals, and that the disease affects, by preference, the jaws, tonsils, and such portions of the body as come into contact with grains. In the case examined by Dr. Belfield, he was unable to trace the entrance of the parasite through carious teeth.

The course of the disease in cattle is various. A certain number of spontaneous cures have been recorded. The disease, as a rule, remains localized, although cases of embolic deposit in every organ of the body are known.

More than thirty cases of actinomycosis occurring in the human species have been reported by German observers. In man the disease seldom remains a local affection, and is invariably fatal. Every organ and tissue of the human body is liable to invasion, and it simulates other diseases very closely. The human body seems to afford a highly congenial soil for the propagation of this parasite.

Actinomyces probably gain entrance into the human system through carious teeth, or abrasions upon the skin surface. The disease is contagious, in so far as it can be conveyed from a diseased to a healthy animal. It has not been demonstrated that it may be conveyed from an animal to man.

Two species of actinomyces have been discovered by German observers, and Dr. Belfield is of the opinion that the plant recently discovered in Chicago presents important points of difference from those already described.

SANITARY INSPECTION OF SCHOOLS.

We are glad to observe that the subject of the sanitary inspection of our schools is day by day eliciting more and more attention in different parts of the country. A recent inspection of some of the public schools in Brooklyn has brought to light unsuspected and serious defects in the sanitary arrangements, which furnishes proof of the necessity for instituting a regular and systematic inspection of the schools of that city. Similar examinations have been made of some public schools in New York City, and thus far with like results. The Board of Health, realizing the situation, have determined to undertake a sanitary examination of all the school buildings, employing for this purpose a large corps of sanitary inspectors who are to make frequent reports upon the results of their labors.

In 1882 the Philadelphia Board of Health requested Councils to authorize the employment of four sanitary inspectors of schools, whose entire time should be devoted to a service modelled after that adopted with such satisfactory results in Brussels. The duties of the single medical inspector in the employ of the city and of the port physician would not admit of the diversion of their time to this new field of labor. The request was not granted. This year the request was renewed and the importance of the subject was fully presented to the Finance Committee, which committee shapes the appropriations of the city and exerts a potent influence upon the legislation of Councils in all matters of finance. The item was not allowed, but in lieu thereof a small appropriation was granted for the expenses of a horse and carriage for the medical inspector, upon the condition that he inspect the schools and report the results of his labors at the end of the year. While this action is an admission of the need of the service, it shows how thoroughly misunderstood are its requirements. We hope the Board of Health will persist in their demands for a proper recognition of the importance of this branch of sanitary administration until the obstructionists in councils shall be obliged to yield to the pressure of enlightened public opinion.

A NEW METHOD OF RESECTING THE KNEE-JOINT.

In the *British Medical Journal* for October 20, Mr. Richard Davy, of the Westminster Hospital, London, describes a new mode of excising the knee-joint, by means of which the bones are maintained absolutely immovable, and the parts need not be disturbed from the date of operation until the patient has recovered. The case he reports was that of a girl, sixteen years of age, suffering from angular deformity of the knee, the result of resection practised thirteen years previously. After removing a rectangular wedge from the femur and tibia, a mortice was cut in the head of the tibia, into which the femur, shaped as a tenon, was impacted up to fixity of tenure by pressure on the foot. The limb was swung in an appropriate splint, and, without any special dressings, the recovery was complete on the one hundred and thirtieth day, the girl walking well with the aid of a cork boot, firm osseous ankylosis having occurred. The operation has been repeated by Mr. Macnamara, the subject being still in the hospital.

Tibio-femoral impaction, as this novel procedure is termed, effectually guards against displacement of the bones, which is one of the most trying circumstances with which the surgeon has to contend in resection, as ordinarily practised. While it is true that the operation interferes with the subsequent growth of the limb in children, Mr. Davy very properly claims that a human foot attached to a shortened ankylosed limb is far more useful than an artificial limb adapted to a thigh stump; and he therefore does not hesitate to recommend his operation as a substitute for ordinary excision in young persons. The same method of impaction is also applicable to ununited fractures.

SAD FATE OF THE YELLOW FEVER MICROBE.

M. LACERDA, of Lisbon, found in the liver and kidneys of yellow fever subjects a parasite, supposed to be the infective principle. Portions of these organs containing the parasite were examined by MM. Cornil and Bebes, but these expert sceptics ascertained that Lacerda's microbe consists of bits of vegetable tissue and pigment. *Exeunt omnes.*

REVIEWS.

THE PRINCIPLES AND PRACTICE OF SURGERY. By D. HAYES AGNEW, M.D., LL.D., Professor of Surgery in the Medical Department of the University of Pennsylvania. Vol. III. Royal 8vo. pp. 784. Philadelphia: J. B. Lippincott & Co., 1883.

WITH admirable dispatch this volume succeeds its predecessors and worthily completes the *magnum opus* of its author. In wealth of illustration, in details of personal experience, in the thoroughness with which the subjects it treats of are dealt with, and brought up to the present state of surgical knowledge, it appears to be in every way the equal of its fellows.

Dr. Agnew is an all-round surgeon, and in this volume treats matters which of late years have been very much relegated to the domain of specialists. Thus in successive chapters are treated surgical diseases of the larynx and trachea; of the nose, nasopharyngeal region, and associated parts; of the eye and its appendages; of the ear, and malformations and deformities. Nor are these subjects treated in a cursory or superficial way, but the practitioner who turns to them will find that, while condensed in form, they represent the very latest knowledge, and include pretty much all that he will care to know. The specialist may wish to study more ample monographs, but he will find in these chapters of Dr. Agnew not only the accretions of special inquiries, but the deliberate judgments of one whose experience has been vast, and who has arrived at his conclusions from the broad ground of a general surgeon, and a careful, acute observer.

The chapter on syphilis will be read with much interest. Dr. Agnew occupies a middle ground, holding that both chancre and chancroid may be derived from the same source, the former being the result of inoculation with a peculiar germinal principle, wherein lies the essence of the syphilitic poison, while the latter results from inoculation with the purulent material accompanying this germinal principle. Dr. Agnew gives the influence of his great name in favor of proper legislation to regulate prostitution, opining that as the State can not be charged with complicity in arson, theft, and fornication, because it passes laws which are restrictive of these crimes, it cannot with justice be charged with winking at immorality because it passes and enforces laws which Dr. Agnew's experience tells him will be highly advantageous to the public health.

In the chapter upon tumors will be found a comprehensive epitome of every recognized form of abnormal growth, and here as elsewhere, the thoroughness with which the pathology has been brought up to the present time is a very noticeable feature of this great surgery.

In other chapters there are considered affections of the muscles, tendons, bursæ, and aponeuroses; surgical affections of the nerves; surgical affections of the lymphatic system, skin, and subcutaneous connective tissue; and diseases of the mammary gland. Full, accurate, and experimental they will all be found.

Electricity in its application to surgical therapeutics; the various operations for nerve-stretching, and massage are the subjects of the last three chapters.

Those who enjoy the personal acquaintance of Dr. Agnew will recall the feeling of relief they experienced when they knew that he had been summoned to the bedside of President Garfield, and the perfect confidence they enjoyed in knowing that every thing would be done that human skill could dictate, a confidence which has been unshaken by notorious criticisms either at home or abroad, and as they turn over the pages of this volume they will be glad that the profession at large has an opportunity to know the extent of the skill and the profundity of the knowledge which was joined with that of Professor Hamilton in the case of the man to whom so many hearts went out in tender sympathy.

We most heartily congratulate Dr. Agnew upon the completion of his arduous task, and do not hesitate to proclaim our opinion that this treatise on surgery is fully entitled to take and maintain a place in the very front rank among works of its kind.

SOCIETY PROCEEDINGS.

NEW YORK SURGICAL SOCIETY.

Stated Meeting, October 9, 1883.

THE PRESIDENT, T. M. MARKOE, M.D., IN THE CHAIR.

CICATRICIAL CONTRACTION FROM A BURN.

DR. A. C. POST presented a patient, for whom he was indebted to the President. A boy, two and a half years of age, was admitted to the Presbyterian Hospital on the 17th of September. One year previously he had been burned by falling against a stove. Only one finger of the left hand was injured, namely, the index, which was bent and held by a cicatricial band. The right hand was burned much more severely; the thumb escaped, but all the fingers were contracted, the amount of contraction diminishing from the index to the little finger. The terminal phalanx of the index was bent at quite an acute angle. Dr. Post divided the bands of cicatricial tissue through the entire thickness of the indurated parts at intervals of about three or four millimetres, and was able to bring the fingers into a straight position. The operation was performed on the 18th of September, upon both hands. The splint was removed from the left hand on the 24th of September, and had not been reapplied. The splint had not been omitted from the fingers of the right hand, although they were perfectly straight and the tissues were flexible. The treatment consisted in free multiple incision through cicatricial bands, forcing the fingers back and applying a narrow splint of malleable iron covered with tissue-paper, extending upward to about half the length of the forearm. Recently, Dr. Post had treated the operation wounds in this class of cases by first dressing the parts with carbolized oil or vaseline, and at subsequent dressings sprinkling them very freely with nitrate of bismuth to fill up all the interstices between the incisions. He had found that the bismuth dressing answered an exceedingly good purpose. The granulations had been kept down in this manner, the wounds had been in a remarkably healthy condition, and with but very little suppuration.

THE PRESIDENT remarked that the restoration was an exceedingly gratifying one to him, as the deformity was very great when he saw the patient.

EXCISION OF A PORTION OF THE SPINAL ACCESSORY NERVE FOR SPASMODIC TORTICOLLIS.

DR. H. B. SANDS presented a patient, thirty-nine years of age, a druggist by occupation, who had consulted him in May, 1882, on account of the disease, which first appeared nine months previously. The attacks of spasm were at first less frequent than they became subsequently, and produced a rotary movement of the head, causing it to turn forcibly to the left side. No effort on the part of the patient could prevent the movement. In the beginning, the turning of the head occurred about once in three minutes; subsequently, it became more rapid, and it was estimated that the intervals between the movements did not exceed three seconds. Before he came under Dr. Sands's care he had been treated by Dr. Seguin, who had thoroughly administered hyoscyamin, the bromides, atropia, conium, and other remedies, but without any beneficial result. The patient, when Dr. Sands first saw him, was quite weak, and the contraction of the sterno-mastoid upon the right side was almost constant. It was decided to excise a portion of the spinal accessory nerve, which was assented to. In a previous operation he had followed the plan suggested by the late Mr. de Morgan of making an incision along the posterior margin of the sterno-mastoid muscle, exposing the nerve and tracing it forward, but he had found this procedure difficult and unsatisfactory. He therefore determined to try an operation by which the nerve could be reached not far from its exit from the skull; just in front of the point where it penetrates the muscle he made an incision three inches in length along the anterior margin of the sterno-mastoid, beginning close to the mastoid process. After exposing the muscle and turning it outward, he readily found the spinal accessory nerve, where it crosses the internal jugular vein, which was felt, though not seen, during the dissection. A piece of the nerve one-fourth of an inch in length was excised, and the wound was closed by sutures and covered with an iodoform dressing. Healing by adhesion was complete on the 24th of May, nine days after the operation. Immediately after the operation, the sterno-mastoid ceased to contract, and it is now paralyzed and atrophied. The patient, however, did not recover immediately from the torticollis, as there still remained a marked tendency to rotation of the head toward the left side, this being due mainly to contraction of the left splenius muscle, which could be felt as a thick, hard mass. On the 7th of June, however, the condition of the patient was very much improved, and by the middle of June he was nearly free from spasm. For six months afterwards he continued to suffer at intervals, and regained entire control of his movements only after going into the country and improving his general health. Even now he occasionally finds that his head is disposed to turn to the left side, but he has no difficulty in preventing this movement, or in turning to the right. Considering his distressing condition when he came under Dr. Sands's observation, the result must be regarded as quite satisfactory.

Dr. Sands also presented another patient, an expressman, aged 31, upon whom he had performed a similar operation and removed two-fifths of an inch of the spinal accessory nerve on the 25th of June of the present year. The patient had been engaged as an expressman for fourteen years, during which time it had been his habit to carry trunks upon his right shoulder, turning his head well toward the left side, thus, in his opinion, laying the foundation of his disease. Four or five months before he came to Dr. Sands, he began to experience some difficulty in turning his head to the right side, and also became subject to clonic spasm of the muscles which turn it to the opposite direction. Seven weeks before the operation he was treated by the application of the actual cautery along the course of the affected muscle, but without any good effect. The treatment, however, was followed by tonic spasm of the muscle, so that from that time there was no longer a rotary movement, but an extreme rotation toward the left side, so that his face looked over the left shoulder. The case, then, resembled more one of ordinary torticollis than it did one of clonic spasm. In this instance, the discovery of the nerve at the time of the operation was more difficult than in the former one, and the internal jugular vein was more distinctly exposed. The wound healed without suppuration, and on the 18th of July, he left the hospital much improved. As in the other instance, the sterno-mastoid and trapezius were paralyzed, yet recovery was gradual. For several weeks he had some difficulty in keeping his head in the proper position. He is now, however, quite well. In this case, two or three weeks after the operation it was noticed that the head was still inclined to turn towards the left side, the left splenius, the trachelo-mastoid, and the inferior oblique being probably the muscles contracting. Dr. Sands believed that it was usual in cases of spasmodic torticollis to find that the sterno-mastoid is not the only muscle affected. In a case reported by Mr. de Morgan many muscles were involved, including those of the eyeball. Dr. Sands had seen a case about a year ago, in which the integument could be observed to be raised during spasmodic contraction of the omo-hyoid.

The cure by division of the nerve seems to be gradually effected, and to be due to the cutting off of the nervous supply of one of the principal muscles involved in the disease. He did not feel certain of a permanent result in either of these cases, but the condition is now such as to afford great encouragement. He regarded the operation by dividing the nerve anteriorly as far better than that suggested by Mr. De Morgan, because by cutting in front the nerve can be reached before it divides into two branches, and a portion of the common trunk exsected quite near to its exit from the skull.

DR. F. LANGE had had a similar case in which he gave temporary relief by stretching the spinal accessory nerve. The benefit remained for only a few weeks. It was evident that the clonic spasms were mostly due to action of the muscles in the rear part of the neck on the opposite side, and he therefore finally cut through the principal muscles upon the opposite side of the neck, which gave an apparent cure for a shorter period of time. But the trouble then recurred, although to a somewhat less degree. What the final result was he was unable to state. It was certain that in this case the action of the sterno-mastoid was entirely paralyzed by the stretching of the nerve. The muscle had been divided frequently by other surgeons previously to the stretching, yet it acted well before Dr. Lange performed his operation.

FOREIGN BODY IN THE LEFT BRONCHUS; REMOVAL; CURE.

DR. R. F. WEIR presented a patient, a woman, twenty-five years of age, who, on the 26th of August, went to have a tooth extracted. While partially under the influence of the anæsthetic, a portion of the tooth escaped from the forceps, and was inhaled. She suffered from marked dyspnœa, which continued for some time, but finally she got easier, and went home. From that time until six days afterwards, she had frequent attacks of dyspnœa, which were relieved very much by the administration of morphine. When Dr. Weir first examined the patient, he found evidence of obstruction at the level of the sixth dorsal vertebra, and two inches to the left of the median line, where could be heard a whistling sound that extended from the lower portion of the lung. When she was in the erect position, this sound disappeared from the chest. After she had entered the hospital, the attacks of dyspnœa were becoming more frequent, and on the thirteenth day after the tooth had become loosed in the chest, the operation for the extraction of the foreign body was performed. Prior to opening the trachea, an attempt was made, while under the influence of the anæsthetic, to dislodge the foreign body by inverting the patient, and shaking her, jarring the chest, etc.; but as it was unsuccessful, tracheotomy was resorted to, with the patient's head strongly thrown back, the opening being made as low down as possible. Several rings were divided, and an opening made sufficiently large to admit the finger, which Dr. Weir endeavored to pass into the trachea, but this he was unable to do. He then introduced a bent forceps, like the ordinary nasal polypus forceps, carrying them to a depth of four and a half inches, entered the left bronchus, and was able to touch the foreign body, but could not seize it. Different bent forceps were then introduced, but he failed with each in catching the tooth. A piece of wire, slightly twisted to form a loop, was tried, and the same loop, bent upon itself to form a hook, was also introduced, but without success. Before ceasing instrumental interference, it was finally determined to use a wire, to which a number of threads had been tied. While this was being prepared, Dr. Little suggested that an ordinary piece of silver wire be bent into the form of a loop, and introduced. This was quickly prepared, and Dr. Weir passed it deeply into the air-passages, and happily it caught upon the foreign body. The resistance, however, was so firm that he did not dare to make very much traction; but with the wire held taut, he introduced the forceps, passing them along by its side, and with the wire and the forceps he succeeded in withdrawing the foreign body, which was the smaller half of a wisdom tooth. The tooth seemed to have been lodged upon the anterior wall of the bronchus—that is, the line of traction seemed to have been in that direction. The opening in the trachea was made so low down that, when the muscles were relaxed, it was found that the lower half of the incision was below the sternum. Only a very slight amount of bronchitis followed the operation, and complete recovery took place.

Dr. Weir also reported a case, that of a child two years of age, who inhaled a coffee-bean two days previous to the one just reported, and in whom he performed also tracheotomy for its extraction. When the patient was first seen, the house surgeon was about to perform tracheotomy, but just as the skin was divided, the child suddenly ceased coughing, and breathed so easily that the operation was abandoned on the supposition that the foreign body had been removed. Two hours later, however, when Dr. Weir first saw the case, the child was breathing with considerable difficulty. He then opened the trachea, searched above and below, but did not feel the foreign body. A suture was introduced on each side of the opening, so that the edges of the wound could be held open, if at any time it became necessary to further explore the trachea. The progress of the case proved that this was a wise precaution, for soon afterward the child was found breathing very peculiarly. The tube which had been introduced was withdrawn; the wound in the trachea was held open by means of the sutures, and out popped the roasted coffee-bean considerably swollen. Pneumonia developed, and the child died on the fourth day afterward.

Dr. Sands said that an unsuccessful attempt to explore the trachea by means of the finger in Dr. Weir's case, recalled to his mind a case which occurred many years ago in St. Luke's Hospital. The man had a portion of an India-rubber tracheotomy tube lodged in the left bronchus, and some difficulty was experienced in determining exactly where the foreign body lay; in that instance Dr. Sands passed his finger down through the tracheal wound and immediately detected the foreign body just below the point of bifurcation. A forceps was then inserted and the foreign body extracted. Since making this discovery, he had often demonstrated upon the cadaver that he could pass his finger into the trachea always as low as the place where it divides, often being able to cause the extremity of the index-finger perhaps to enter either bronchus a distance of half an inch. This mode of exploration may be of great value, by enabling the surgeon to determine exactly where a foreign body lies, so that it can be readily seized with a forceps.

The President remarked that these cases illustrated one point in diagnosis which had interested him. In a case which he had some time ago, one in which a shirt-button passed into the right bronchus, and which he extracted with the forceps after tracheotomy, Dr. J. R. Leaming made the diagnosis as to location of the foreign body. In that instance the obstruction was manifestly in the two lower lobes of the right lung; the upper lobe being perfectly resonant and the respiratory murmur distinct. In the case which Dr. Weir has now reported, the position of the foreign body was determined by the fact that the whole left side showed absence of respiratory murmur. In the right bronchus, the bronchial branch which goes to the upper lobe, sometimes comes off very near to the bifurcation, and from this point there is quite a distance before the next division takes place. It is between the first branch and the second point of division of the bronchus that the foreign body lodges when it enters the right bronchus. When a foreign body enters the left bronchus there is no branch until the tube breaks into its final divisions, nearly two inches from the trachea; and, therefore, when this left bronchus is obstructed, all entrance of air is excluded from the whole of the left lung.

REMOVAL OF ENTIRE TONGUE, SUBMAXILLARY, AND SUBLINGUAL GLANDS AND THE LATERAL WALL OF THE PHARYNX, BY KOCHER'S METHOD; CURE.

Dr. Bull presented a man forty-one years of age, who had been in good health up to four months before admission to hospital. At that time he observed a small ulcer on the left side of the tongue, and at the same time a swelling under the jaw. Both increased rapidly in size, the tongue becoming hard about the edges of the ulcer, and causing severe pain at night and while eating. His appetite had continued good, and he had not materially depreciated in weight or strength. On examination, a ragged, excavated ulcer was found on the left side of the tongue about its middle, reaching upwards to the dorsum, backwards as far as the palato-glossal fold, along which it extended to the mucous membrane covering the posterior end of the internal pterygoid muscle. Its edges were indurated, surface sloughy, discharge sanious. The submaxillary gland formed a mass of twice its normal volume, but was not hard nor tender. No other enlarged glands. A piece of the edge of the ulcer under the microscope proved to be epithelioma.

Operation August 11th. Preliminary laryngotomy was done and the pharynx stuffed with sponges on strings. By raising a triangular flap the submaxillary triangle was explored, the facial artery and vein ligated, the submaxillary gland removed, then the lingual artery and vein tied, and the sublingual gland with one-half the tongue removed with the scissors as far back as the hyoid bone. The other half was removed in the same way, as well as the mucous membrane of the pharynx beyond the posterior pillar of the fauces, and as low down as the hyoid bone—including that covering the inferior and posterior part of the pterygoid muscle. A hard enlarged gland was now found under the sterno-mastoid, closely adherent to the carotid sheath, and extirpated. Several bleeding spots were touched with the cautery. Moderate bleeding occurred during the operation, as all the large vessels were tied before being cut, and the forcé-pressure forceps were freely used. The wound was left open, the raw surfaces covered with iodoform gauze and absorbent cotton, and percha tissue applied over it. The pharynx and mouth were stuffed with gauze moistened with Thiersch's solution of boracic acid one part, salicylic acid six parts, water five hundred parts; the tracheal tube was covered with a carbolized compress. The only nourishment given during the first twenty-four hours was two enemata of beef-peptonoids with whiskey; after that the stomach-tube with a funnel attached was introduced twice daily, the gauze in the mouth being renewed each time. Between two and three pints of milk, and later, beef-tea, soup, and milk-punch were administered at one time. The iodoform gauze was not changed till the sixth day; after that the gauze in the mouth was discontinued, and the iodoform gauze renewed once or twice daily, the granulations being sponged with the boro-salicylic solution. There was no constitutional reaction, the pulse not going above 90, nor the temperature above 99°. On the fourth day the man sat up for several hours. On the seventeenth day he took food himself, although the wound would admit three fingers. The discharge was moderate, never offensive. The wound was the size of a goose-quill at the end of five weeks, reduced to a trifling sinus a week later, and entirely closed at the end of seven weeks. The cicatrix is drawn up behind the lower jaw, the motions of which are not impeded. There is no sign of recurrence. The contraction of the cicatrix has drawn the anterior pillars of the opposite side of the fauces markedly towards the median line.

Dr. Weir exhibited several new instruments designed to aid in controlling hemorrhage during operations. Among these were Tait's and Esmarch's forcé-pressure forceps, Jouillard's forceps for removal of goitre, and a ligature-carrier of his own device.

COMPOUND FRACTURE OF THIGH AT JUNCTION OF SHAFT WITH LOWER EPIPHYSIS; AMPUTATION OF THIGH.

Dr. A. C. Post presented a specimen with the following history: September 16, 1883, I was called to see W. D., a boy, eight years of age, in consultation with Dr. Lathrop, of Wurtsboro, and Dr. Van Winkle, of this city. About two months before I was called to see him, he was with his father's family in the country, and, riding in a wagon, his left knee was caught between the spokes of a wheel, and violently wrenched. The result was a fracture of the thigh at the junction of the shaft with the lower epiphysis, the end of the shaft projecting through an extensive wound on the outer side of the knee. The severity of the injury was such that Dr. Lathrop, who was called in, recommended immediate amputation; but the parents would not consent. The patient was brought to town the day before I was called to see him. I recommended that the patient should be etherized, and the limb thoroughly examined.

17th.—The patient was etherized. The limb was much swollen from the middle of the thigh to the foot There was an extensive wound on the outer side of the knee, through which protruded the end of the shaft of the femur, detached from the epiphysis, and in a state of necrosis. Sinuses extended through different parts of the thigh, leg, and foot. There were sloughs over the sacrum and over the heel. The posterior part of the os calcis was exposed and carious. Portions of the shaft, of the tibia, and fibula were exposed and rough, indicating superficial necrosis. The anterior extremities of the astragalus and cuboids were exposed and rough. Several of the other tarsal bones were in a similar condition. The patient was very pale and emaciated, but his appetite and digestion had been pretty good. I performed amputation in the middle of the thigh. The incision passed through the upper end of an abscess, through which a finger could be passed up four or five cm. The operation was well borne, and very little blood was lost. The wound was thoroughly washed with carbolic acid, 1 to 40, a tent introduced into the suppurating cavity, and the edges of the wound brought together with sutures. Absorbent cotton was applied, and pressure made with a roller-bandage. On examining the limb, the epiphysis was found *in situ*, but eroded, and almost denuded of cartilage. The head of the tibia was in a similar condition. The knee-joint was disorganized. The medio-tarsal articulation was open; the cartilaginous surfaces of the astragalus, cuboids, navicular, and two of the cuneiform bones were eroded. One of the cuneiform bones had been discharged.

18th.—Patient was troubled with vomiting after the operation, and he has not regained his appetite. He has slept for a number of hours; his pulse is steady, and not very feeble. Directed milk with arrowroot and a little brandy, as the patient can be induced to take it.

19th.—Dressed wound, and removed several of the sutures. Patient has moderate diarrhœa, but no vomiting. Ordered t. opii camphor. p. r. n.

21st.—Dressed wound again; the edges have receded at lower part. Removed all the sutures; washed wound with carbolic acid, 1 to 40. Applied emp. adhes. and bandages to close wound. Diarrhœa continues. Ordered mist. creta with t. op. camphor.

25th.—Decided improvement in general condition. Wound granulating.

Oct. 3.—Wound rapidly healing. General health steadily improving.

9th.—Continued improvement.

Dr. W. T. Bull presented a specimen of

SUBPERITONEAL FIBROID TUMOR OF THE UTERUS, WITH BOTH OVARIES AND STUMP OF THE UTERUS REMOVED BY LAPAROTOMY.

A single woman, æt. 34, was admitted to his service at St. Luke's Hospital, in August of this year, with a history of frequent backache, dragging pains in lower part of abdomen, and vesical tenesmus for three years previously. Menstruation regular. In the middle line of the lower part of the abdomen was a smooth and rounded tumor as large as a child's head, plainly felt above the pubes and in the cul-de-sac of Douglas. It was movable, not tender, apparently cystic, and the uterus, which lay in front of it, was anteverted and thrown over to the right, where the fundus could be felt through the abdominal wall. I had seen the woman six months before, when the tumor was no larger than an orange, but after Dr. Thomas and Dr. Hunter had advised against operation, I decided to wait. On her entering the hospital again, Dr. C. S. Ward agreed with me as to the advisability of operation, which was performed on August 14th. After exposing the tumor by an incision five inches long, adhesions were found to the ovaries and uterus. A double silk ligature, carbolized, was passed round each broad ligament. The uterus, just above the vaginal junction, was first temporarily constricted with an écraseur, and the tumor cut off an inch and a half beyond this. The pedicle (uterus) was then transfixed and tied with carbolized silk, cut off again half an inch beyond the silk, rubbed with iodoform and returned. On the left side of the pelvis the torn surface of the broad ligament bled; one silk ligature was applied and the surface rubbed with iodoform.

The sutures were removed on the fifteenth day; temperature ranged between 98° and 99.5° F. On the second, third, and fourth days there were vomiting and slight abdominal pain and tympanites.

The tumor was examined by Dr. Ferguson, who reported that it was a fibro-myoma; subperitoneal, from the posterior surface of the uterus, about equally from the body and neck. The ovaries are normal in size, the left containing two small cysts. The uterine body is slightly enlarged and laterally flexed. The neck above the point of section is elongated. The mucous membrane is normal.

Dr. E. L. Keyes exhibited the different kinds of forceps used by Sir Henry Thompson in *removal of tumors of the bladder.*

CINCINNATI ACADEMY OF MEDICINE.

Stated Meeting, November 5, 1883.

The President, W. W. Seely, M.D., in the Chair.

(Specially reported for The Medical News.)

Dr. Joseph Ransohoff, F.R.C.S. Eng., reported the following case of

RETRO-PERITONEAL CYSTO-SARCOMA:

J. H., æt. 33, a baker. Father died aged 73; mother died when patient was a child. Three brothers and sisters died in childhood. Patient states that he has never been seriously ill prior to the beginning of the present illness, although for a number of years he has been addicted to drinking beer in large quantity. When the present trouble commenced, he also averaged nearly a pint of whiskey daily. Has had gonorrhœa twice, but has never had syphilis. Has had an inguinal hernia of right side from childhood. Two years ago he observed a swelling of the left foot, followed in the course of a week by that of the right. The œdema rapidly involved the legs and thighs and reached the abdomen. The abdomen has since continued to enlarge in its uppermost part, although the swelling of the extremities speedily subsided. Nearly a year ago, a physician in Covington tapped him for ascites, but no fluid escaped. While considerable dyspnœa has been felt during a year past, there has never been any marked pain. Vomiting has never been a symptom of the case. The bowels have been regular, but a decided loss of appetite has existed. Suffered six months ago from hemorrhoids. Emaciation has been marked. Two years ago the patient weighed one hundred and eighty-five pounds, his present weight is one hundred and forty-five pounds.

The present condition of the patient, as revealed by his facial expression, is that of anxiety rather than of suffering. The skin is of a sallow hue; lips pale. The nostrils play freely during the respirations, which number thirty per minute. Patient walks with difficulty and is unable to assume the recumbent posture at night. Physical examination reveals no abnormity of the thoracic viscera. The upper portion of the abdomen is greatly distended, particularly in the right hypochondrium. Running from the umbilicus towards the iliac fossa and towards the chest are numerous large varicose veins. Palpation reveals, occupying the upper portion of the abdominal cavity, a firm mass which moves with respiration and is absolutely smooth upon its surface. Measurements of abdomen: at umbilicus, forty-two and one-half inches; at greatest prominence, three inches above, nearly forty-five inches. Percussion elicits a flat sound extending in right mammary line from the fourth rib to the level of the umbilicus; and in the axillary line to within two inches of the iliac crest, in the median line to the umbilicus. In the left mammary line it extends two inches below the margin of the thorax. The lower portion of the abdomen yields normal resonance. Palpation over this region revealed an absolutely smooth surface and unmistakable fluctuation over the region of greatest enlargement. Repeated auscultation failed to reveal anything like a vascular growth. The needle of an aspirator was introduced here, and two ounces of fluid withdrawn. Chemical and microscopical investigations of this fluid by Drs Kebler, French, Eichberg, and Forchheimer showed that it contained large numbers of liver-cells in diverse stages of disintegration, numerous red and white blood-corpuscles, crystals of tyrosin and albumen.

All these studies of the tumor led us to the conclusion that it must be intimately related to the liver, if not an integral part of it. For a basis of diagnosis there were but two possibilities, between which a positive final diagnosis could not and was not made. These two lesions were echinococcus and malignant disease of the liver. The age of the patient, the absence of marked cachexia, of ascites, and of pain; the slow growth of the tumor, its even surface; fluctuation; the absence of primary malignant disease in other parts, and the non-implication of the lymphatic glands rendered the presence of a malignant growth exceedingly improbable.

The symptoms all pointed more directly toward an uncomplicated echinococcus cyst, the turbidity of the fluid withdrawn being due to inflammatory changes and hepatic detritus.

At the urgent request of the patient, whose life was useless and a burden to him, and with the consent of his family, an exploratory incision was determined upon. This was made in the presence of Drs. Whittaker, Palmer, Kebler, Eichberg, Ravogli, and Krouse. The patient was anæsthetized, and an incision four inches in length was made over the greatest prominence in right hypochondrium. A few ounces of serous fluid escaped. The surface of the liver lay exposed, smooth, glistening, and free from adhesions. The fluctuation was now quite superficial. After due consultation it was decided to open the cyst. The surface of the tumor was firmly fixed to the edges of the incision by a number of silver wire sutures. The exposed surface of the growth was divided by the thermo-cautery. A half-pint of clear fluid escaped and was followed at once by the discharge of a soft friable substance, like disintegrated brain-matter. The hemorrhage attending this discharge was alarming. The finger introduced felt a large cavity filled with this same detritus.

The diagnosis was no longer questionable. Recognizing the malignant character of the growth and appreciating the uselessness of further procedures, the cavity was plugged with sponges covered with boracic acid, and the wound dressed. Whiskey, morphia, and ergotin were freely administered during the following night.

On the day after the operation, the dressing became stained with blood and was removed, but the sponges were not disturbed. The patient complained of no pain or tenderness. The abdomen below the tumor was soft. The internal treatment was continued. Forty-eight hours after the operation the sponges had to be removed because of the offensive odor emanating from the discharge. This was done with little loss of blood. On the evening of the third day, the condition of the patient became much worse; his extremities were cold, his face was pinched and covered with a cold perspiration; pulse 130 and feeble; consciousness still present, and pain not complained of. Seventy-six hours after the operation the patient died.

The report of the *autopsy* by Dr. F. Kebler, embraced the following: The body was emaciated; rigor mortis pronounced. A bloody fluid containing gray friable masses of tissue, giving a greasy feel when crushed between the fingers, flowed from the wound in the hypochondriac region. On section, the diaphragm was found to extend as high as the third intercostal space. The liver appeared to contain an enormous tumor, and extended across the entire width of the abdomen. When about to remove it, there was found attached to it and extending from the under surface of its right lobe, a cystic tumor, reaching as low as the umbilicus. The tumor was about twice the size of an adult head. The capsule had become so intimately blended with Glisson's capsule as to leave no groove to indicate where liver ended and tumor began. Careful examination, however, showed the margin of the liver about one-half inch below the border of the ribs. The tumor was covered over by peritoneum reflected from the right side of the spinal column in the region of the right kidney. The lower part of the tumor was solid and nodular, of a grayish color, rather soft, and containing in various parts extravasated blood. Above and overhanging the solid part was the cystic portion. The surface of this was smooth. The internal surface was rough and uneven, due to the presence of red and gray friable matter like that which presented at the external wound. In places the cyst-wall was very thin. The edges of the incision through the abdominal wall were united to those of the corresponding incision in the tumor by young, easily broken-down inflammatory adhesions, which completely encircled the incision. The peritoneum presented no evidence of inflammation except that just referred to. The under surface of the right lobe of the liver was infiltrated by the tumor to the depth of about one-third or one-fourth of an inch. The abdominal organs were anæmic, with the exception of the right kidney, which was enlarged and hyperæmic.

Microscopic examination of the tumor revealed that it was a mixed-celled sarcoma, consisting of small and large round- and spindle-cells, imbedded in a clear, homogeneous basis substance, in which were found bloodvessels with thin walls, and here and there extravasated blood. The contents of the cysts consisted of red and white blood-cells, a large amount of granular detritus. and large, free, granular, nucleated cells. In the opinion of the pathologist, the tumor sprang from the region above the right kidney, then extending upward, attached itself to the liver, infiltrated its substance, and, finally, by its weight, pulled upon the right lobe in such a way as to cause its border to become exceedingly thin.

The speaker said, further, that in the consideration and unbiassed appreciation of this case, a number of leading features should be taken into account, viz., a positive diagnosis was not made prior to making the incision; this incision was intended to be exploratory. After the incision, the surface of the tumor resembled so closely hepatic tissue that no one doubted its identity. Even at the autopsy the same tissue was at first mistaken for liver, and it was only microscopic examination that revealed the fact that the incision had been made through the cystic wall of an enormous neoplasm. The liver appeared as an enormous viscus, filling almost the entire abdominal cavity, and no suspicion of a tumor arose until the pathologist, with a view of removing the liver, raised its lower margin, when the neoplasm attached to its under surface was discovered. Springing from the loose connective tissue, or from a lymphatic gland behind the peritoneum and above the kidney, this new growth encroached upon the right hepatic lobe, displacing the entire viscus to the left and at the same time tilting it upon its transverse axis in such a manner that its upper surface was directed forward.

The post-mortem examination, he said, revealed to his entire satisfaction the applicability of the *technique* of the operation practised, to cases of hepatic abscess, cysts of the liver or pancreas, and even of the kidney. Not a sign of peritonitis was present, and no blood was found in the peritoneal cavity. The margins of the abdominal wound were everywhere adherent to those of the cyst-wall, and none of the cystic contents escaped into the peritoneal cavity. While in this case the operative procedures hastened death, the result cannot be attributed to the character and *technique* of the operation.

In this case, the diagnosis of retro-peritoneal sarcoma, although considered, was excluded because, first, this disease, unconnected with the kidney or supra-renal capsule, is exceedingly rare. Of eight hundred and ninety-four sarcomata tabulated by Gurlt (Langenbeck's *Arch.*, 25, 436), only one sprang from the retro-peritoneal connective tissue. Prior to Lobstein's investigations, nothing was known concerning them. To this investigator and to Virchow we are indebted for most of our knowledge on the subject. These tumors are mostly solid, and the reporter had been able to find in literature but one retro-peritoneal sarcoma that had undergone cystic degeneration. In this case, which was successfully operated upon by Czerny (Langenbeck's *Arch.*, 25, 869), the tumor occupied the central portion of the abdomen, and over its free margin the liver could be distinctly felt. Aspiration was also practised, and unmistakable evidences found of a sarcoma undergoing myxomatous degeneration. Upon this the diagnosis was based. Again, in this case the growth did not follow the lines of growth common to those of the kidney, as sarcomata springing from this neighborhood usually do. Growing forwards and downwards, they displace, as Simon has shown, the colon to the median line. They are fixed to, and unaffected by movements of the diaphragm. Both of these signs failed in this case.

Fortunately, the difficulties which surrounded the recognition of this case, the speaker said in conclusion, are not frequently encountered. That they do, however, present themselves at rare intervals is only a more cogent reason that individual cases, whatever their termination, should be published, in order that the profession may be profited by the accumulation of individual experience. In the discussion that ensued, the following remarks were made:

DR. J. T. WHITTAKER said that the point of especial interest to him had been the diagnosis. There seemed to have been no question in the minds of those who examined the case previously, or at the time of operation, that the tumor was situated in the right lobe of the liver. As already stated, the diagnosis was narrowed down to two things—echinococcus and cystosarcoma. The symptoms rather favored the diagnosis of an echinococcus cyst. The tumor had existed two years without causing any pain until within a week or two preceding the operation. This slow growth, the absence of marked cachexia, of pain, or of hemorrhage from the bowels, and the presence of fluctuation, together with the location and appearance of the growth, all seemed to indicate an echinococcus tumor. He was not willing, he said, to accept the diagnosis of a cystic sarcoma of the liver without the recognition of a sarcomatous growth elsewhere. Two or three punctures had been made, as stated in the essay, and a fluid withdrawn, which, while it was by no means characteristic of a hydatid cyst, did not present features that would necessarily exclude it. The fluid obtained was turbid, sanguineous, contained flocculi, and gave the reactions indicative of albumen. It contained no hooklets. This, however, would not exclude the possibility of a hydatid tumor, for in the majority of cases they are not found. The presence of albumen was expected, inasmuch as blood was present. In view of these facts, the speaker believed that an exploratory incision was not only perfectly justifiable, but called for. But when the incision was made, the smooth, glistening surface, with the color and feel of liver-tissue, made the diagnosis as uncertain as before.

The nature of the tumor could not be made out until it had been entirely removed from the body. Perhaps, if the microscopic examination had been carried a little further, something characteristic of a sarcomatous growth might have been found. The pathologists could not make a diagnosis until the tumor was removed, and it is no wonder the physician and surgeon should not entirely succeed.

The speaker believed this to be a case in which a diagnosis *intra vitam* was impossible, and he felt that every step had been taken in the interest of the patient. The symptoms had been summed up, repeated aspirations had been made, the contents of the aspirator subjected to microscopic examination by several competent observers, and finally an exploratory incision had been made. But the case was surrounded with such inherent difficulties that even upon the post-mortem table, after laying open the abdominal wall, the character of the growth, or even its exact situation, could not be determined.

Another interesting subject, he said, was the etiology of sarcomatous neoplasms. The development of tumors in regions like this, where no injury could be received, he thought, added strength to the theory of Cohnheim, that such growths spring from islands of embryonic tissue remaining undeveloped after the maturity of the organs and tissues for the formation of which they were intended. The experiments of Zahn lend support to this view. This observer found that, while mature tissues, cartilage, bone, etc., could not be transplanted, immature tissues, periosteum, deep layers of epithelium, could be made to grow when transplanted. Leopold has since transplanted, in this way, not only parts, but whole fœtal tissues and organs, as the whole heart. In one instance, where he had inserted bone tissue into the aqueous humor, growth occurred to such extent as to destroy the whole eye. It is at least pleasing to have a theory or a rational hypothesis in illumination of a subject so obscure.

Dr. Forchheimer stated that he must correct the author of the paper in his statement that he had pronounced the cells, seen in the fluid sent him for microscopic examination, liver cells. He was always opposed to positive statements, with regard to the character of isolated cells. The fluid sent him was a turbid sanguineous fluid containing flocculi and shreds of tissue. Under the microscope he found numerous red blood-corpuscles, quite a number of leucocytes, cholesterine crystals, and numerous cells in an advanced stage of fatty degeneration. In regard to the pathologist's report, he said that this tumor must have differed greatly from the sarcomata usually found originating in the retro-peritoneal glands, inasmuch, as it was a mixed sarcoma containing both round- and spindle-cells. As a rule, he said, and almost without exception, these tumors were made up of large round cells and giant cells, growing rapidly, but he had never seen one containing spindle-cells.

Dr. Ransohoff, in conclusion, expressed regret that more had not been said with reference to the diagnosis of cases like the one reported. He thought the case reported differed widely enough from the recorded cases of cystic sarcoma in this situation to be of interest. They usually develop with great rapidity, proving fatal in a short time. In a case which he had seen with Dr. Bramble, the patient suffered lancinating pains in the lower extremities, and had previously been treated for rheumatism and neuralgia. A fluctuating tumor twice as large as a fœtal head was found, which proved, upon autopsy, two months later, to be a round-celled sarcoma. The entire duration of that case was only four months. With regard to the microscopic diagnosis of such tumors, he said more attention ought to be paid to such examinations. But in the case reported he had himself examined the fluid, and could confirm the statement that it contained nothing characteristic except shreds of tissue undergoing fatty degeneration. Could a portion of the solid tumor have been removed, a diagnosis would doubtless have been made. Where portions of a tumor can in this way be removed and examined, the speaker considers the use of the microscope invaluable. An inaccuracy of diagnosis, he said, had been committed in considering the tumor as situated in the liver instead of behind it, and involving it only secondarily.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, November 15, 1883.

The President, Fordyce Barker, M.D., LL.D., in the Chair.

After the reading of the minutes, Dr. F. V. White, the Statistical Secretary, announced

THE DEATH OF DR. J. MARION SIMS,

for many years an honored Fellow of the Academy.

The President, in speaking of this sad occurrence, said that by the death of Dr. Marion Sims the Academy of Medicine and the profession of New York, and, indeed, of the whole country, had lost its most brilliant and original genius in the department of surgical gynecology. If circumstances had forced him into other branches of surgery, his promptness and fertility in practical procedure, his intuitive power of conception of new means to secure any desired result, his endowment of invention, and his wonderful mechanical adroitness, would undoubtedly have secured for him equal eminence in any of its departments. No one, he thought, could be compared to him in his own special field except the late Sir James Y. Simpson, whom, indeed, he closely resembled in many respects. The resemblances of these two great men were much more numerous and striking than their points of contrast. To speak of the greatest achievements of each, the one had won for himself imperishable fame by his courage and ardent zeal, carried almost to rashness, in successfully introducing the use of anæsthetics for the relief of the agonies of parturition, and the other by devising new methods of physical exploration, and new surgical procedures. Both men were incessant, zealous workers, who for many years were constantly making contributions of positive worth to the store of knowledge of the profession. The former added more to scientific literature, and the latter more to the practice of his art.

In concluding, Dr. Barker announced that he would appoint Dr. Thomas Addis Emmet to read a memoir of Dr. Sims at the first meeting of the Academy in January.

DR. FRANCIS DELAFIELD then read a paper on

TYPHOID FEVER IN NEW YORK.

All the members were interested at present, he said, in the study of typhoid fever, as all had been engaged during the past year in treating a constantly increasing number of cases of the disease. It would, therefore, be of some service to collect such facts in regard to typhoid as it existed in New York, as were of practical import. Statistics, although dry, were sometimes wholesome and necessary. As physicians went about seeing and treating disease, the impressions which they gather are not always correct. The importance of certain symptoms, the efficiency of special methods of treatment, the relative number of cases and such like points were apt to assume too great prominence; but when we looked back afterwards over the whole field, we were enabled to correct our errors and obtain a much more accurate view of the subject engaging our attention.

The records of the Board of Health for a number of years showed that for several years preceding 1863 the yearly mortality from typhoid fever averaged from one hundred to two hundred cases. Between 1863 and 1866, when typhus fever prevailed in New York, the number of deaths from typhoid ran up to from five hundred to six hundred cases a year. Since then the deaths from it had ranged from two hundred to four hundred a year. In 1879 there were one hundred and seventy-eight deaths; in 1881, four hundred and forty-six deaths; and in 1883, up to October 1st, two hundred and seventy-four deaths.

In New York, as in most other places, typhoid fever was most prevalent at the end of summer and beginning of autumn, or during the months of August, September, and October. The number of cases was then the largest, but no month of the year was exempt from the disease. In the various hospitals in New York in which typhoid fever patients were admitted, there were treated, from January 1, 1878, to October 1, 1883, thirteen hundred and five cases. A review of these would, therefore, show the hospital experience with the disease during this period. In the different years included in it the percentage of mortality, as well as the number of cases treated, had varied, as shown in the following table:

Year.	Number of Cases.	Percentage of Deaths.
1878,	124	27
1879,	114	20
1880,	110	30
1881,	319	22
1882,	313	23
1883 (to October 1st),	190	26

From this it would seem that the highest rate of mortality occurred in 1880, and the lowest in 1879.

As to the age of the patients, an allowance was to be made for the fact that, as a rule, the population of the various hospitals was made up almost exclusively of adults. The figures were as follows:

Between the ages of 5 and 10 years, 49 cases.
" " 10 " 20 " 336 "
" " 20 " 30 " 604 "
" " 30 " 40 " 186 "
" " 40 " 50 " 77 "
" " 50 " 60 " 16 "
" " 60 " 70 " 2 "
Over the age of 70 years, . . 4 "

The ordinary rule in typhoid—of preferring young adults—was, therefore, observed, nearly one-half of the entire number of patients being between the ages of 20 and 30.

As regards that most important consideration, the etiology of the disease, Dr. Delafield remarked that he had very little to say. Many of the cases originated outside of the city, and of the origin of cases in New York it was difficult to speak with any certainty. Perhaps the investigations that were at present being made by the Board of Health might throw some light on the subject.

In the autopsies recorded, the regular intestinal lesions of typhoid fever were observed, the pathological changes, even in the worst cases, being confined to the agminated and solitary glands. In some epidemics the large infiltration of the walls of the intestines was wanting. Perforation of the intestine was noticed in only a small number of cases. In two of these the perforation was through the wall of the *appendix vermiformis*. The colon was involved in only a few instances. In only one case were the multiple new growths of lymphatic tissue, sometimes met with in the stomach in typhoid fever, seen. The mesenteric glands were found in a swollen condition in all the cases, the amount of the swelling varying with the gravity of the other lesions. Suppuration of the mesenteric glands, however, was seen in only two cases. The spleen was soft in all the cases. In some it was enlarged, in others of normal size, and in still others, even smaller than normal. In a single case (that of a boy eight years of age), rupture of the spleen occurred, with a large extravasation of blood into the peritoneal cavity. Suppuration of the parotid gland was not seen in any instance. The liver was found enlarged in many cases. The kidneys, also, often exhibited swelling, with degeneration of the epithelial cells. In such cases there was sometimes albumen in the urine during life, and sometimes not. The heart was firm, and with normal muscular structure, in the majority of cases. The lungs exhibited a variety of changes, though the evidences of severe bronchitis and bronchopneumonia were seen in only a few cases. Lobar pneumonia existed in two cases. Hypostatic congestion of the posterior portions of the lungs was very common; but extreme hypostatic congestion was not frequent. The voluntary muscles of the abdomen exhibited the characteristic granular and waxy degenerations in very few cases. There were no lesions in the brain. It was evident, therefore, that the anatomical type of the disease had not been a severe one, neither the characteristic and ordinary, nor the accessory lesions being more than fairly marked.

In studying the symptoms that had characterized typhoid fever of late in New York, Dr. Delafield had collected the data of one hundred and two cases, occurring during the last five years. All were undoubted cases of the disease. A distinct prodromic period was recorded in only eighteen of the cases, and in all of these the symptoms were much the same. Sometimes bronchitis was among them. This period varied in duration from four days to several weeks.

The character of the invasion was ascertained in eighty-three cases. In thirty-seven of these a chill occurred on the first day. It was in some cases mild, and in others severe, and was sometimes repeated on successive days. It was followed by febrile movement, which was usually accompanied by headache, nosebleed, diarrhœa, and other symptoms. There were forty-four cases altogether in which diarrhœa was one of the first symptoms. In three there was blood in the passages from the beginning. In fifteen headache and fever were the first symptoms; and in six bronchitis was the most prominent trouble during the first week. Pain in the right iliac fossa or over the abdomen was noted in a number of cases at an early period, but it was often difficult to ascertain with certainty whether this symptom was present or not. In some of the cases it could not be ascertained just how or when the disease commenced.

In regard to the temperature during the first week, this was the period in which the record was most incomplete. In the cases where it was noted during the first week it did not rise in the regular way, which was characteristic of the schematic curve of typhoid fever, but was more or less irregular in its variations. It had been repeatedly noticed that the transfer of the patient to the hospital often produced a temporary increase in the temperature, so that this was sometimes higher on the day following admission than at any other time during the course of the fever. In some cases there was a sudden fall of the temperature during the first week, lasting six, twelve, or twenty-four hours. In others there were morning chills, followed by afternoon fever, and this by sweating; the whole being repeated several times.

In the second week, the temperature approached more nearly that of a regular continued fever. In some cases there was a decided remission in the morning (sometimes the thermometer indicating only 99°); and in others the morning temperature was higher than the evening. In some cases convalescence was established after the fifteenth day. In others there was a temporary remission in the fever at this period, and then the disease would go on for several weeks without abatement. In fatal cases the temperature was sometimes highest a day or two before the termination of life.

In the third week the course of the temperature was much the same as in the second; while in the fourth week there was usually a more decided fall in the morning. In some cases, the temperature after falling for two or three days in succession, would rise again and continue high for one or two weeks longer. As a rule, the temperature varied according to the severity of the disease; but there were many exceptions to this. There were mild cases in which the temperature was from 103° to 105°, and severe cases in which it was from 100° to 103°. The effect of a high temperature upon the patient's sufferings varied very greatly in different instances, some bearing it with apparently very little discomfort. The pulse varied at first from 80 to 120. In the third week it was apt to be more rapid, and was sometimes dicrotic. It was sometimes both full and slow. Generally a very rapid pulse was an unfavorable sign, but this was not invariably the case. In the patients who died with low temperature, the pulse was usually rapid and full. The appearance of the facies was usually characteristic of the disease. The tongue, as a rule, was coated down the centre with a thick white fur, and afterwards became brown and dry; or it remained clean from the first, but became dry and fissured. The moistening of the tongue was generally one of the first signs of the breaking up of the fever. Delirium was well marked in forty-one cases, and was worse during the night than in the daytime. It was sometimes very severe, and cases are on record in which it was so violent that it was mistaken for acute mania, and the patient was sent to an insane asylum instead of a hospital.

Diarrhœa existed in eighty-one cases. In forty-four it commenced at the outset, and in fifty-one continued throughout its course. Constipation of a well-marked character was noted in eighteen cases, and it was apt to be associated with excessive tympanites. The characteristic eruption of typhoid fever was noted in forty-four cases, but Dr. Delafield thought it was probably present in a larger number than this, but had been overlooked. During the present autumn he had noticed that the eruption was considerably more common than had usually been the case in New York for the last few years.

He next spoke of the complications met with. Hemorrhage from the bowels was noted in twenty-three of the one hundred and two cases. In six of these the hemorrhage seemed to be the immediate cause of death. The characteristic hemorrhage of typhoid fever, resulting from ulceration of the intestines, was most frequently met with in the second week of the disease. In three cases at the very onset of the attack there were diarrhœal passages mixed and streaked with blood; but here, of course, the hemorrhage could not have been the result of ulceration. In one case the intestinal hemorrhage was accompanied with bleeding from the gums and other parts of the body, and was, therefore, apparently due to a general hemorrhagic tendency. In two cases there was a constant bloody discharge from the bowels, like that which occurred in cancer of the rectum, and in both instances it occurred late in the disease (the sixth week.) In those cases in which the characteristic hemorrhage of typhoid was noted there was usually a well-marked fall of temperature within a few hours after its occurrence. There were, however, many exceptions to this. As had been remarked, the hemorrhage proved directly fatal in six cases, and it was always an alarming symptom. Of the twenty-three cases in which it was noted, only nine finally recovered.

In three cases a well-marked pustular eruption broke out all over the body, the pustules often amounting to small abscesses, and in five cases there was suppurative inflammation of the middle ear. There was severe pharyngitis with false membranes over the pharynx and tonsils in one case (during the first week), and a moderate degree of catarrhal pharyngitis was met with in a large number of cases.

Bronchitis of severe type or broncho-pneumonia occurred in twenty-four cases. In some of them the symptoms connected with the bronchitis were more severe than those of the fever, and in some the bronchitis was the immediate cause of death. Slighter forms of bronchitis were very common. Lobar pneumonia was seen in two cases, and in both it was apparently the cause of death. Enfeebled heart-action was frequently noted, and in one case several attacks of syncope occurred.

Peritonitis was noted in only four of the cases. In two it was caused by perforation of the small intestines by ulceration, in one by perforation of the *appendix vermiformis*, and in one was due to inflammation of the mesentery. All four of the cases proved fatal. Dysentery was noted in five cases, four of which recovered after lasting a number of days. In the other the patient died.

Of the cases which recovered (exclusive of those in which relapses occurred), the duration of the disease was ascertained in sixty-one cases. Of these, one recovered in sixteen days, four in eighteen days, six at the end of the third week, nineteen at the end of the fourth week, twelve at the end of the fifth week, four at the end of the sixth week, four at the end of the seventh week, one at the end of the eighth week, nine at the end of the ninth week, and one at the end of the tenth week The largest number of recoveries occurred, therefore, at the end of the fourth and fifth weeks. In cases which lasted longer than the fifth week there were often periods when the temperature fell and, after remaining reduced for a time, went up again.

Well-marked relapses were observed in only seven cases; all of which recovered. In three of these the interval of convalescence commenced in the fourth week and lasted from five to fourteen days. In three cases it occurred in the sixth week and lasted from five to thirteen days, and in one case in the tenth week, lasting five days.

Of one hundred and two cases, thirty-four proved fatal. In fifteen death seemed to be directly due to the disease itself. In most of them the temperature ran high, ranging from 104° to 107°. The high fever was not continuous, however, and did not extend up to the time of death. The pulse was feeble, and usually rapid. Six patients died of hemorrhage, one of syncope, on the twenty-eighth day, four of peritonitis, three of bronchitis or broncho-pneumonia, two of lobar pneumonia, one of rupture of the spleen, and one of dysentery occurring during convalescence. In one case death occurred from collapse (the temperature falling to 95° in the rectum), after a very thorough sponging with ice water and lumps of ice. In eighteen cases, therefore, death was due to complicating conditions.

In regard to the treatment, Dr. Delafield had endeavored to gather the prevailing ideas at the various hospitals. In mild cases, as a rule, the patient was simply put to bed and placed on a milk diet, and no further treatment was attempted. In some hospitals peptonized milk was preferred. Alcohol in some shape was given by some physicians in all cases without exception. By others this agent was reserved for cases with feeble heart-action. Besides alcohol, digitalis, convallaria, and caffein were employed as heart tonics. In some hospitals quinine was given in nearly every case. In others it was resorted to only when the temperature rose as high as 103°, and in still others it was scarcely used at all.

General bathing seemed to have been almost abandoned in New York during the past year, although before that it had been used to a large extent. Sponging the whole surface of the body with water, or with water and alcohol combined, the Kibbe fever-cot, and the cold pack were still used to some extent in some hospitals; but in others the use of cold water in any shape as a means of reducing temperature had been entirely abandoned.

For tympanites, turpentine given internally and applied locally, continued to be the standard treatment. For intestinal hemorrhage, opium and ergot were used. For sleeplessness and restlessness, opium was used with considerable freedom. When diarrhœa was troublesome, opium either alone or combined with bismuth and pepsin, was given, and in some hospitals a solution of acetate of aluminia was resorted to. In one institution large doses of calomel were given if the disease was seen in its early stages, with the idea of aborting it. Salicylate and benzoate of soda, tincture of iodine and carbolic acid combined, and similar agents were occasionally tried with the idea of counteracting the typhoid poison, but, as a rule, were but very little used.

The President thought that all would be astonished to find how many cases of typhoid there had been in the city during the last few years. Dr. Delafield's paper seemed to him to be the most exhaustive analytical paper on this disease since those of Murchison, and he would simply touch upon a few points which had struck him during the reading of it, and which might afford profitable topics for discussion. In the *first* place, the rate of mortality seemed to be quite high, as compared with that of the disease in other places and periods. Thus, during twelve years, according to Murchison, the average mortality from typhoid in the hospitals of London was twelve per cent. *Second.* The small proportion of cases in which there was a prodromic period. This was probably due to the fact, however, that in hospital patients it was often difficult to obtain satisfactory information on such a point as this. *Third.* The fact that the degree of temperature was not by any means always a measure of the severity of the disease. This point had attracted his attention for several years past. *Fourth.* The larger proportion of cases in which diarrhœa appeared as a symptom during the first week. *Fifth.* The percentage of deaths from hemorrhage, which corresponded with his own experience.

Dr. A. L. Loomis said that he had been anxious to know what definition Dr. Delafield would give of typhoid fever. He had given a very careful retrospect of this disease as it had appeared in our hospitals during the last few years. He had not, however, in this carefully prepared record of the characteristic symptoms of typhoid fever as seen in New York, described the typical symptoms of typhoid fever as we had been led to suppose that it existed in other countries. The description of Liebermeister, for instance, as given in Ziemssen's *Cyclopedia*, would not tally with that of Dr. Delafield. The question came back to us, therefore, What is typhoid fever? Was it a specific fever, originating from a specific cause, characterized by specific symptoms, and marked by specific pathological lesions? Among the chief characteristic symptoms attributed to it might be mentioned a typical range of temperature, as follows: A gradual rise during the first week; stationary temperature during the second week; remittent during the third week; and intermittent during the fourth week. Such a range as this, however, had not been described in the paper of the evening, nor had he seen it in any of the cases of typhoid which he had met with in New York.

The second characteristic symptom described in the books was the eruption, appearing on the seventh or eighth day, each spot lasting for three days, and one crop following another in regular succession for two weeks. Here, however, the eruption was seen in hardly half the cases, and in his own cases it had been the exception. When it was present, it appeared late, and was not often the characteristic rose-colored eruption, while the spots might last for three days, or six days, or indefinitely. The third supposed characteristic symptom was diarrhœa of a "pea-soup" character. But diarrhœa was frequently absent, and that described by Dr. Delafield (and usually met with in typhoid fever here) had nothing characteristic about it.

Dr. Delafield had avoided one very difficult point, and that was the etiology of the disease. Now was this fever prevailing in New York of spontaneous origin, or did it depend on a specific germ, which had to be developed and undergo certain changes before it became infectious? In other words, could we have typhoid fever without a typhoid germ? Of course, this was a very difficult matter to investigate. Dr. Loomis then read a *résumé* of the cases of typhoid which had been under his care at Bellevue Hospital since the last week in September. They were seventeen in number, and of these, four had proved fatal. In three of these, however, the patients died within three days after admission. The highest range of temperature was 105⅖°, and the average range was 101¼°. The eruption appeared in four cases, and diarrhœa in four. Constipation was present throughout in thirteen cases. Hemorrhage occurred in two cases, and peritonitis in two. In each of the latter there were ulcerations involving the large as well as the small intestine. In one case, there was complicating dysentery during convalescence.

From the characteristics of typhoid as seen here, therefore, he thought it was necessary either to regard the disease simply as a continued fever, with typhoid symptoms, or else to give up all idea of there being such an affection as typhoid fever. In New York, at least, there was no longer such a thing as a specific typhoid fever, or else the majority of the cases described by Dr. Delafield were not true typhoid. The so-called typhoid fever seen here did not correspond to the European type, or to that which used to be seen in New

England, although he believed there were some localities where typhoid was endemic. Not long since he had seen in consultation a Connecticut physician, and had inquired of him if he saw much old-fashioned typhoid in his practice now; to which he replied, that the disease was not like what it used to be before malarial fever was prevalent in the community. This, he believed, was the general experience of the profession at the present day, typical cases of typhoid being no longer met with.

Dr. Frank P. Kinnicutt, in referring to the constipation met with in typhoid, remarked that several years ago Sir William Jenner had called attention to the fact that a single deep ulceration of Peyer's patches might cause a paralysis of the bowels. Of course, however, there were other causes of constipation also. With reference to ascertaining the frequency of constipation, he had examined the records of all the cases of typhoid fever treated in St. Luke's Hospital in the summer and autumn months of 1882 and '83. In 1882 there were twenty-six cases, with seventeen recoveries and nine deaths; and in 1883 there had been eighteen cases, with fourteen recoveries and four deaths. Of the cases occurring during the present year, constipation had existed in seven, and diarrhœa in nine. Constipation was always a disadvantage to the patient, and was oftentimes of dangerous import. It was therefore necessary to adopt measures to relieve it, and as he did not think it right to give laxatives by the mouth, he was in the habit of using small enemata of thin gruel, frequently repeated if necessary. This answered perfectly, and was a better plan, he thought, than to give larger enemata at longer intervals.

In regard to relapses, he said he was convinced that these were wholly independent of any error of diet, and were unavoidable, as there seemed to be a distinct form of relapsing typhoid, in which a portion of the poison seemed to remain latent for a time, as pointed out by Da Costa. In the treatment, the question of the advantage of alcohol was a very difficult one to decide. The symptoms were the best guide, and his own rule was to withhold it until the third week, and then only give it when absolutely necessary. While alcohol might do good in some cases with delirium, he had seen two instances in which marked delirium and tremor had been wonderfully relieved by the withdrawal of alcohol, which had previously been given freely. In general, simple rest was the best treatment, medical treatment being reserved for special symptoms.

Dr. Edward G. Janeway believed it a mistake to consider typhoid fever more prevalent of late years in New York than it had been formerly. The statistics of the Board of Health showed that neither absolutely, nor certainly in proportion to the population, were there more cases of typhoid now than before. He differed from Dr. Loomis, and believed that the typhoid fever seen in New York was identical with that described as existing in Europe, because the lesions were the same. If there were discrepancies, their cause was to be looked for in other directions, and one great cause of discrepancy, he thought, would be found in the treatment adopted here. Quinine was almost universally given, and many physicians were in the habit of prescribing it in large doses in the beginning of typhoid in order to make a differential diagnosis between it and malarial fever. Both Liebermeister and Murchison admitted that there were atypical cases, such as were frequently met with here. The etiology of the disease was often very difficult to trace, but his experience, especially in epidemics occurring at the Roman Catholic Half-orphan Asylum, the Deaf and Dumb Asylum, and Princeton College, had convinced him that the disease was of specific origin. In these different epidemics the symptoms varied very greatly, but the lesions were always the same. At the Deaf and Dumb Asylum diarrhœa was the rule, while it was the exception at the Half-orphan Asylum. In one case at the former institution he met with the highest temperature which he ever saw reached without a fatal result, viz., 109°. It was attendant upon the development of pneumonia, and lasted only for a very short time. Typhoid he believed to be a disease which was due to poison capable of producing a fever which might last from three days to eight or ten weeks. In all outbreaks of the disease there were cases which lasted only a very short time. As regards certain features of typhoid as it was now found in New York, he had found, like Dr. Delafield, that the eruption was particularly well marked, and he had not seen a case of the disease in an adult which had reached the tenth day in which it could not be detected if careful search was made for it over the abdomen, breast, and back. He had never seen any special difference between city and country cases of typhoid, and thought that the disease as seen in New York was very much like that met with in other places. It was always of interest to try to trace the origin of an outbreak of typhoid, but that it was a very difficult matter was well illustrated in a case which had recently come under his notice. This was that of a pedler who, for a week after typhoid had set in, although suffering from severe diarrhœa, had continued to ply his vocation among the tenement-houses of the city, and it was estimated that it was possible for him to have infected the closets of no less than forty-eight houses during this time. As a rule, it was very unsatisfactory to attempt to trace the disease to milk supply in this city; but in the case of the epidemic at Fort Washington last year, such an origin seemed to be well established. In the outbreak at Princeton, the first six cases occurred in April, and it was found that all the six students had been taking their meals at one house. On investigation it proved that there was a cesspool within forty feet of the well from which the drinking water of this house was drawn. Later on, the disease was spread through the drain-pipes and in other ways.

Dr. T. A. McBride spoke of the cases which he was accustomed to see at the out-door department of the New York Hospital. There were ordinarily diarrhœa and elevated temperature, and on examination he found an enlarged spleen and often an enlarged liver. The spots were almost always present. Some of these cases were sent to the hospital, but many of them did not remain there more than one or two weeks. He had recently had a case of typhoid in which a number of hemorrhages had occurred, and he would like to ask Dr. Delafield how long albumen, unassociated with tube-casts, appeared in the urine after such hemorrhages.

In the treatment he was in the habit of using kairin. In one case he had been unable to employ quinine in any form; and trying the kairin, he had found it to act very satisfactorily. He sometimes used from fifty to sixty grains of it in the twenty-four hours. When the temperature rose to 103°, or higher, his rule was to give seven grains of kairin every hour until it was reduced to 101°. If the temperature was not higher than 102°, he used only three and a half grains every hour until it fell to 101°. Invariably he had found that seven grains reduced the temperature from three-fourths to one degree, and it was seldom necessary to give more than two doses in successive hours. It almost always caused a copious perspiration; and the reason that he made 101° the limit was, that if the temperature was brought lower than this the patient would be apt to have a chill, when the fever would run up again very rapidly. The drug was given in capsules or pills, after milk or other food had been taken; and he had never seen it produce any unpleasant effect upon the stomach. After kairin had been taken, the urine assumed a greenish hue, and was usually found to contain albumen.

The President, after brief remarks by Drs. Pinckney and Fruitnight, said that it was his practice never to disturb the bowels when there was constipation until the patient began to suffer from inconvenience from it, and he then gave a single powder of five grains of calomel worked up with fifteen or twenty grains of bicarbonate of soda, which he found of great service.

Dr. Delafield, in closing the discussion, said that there was much atypical typhoid in New York. The fact that the disease did not always have typical symptoms was known to all, and this was the very reason why he thought it would be of service to bring these cases together. But, after all, typhoid fever was very much the same as other diseases in the respect that it varied very greatly at different times and in different localities. The lesions were the characteristic feature of the disease, and yet, while they were the same in kind, they differed greatly in degree. He was very familiar with Liebermeister's article on typhoid, as he had translated it for the American edition of Ziemssen, and he thought it was undoubtedly true that he had misled many persons. When he was translating the article, he was struck with the fact that it was unquestionably made up, the author's descriptions being more definite and precise than if they had been taken directly from nature. In short, he had sacrificed truth in order to present a clear and striking picture of the disease. Constipation, he thought, had nothing to do with ulceration of the small intestines, and he doubted whether the diarrhœa depended on the intestinal lesions. The constipation, in all the cases in which he had mentioned it, had been of a positive character, and this he considered a decided evil to the patient, so that he never hesitated to give laxatives during the first week if they were required; after that, enemata were better. He agreed with Dr. Kinnicutt in regard to relapses being independent of incidental circumstances, and with Dr. Janeway as to the frequency of the occurrence of the eruption during the present season. In answer to Dr. McBride's question as to albuminuria after hemorrhage, he said that he had had no experience in the matter, although the kidneys, as he had shown, were exceedingly apt to be affected in typhoid.

THE AMERICAN PUBLIC HEALTH ASSOCIATION.

Eleventh Annual Meeting, held at Detroit, November, 13, 14, and 15, 1883.

(Specially reported for The Medical News.)

The Eleventh Annual Session of this Association convened in the city of Detroit, Mich., Tuesday, November 13th. The place of meeting this year had been held to have about equally balanced advantages and disadvantages as to attendance and increase of membership; the advantage being chiefly in the fact that Michigan is perhaps the best enlightened State in the Union sanitarily, thanks to the work of its State Board of Health, while the fact that transportation facilities to points like Detroit, reached mainly by pool lines, are not afforded, constitutes the chief disadvantage. This view proved correct, and the attendance was about the average of recent meetings.

The experience of the last few years has pretty definitely shown that the southern and southwestern cities are by far the most favorable places for meetings of the Association, those communities being keenly alive to the money as well as the physical value of health.

The arrangements for the meeting at Detroit, having been in charge of an able local committee, of which Dr. Wm. Brodie was Chairman, were very satisfactory, save in the one important particular that Merrill Hall, the place of meeting, can, beyond doubt, establish a claim to having as bad acoustic properties as any hall in the land.

Tuesday, November 13th, First Day.

Morning Session.

The Association was called to order by the President, Ezra M. Hunt, M.D., of Trenton, N. J. After the opening business of the morning, including the Treasurer's Report, which showed a handsome balance on hand, the call for reports of committees brought forward that of the special committee on

CATTLE DISEASE,

by Dr. J. M. Partridge, of Indiana, Chairman, which was brief and unimportant, except as it served as the introduction for several very able papers which followed, upon the subject of cattle disease. Additional interest existed in this one of the four main topics assigned for special consideration at this meeting, from the fact that the Cattle Disease Convention was about to open at Chicago, and that the veterinarian experts of the two rival cattle-disease authorities of the United States, Prof. D. E. Salmon, of the Agricultural Bureau, and Prof. Law, of the Treasury Cattle Commission, were both present.

The first paper of the session was by the former of these gentlemen, Dr. Salmon, of Washington, its title being

TEXAS CATTLE FEVER: IS IT A CHIMERA OR A REALITY?

The paper was strong in its construction, clear and logical in its deductions from the data it gave, and will form a valuable contribution to the constantly lengthening chain of evidence which goes to establish the positions taken by Prof. Salmon: that Texas fever *is* a reality; that its origin is confined to a certain belt of territory; that its seeds are portable; and that the danger of its wide extension, except it be carefully and strongly controlled, are great.

There will be, perhaps, many who will join in the dissent expressed by Dr. O. W. Wright, of Michigan, to the postulate of Dr. Salmon: that it must require a disease in an animal (though it might be undeveloped) to produce the disease in other herds.

The discussion of the paper was short, and not important, being briefly participated in by Dr. J. H. Rauch, of Illinois; Dr. Hilary Ryan, of Texas; Dr. Wright, of Michigan; and Prof. Law.

The second paper of the morning, its title being *Swine Plague*, by Dr. J. M. Partridge, of Indiana, was an interesting statement and analysis of the features of this disease, well condensed, but containing nothing specially new. There was no direct discussion of the paper.

The third paper, by Dr. W. T. Belfield, of Chicago, which was in the form of a report by this gentleman to Dr. O. C. DeWolf, Health Commissioner of that city, was forwarded to the Association by the latter at so late a time that it was not included in the programme of the day, and was read by the Secretary. It was entitled.

SWELL HEAD IN CATTLE.

The true character of this disease, which has recently been very prevalent in the Chicago stock-yards and elsewhere, has been only of late determined, though its prominent features, viz., tumors of varying degrees of hardness upon the jaws, etc., have long been dealt with by veterinarians, and associated with the lodgment of foreign substances in the jaws, etc. The fungous character of its etiology, the *actinomyces* and their growth, the establishment of the disease as *actinomycosis*, and its relative features in animals and man, were clearly portrayed. It was considered one of the best contributions of the session.

Prof. Law, in the brief discussion which followed, was not ready to admit that the recognition of the actinomycocic character of the disease was of so recent a date as claimed.

The Association took a recess till 3 P. M.

AFTERNOON SESSION.

The subject of malaria, as one of the four principal topics, was assigned to this session, and its consideration was opened by a very long, able, and exhaustive review of

THE ETIOLOGY OF MALARIA,

in a paper by Surgeon GEORGE M. STERNBERG, U. S. Army. This was followed by another on "The Etiological Association of Organic Matter with Malaria," by Surgeon ALFRED A. WOODHULL, U. S. Army, equally careful and elaborate in analysis, and a third paper by Surgeon CHARLES SMART, U. S. Army, on

THE PREVENTION OF MALARIAL DISEASES,

as clear and able in its scope as its predecessors, completed a trio of remarkable papers on the general subject, all by distinguished officers of the medical staff of the army; prepared without coöperation or mutual understanding, from different standpoints, and mainly from different data. That nothing which could be said to be absolutely new to science was presented in these papers is true, but as complete statements of what has been determined in regard to malaria, as setting the stakes of recorded observations, and as showing the routes along which inquiry for the future must be directed, they will stand quite unexcelled if not unrivalled, and in them the medical staff of the army certainly gathered new laurels. The agencies of heat, moisture, and vegetable decomposition received full and elaborate consideration in the several papers, and the low-resistance powers of the system were given credit for the part played by them. Dr. Sternberg expressed himself as hopeful as to the complete solution of the cause of malaria in the not remote future. The data showing the increased percentages of malaria in relation to latitudes was most effectively and logically used. Dr. Woodhull reviewed the etiological power of subsoil and stagnant waters with some detail, and placed some stress upon the probable responsibility of drinking-waters in causing the disease. Dr. Smart coincided with more emphasis in the latter view, and gave some facts in support of the theory. He advised filtration of suspected waters.

EVENING SESSION.

The evening session was devoted to addresses of courtesy, His Excellency, GOVERNOR BEGOLE, of Michigan, welcoming the Association in a remarkably fitting and graceful address, in which he remarked in effect, that so significant and gratifying was the sight of doctors endeavoring to prevent disease, by ministering to which they had their living, that he now only looked forward to a convention of lawyers, intent on preventing litigation, to be prepared to say, like Simeon of old, "Lord, now lettest thou thy servant depart in peace."

DR. WM. BRODIE, of Detroit, was introduced in behalf of that city in the absence of His Honor Mayor Thompson, and made a characteristic speech of welcome. Dr. John Avery, President of the State Board of Health, followed with an address of welcome on the part of the sanitarians of the State, which was graceful and strong.

The President of the Association, DR. EZRA M. HUNT, of Trenton, N. J., then delivered

THE PRESIDENT'S ANNUAL ADDRESS,

which opened with a brief reference to the birth and early work of the Association, followed out graphically the lines of sanitary thought running through the years since its organization, and considered at length the needs and reforms in the sanitary world. The illiberal action of Congress in vital sanitary matters was aptly characterized, and the address, which was replete with historical reference, strong statements of scientific truth, and the analysis of the character of sanitary work, was conceived and delivered in a high and elevating plane of thought.

At the close of the address, the Association adjourned till Wednesday morning.

Immediately upon adjournment, the members proceeded to the Russell House, by invitation of the Local Committee, where a citizens' reception had been arranged. An hour of social converse, followed by an elegant banquet, formed a pleasant feature of the meeting, and was a most enjoyable phase of the hospitality extended.

WEDNESDAY, NOVEMBER 14TH, SECOND DAY.

MORNING SESSION.

After the morning hour, the subject of malaria was resumed. DR. R. D. WEBB, of Alabama, presented a paper, which was read in his absence by Dr. English, of New Jersey, on

CHANGES OF TYPE IN MALARIAL FEVER

in Sumter County, Alabama, from 1833 to 1883.

As its title indicates, it was a synopsis of the clinical observation of fifty years in one locality, and as such was entitled to and received careful attention, and is one of those contributions to the volume of recorded facts from which in time careful analysis will deduce new knowledge.

The Secretary read a series of carefully formulated interrogations on malaria, put by Dr. J. W. Penn, of Tennessee, to answer which would be to settle all the questions involved in its study.

A paper on

THE CLINICAL THERMOMETER IN THE PREVENTION OF MALARIAL DISEASE,

by DR. THOMAS F. WOOD, Secretary of the State Board of Health, of North Carolina, was read by synopsis by the Secretary.

Dr. Wood holds, as the result of his observation, that there is special liability to attacks of malaria on the part of sailors upon vessels lying in the rivers and streams of his State, and that the use of the thermometer, as indicating by the temperature with great certainty the approach of the attack, gives the hint for prophylactic treatment. The evidence was well arranged and of weight.

COL. GEORGE E. WARING, Secretary of the National Board of Health, opened the discussion upon the papers on

MALARIA

by an allusion to the malarial condition prevailing at Washington, and his disbelief that the Potomac marshes causes it.

He was followed briefly by Dr. Gustavus Devron, of Louisiana, who believed that drying up swamp-water set free malarial germs; by Dr. O. W. Wright, Health Officer of Detroit, who thoroughly believed in perfect drainage as the preventive of malaria; by Dr. G. E. Ranny, of Michigan, who expressed his disbelief in the existence of typho-malarial fever and in the contagiousness of typhoid; by Drs. Wm. Oldright, of Ontario, and Trescott, of South Carolina; by Dr. George M. Sternberg, U. S. A., in remarks intended to supply an omission in his paper; by Dr. M. Formento, of Louisiana; Dr. E. L. Griffin, of Illinois; Prof. V. C. Vaughan, of Michigan, and Dr. P. H. Bryce, of Ontario, the latter of whom advocated the soil germ theory.

Dr. W. K. Newton, of Paterson, N. J., presented a paper on *Food Supply*, but did not complete it before the noon recess was taken.

Afternoon Session, Wednesday.

Dr. Newton, of New Jersey, continued the reading of his paper, which was a long and careful compilation of much that is known as to the adulteration of food, and a review of the sanitary and legal bearings of the processes and their results.

In the absence of one of the readers, Dr. Albert L. Gihon, Medical Director U. S. Navy, followed with a paper on

VITAL STATISTICS AS SANITARY MONITORS,

suggesting certain changes in the registration of statistics, so that better information should be had as to the prevalence of disease, instead of deaths, and of the causes attached.

The subject of the

ADULTERATION OF FOODS

was resumed by a paper on that subject by Prof. A. R. Leeds, of New Jersey, read by Prof. R. C. Kedzie, of Michigan.

The paper and its subject in general were discussed by Profs. V. C. Vaughan, R. C. Kedzie, and T. P. Wilson, of Michigan.

A synopsis of the paper on the *Yellow Fever Epidemic of 1884, in Pensacola, Fla.*, by Dr. R. B. S. Hargis, was read by Dr. Devine, of Louisiana.

A paper on

SCHOOL HYGIENE,

was presented by Dr. Chas. J. Lumly, of Detroit. The paper dealt pleasantly and well with several of the well-recognized forms of error in modern school hygiene, notably the over-length of time required for study per day, the want of ventilation and proper lighting, the too greatly exalted temperature, the enforced stooping posture at the desk, the myopic tendency, the want of physical training, the errors of cross-lights, etc.

Discussion upon the paper was opened by Dr. A. N. Bell, of New York city, special reference being made to the want of closet accommodations. Drs. U. K. Jones, of Massachusetts, J. F. Noyes, Prof. T. P. Wilson, of Michigan, and Dr. A. L. Gihon, U. S. N., participated briefly in the discussion; Drs. Jones, Noyes, and Wilson urging shorter hours, and Dr. Gihon condemning the attention demanded to mental arithmetic.

A recess was taken till 7.30 o'clock.

Evening Session.

The evening session, without being assigned to Physical Culture, opened with a paper of rare excellence by Prof. J. Madison Watson, of New Jersey, on

PHYSICAL TRAINING,

and this was followed by a masterly essay on *Physical Culture*, by Prof. D. A. Sargent, of Massachusetts. The burden of both papers was the necessity of laying broadly and well the bodily basis for the mental superstructure, and then of constantly caring for and strengthening it, as mental processes made larger drafts.

Both papers were considered of a very high type, and were ably supplemented by that of Dr. James E. Reeve, Secretary of the State Board of Health, of West Virginia, on *The Eminent Domain of Sanitary Science and the Usefulness of State Boards of Health in Guarding the Public Welfare.*

Dr. Reeve's paper was a scholarly and able inquiry into the relations of the people to the State, the close inter-relation of all parts of the community, and a clear exposition of the necessity of holding State and citizens to a greater responsibility for good health.

Thursday, November 15th, Third Day.
Morning Session.

The greater part of the morning session of Thursday, was devoted to business of the Association.

The Secretary reported from

THE EXECUTIVE COMMITTEE,

with favorable recommendation, several communications received from the Advisory Council. The first was a long preamble and resolutions reciting the importance of governmental stimulus to scientific investigation into the causes and prevention of disease, and in the name of the Association calling upon Congress to appropriate $25,000 for this purpose, to be expended under the direction of the National Board of Health. The second invoked the consideration of Congress in aid of the National Board. The third was a complimentary expression to Surgeon-General Philip S. Wales, of the Navy, for his interest in and aid of the cause of sanitary science by his efforts in behalf of the National Museum of Hygiene. The fourth was in the shape of preamble and resolutions in aid of the Army Medical Library and Museum, asking appropriations from Congress for both, and for the erection of a suitable building for their safe-keeping. With a few emendations all were adopted, as was the recommendation of the Advisory Council that St. Louis be the place of meeting next year.

Under the call for the reports of committees, Dr. Henry P. Wolcott, of Massachusetts, Chairman of the Standing Committee on

NATIONAL MUSEUM OF HYGIENE,

submitted the report of that committee, detailing the present very satisfactory condition of that institution, and the hope of the Surgeon-General of the Navy soon to avail himself of much larger accommodations, which will before long be required.

AN INVITATION.

Dr. Wm. Oldright, President of the Provincial Board of Health of Ontario, Canada, invited the members of the Association to attend the meeting of the Canadian Sanitary Association, to meet at London on Monday the 19th inst.

Dr. Samuel W. Abbott, Health Officer of Massachusetts, in behalf of the Committee on

COMPULSORY VACCINATION,

submitted a report from that committee. It combated the idea of any prevalence of transmission of disease by vaccine virus, and strongly upheld the practice of general vaccination.

ELECTION OF OFFICERS.

The nominations of the Advisory Council, acting as a nominating committee, were then reported, and by vote the Secretary was directed to cast one ballot for the several officers named, who were then declared elected, as follows:

President.—Dr. Albert L. Gihon, Medical Director, U. S. Navy.

First Vice-President.—Dr. James E. Reeve, Secretary of the State Board of Health, of West Virginia.

Second Vice-President.—Hon. Erastus Brooks, of New York.

Secretary.—Dr. Irving A. Watson, of Concord, N. H.

Treasurer.—Dr. J. Berrien Lindsley, of Nashville, Tenn.

Executive Committee.—Dr. Thomas L. Neal, Dayton, O.; Dr. J. D. Gatch, Lawrenceburg, Ind.; Dr. Henry P. Walcott, Cambridge, Mass.; Dr. Gustavus Devron, New Orleans, La.; Dr. Charles Smart, U. S. Army; Dr. Henry D. Fraser, Charleston, S. C.

A very elaborate paper accompanied by large diagrams, etc., on *The Removal of Decomposable Material from Households*, by Rudolph Hering, C. E., of New York City, was read by Prof. Kedzie, in the absence of the author. It was replete with valuable information for builders and householders, and will form a valuable contribution to the literature of sanitary construction.

Dr. William Oldright, of Ontario, Can., read a paper on *Overhead Ventilation of Sewers*. The paper contained practical suggestions for removing safely the sewer-gas from the old combined form of sewers, which the writer illustrated in part by model.

The Association here took a recess until 3 P. M.

Afternoon Session.

The following gentlemen were appointed as *delegates to the International Medical and Sanitary Congresses, at Copenhagen and the Hague, in 1884:* Prof. R. C. Kedzie, Michigan; Dr. O. W. Wight, Michigan; Dr. Stephen Smith, New York; Dr. Azel Ames, Jr., Massachusetts; Drs. W. K. Newton and E. M. Hunt, New Jersey; Dr. J. T. Linn, Indiana; and Geo. E. Waring, Washington, D. C.

A paper on

THE SANITARY CARE OF HOUSEHOLDS,

by Dr. Joseph H. Raymond, Health Commissioner of Brooklyn, N. Y., was read by Dr. A. N. Bell. The paper contained nothing new, and Col. Waring's criticism that the toleration it permitted of the pan-closet, even though occasionally burned off and varnished, was an error, was evidently approved by many. The subject-matter of the paper was discussed by Col. Waring; Dr. A. N. Bell, of New York; Col. D. P. Haddin, of Tennessee; Dr. Wm. Brodie, of Detroit; Dr. O. W. Wight, of Detroit; Dr. Gustavus Devron, of Louisiana; and the Secretary, Dr. Ames, of Massachusetts. The latter in reply to Col. Waring's advocacy of the separate system, and so the avoidance of sewer-gas in all places, showed the impossibility in many old cities having an expensive combined system and large indebtedness to build new systems; and contended that by proper effort freedom from harm even under such conditions was available.

A paper on *The Drainage of Level Lands, etc.*, by Prof. W. C. Van Bibber, of Maryland, was read by title; and one on *Dangers of Fecal Matters Disseminating Disease*, by Dr. W. S. Rosa, of Kentucky, was summarized.

A very able and exceedingly interesting account of

PULLMAN, FROM A SANITARY POINT OF VIEW,

by Dr. Oscar C. De Wolf, Health Commissioner of Chicago, Ill., was read by Mr. John K. Allen, of Chicago. The water, fire, drainage, sewage, irrigation, etc., systems of the place were given in detail, and created a genuine desire for more intimate knowledge of the town on the part of many. If what has been done here can, as appears, be made a success, it is to be hoped that it may prove but the forerunner of many model industrial communities which, with a basis of pure air, pure water, and pure soil, shall permit conditions of life now generally unobtainable by the working classes.

A paper on *Modern Sanitation*, by Dr. L. H. Montgomery, of Chicago, Ill., was read by title.

Dr. Edward H. Janes, Assistant Sanitary Superintendent of New York City, presented a paper on *Typhus Fever in New York City*, which, for want of time, was read by title, and referred to the Publication Committee.

A paper on *Catarrhus Baltimoriensis*, by Dr. John Morris, of Baltimore, Md., was summarized by Dr. Rohé of that city.

Dr. J. N. McCormack, of Kentucky, read a very brief paper on *The Restriction of Smallpox*.

The Secretary read by title a paper on *Preventible Contagious Diseases*, by Dr. David Ferguson, of Detroit.

Dr. Forment, of Louisiana, suggested cremation as a subject for discussion for the next annual meeting.

The Association took a recess until 7.30

The Evening Session

was opened by an able address by Right Rev. Hugh Miller Thompson, D.D., Assistant Bishop of Mississippi, on

SANE HUMANITY.

The address dealt vigorously with the moral features of sanitary duty, and that of man to his Creator to make the best of himself, and was a strong presentation of the obligation of the State and the individual.

Dr. Foster Pratt, of Kalamazoo, Mich., presented, as the closing paper of the meeting, an almost startling review of

INCREASED INSANITY IN THE UNITED STATES, ITS CAUSES AND SOURCES.

The paper, whose facts and figures were drawn from the last census returns, gave a most interesting and significant showing of the great increase of insantity in this country, and placed its source and cause largely to foreign immigration, much of it alleged to be of deliberate intent to fasten upon this country the burden of support of the imbeciles. In view of the fact that at the coming session of Congress the census returns will come up for much consideration, Dr. Pratt's forcible presentation of the subject is timely, and will not fail to attract attention. The paper, though very long, secured close attention.

At its close, Prof. Kedzie, of Michigan, offered a preamble and resolutions calling for Congressional action to prevent the

IMMIGRATION OF IMPROPER PERSONS, ETC.

The rules were suspended to allow immediate consideration of the resolutions. A spirited debate followed, participated in by Drs. Wright, of Michigan; Devron, of Louisiana; Walcott, of Massachusetts; the Secretary, and Dr. Gihon, of the Navy.

After some filibustering motions, the preamble, which was thought to state too strongly the degree of trouble arising from immigration, was amended, and then, together with the resolutions, was carried by a very large majority. The force of the resolutions is simply to call on Congress to take some suitable steps to put a stop to the immigration of persons, whether paupers, criminals, or imbeciles, who are almost sure to be added to the troublesome roll soon after, or upon their arrival. There seemed to be a gaining feeling that the consular service should be so enlarged in its force and scope, that insight of this condition might be placed in its charge.

An omnibus resolution of thanks to those by whose services the Association had been benefited was passed unanimously on motion of Dr. Reeve, of West Virginia.

A resolution of thanks for efficient services was given on motion of Dr. Gihon, of the Navy, to Dr.

Ames, the retiring Secretary, who, at the end of his three years' term, declined reëlection.

The retiring President then introduced his successor, Dr. Albert L. Gihon, U. S. N., who, in a few felicitous words, assumed the duties of the office.

The Association then adjourned to meet at St. Louis, Mo., at such date as the Executive Committee shall determine.

CORRESPONDENCE.

AN ANSWER TO "A PROTEST AGAINST THE USE OF THE METRIC SYSTEM IN PRESCRIBING."

To the Editor of THE MEDICAL NEWS.

SIR: In your issue of November 3d inst. appears a letter from Dr. James Orr, of Texas, under the above heading. I do not desire to provoke a controversy, but, as an advocate of the "metric system," I cannot let this statement go unanswered.

Your correspondent is peculiarly unfortunate in the three points which he submits as arguments against the new system, for in each one of them he is in error, and in each one of them is the converse of his conclusion true. He says: "1. In calculating the given quantity of a drug desired in a prescription, it can be done quicker by our or the English weights—grs., ʒ, ℥, etc."

This is true certainly of a physician who knows doses only in the old system. But if he knows the doses in the metric system equally as well as in the old—which is the proper standard of comparison—the metric system is infinitely the easier and quicker method of calculating quantities. Let us take an example. The dose of *morphia* is one centigram (0.01); the dose of *chloral hydrate* is one gram (1.00). We wish to write a prescription which shall contain six doses, of a tablespoonful each. Six tablespoonfuls make one hundred grams. We have

	Grams.	Decimals.	Old System.
℞.—Morphiæ Sulph. . .	0	06	gr. i.
Hydrat. Chloral. . .	6		℈ivss.
Syr. Aur. Cort. . .	25		ʒiv.
Aquæ, ... *ad*	100		℥iij.

What can be simpler than this? There is but one unit, the gram and its decimal parts, written in plain Arabic numerals. It is equally easy to write the same or any other prescription for any number of doses, the only thing requisite being a knowledge of the dose in *metric* terms. Of the difficulty encountered when one does not know the dose in metric terms, but must laboriously translate it from the incongruous weights and measures of the old system, I have nothing to say.

The same ℞. in the old system is given alongside the metric ℞. Who that is unprejudiced can say that it is simpler? There are four different units—grains, scruples, drachms, and ounces—related to each other by different and arbitrary ratios.

Three of them, scruples (℈), drachms (ʒ), and ounces (℥), are represented by arbitrary and unmeaning hieroglyphics, and the quantities are expressed in the awkward Roman numerals, instead of the Arabic numerals in common use. Another point which illustrates the superiority of the metric over apothecaries' weights in calculating quantities, is the use of percentages.

In making lotions, collyria, etc., we speak of so much per cent. strength; as a five per cent. solution of carbolic acid for a dressing to a wound.

What is simpler than writing

℞.—Acidi carbolici, ...	5 grams.
Aquæ, ...	100 " —M.

Use as lotion.

Calculate a five per cent. solution in grains and ounces, and see how great is the difference in simplicity and trouble. With just as great ease can *any* percentage be written for.

2. The second point of Dr. Orr is, that there is greater liability to error in the metric prescription than in the old form. If he compares a physician familiar with the old system, writing in the old way, with one who is also familiar with the old, but does not know the new—writing in the metric terms—he is probably right. But such a comparison is unfair. If we compare physicians equally familiar with the system in which they write, the advantage is altogether in favor of the metric.

In the latter there is but one unit; the quantities are written in plain figures and the aggregate shows the proportionate quantity of each. In the former there are as many units as are found in the tables of apothecaries' weights and measures; they are expressed by arbitrary hieroglyphics; quantities are in Roman numerals, and the aggregate does not show the proportion.

How often does it happen that a physician looking over a prescription he has written, finds he has written the drachm mark where he meant scruple, or *vice versâ*.

How is the pharmacist to know which is meant? To be sure it is careless writing, but it occurs continually, as the pharmacist's ℞ files will testifiy. Such a blunder cannot be made in the new system. As to the danger of misplacing the decimal, this is obviated by the use of the decimal line; then if a mistake is made, we have no apology to offer. It is just as reasonable to expect the merchant in his ledger, to charge his customer ten cents a yard for silk, instead of ten dollars, by putting it in the wrong column.

In fact, the decimal system applied to medicine is identical with our cental currency applied to money. It needs no argument to prove that our present money system is preferable to the old-fashioned "fips" (6¼ cents), "levies" (12½ cents), "picayunes," and "York shillings," or that it is far superior to the English system of £, shillings, pence, and farthings. Yet exactly the same differences hold in medicine between the new, or metric system, and the old, or apothecaries' weights and measures. I think, however, no one among us, not even the "oldest inhabitant," would be willing to exchange our dollars, dimes, and cents for the British coinage, or even return to the good old times of Colonial coinage.

The third point of Dr. Orr is that "It takes less time and space to write the old method." The only answer we need make to this statement is, that the difference in point of space between the old and the new is that in the former the value of each quantity, as gr. ℈, ʒ, or ℥, must be written with the amount, whereas, in the latter, there is but one unit, and only the quantities are given. This would make it appear that the "old method" takes *more* space than the new.

In the specimen of prescription given, a very poorly written metric prescription is chosen. I repeat it here in order to show how such a prescription should have been written, and then leave it to the impartial reader to judge whether it is so complicated or difficult to understand. The prescription Dr. Orr gives is as follows:

"℞.—Morph. Muriat., . . .	.0060.
Tinct. Cannab. Ind., . . .	.0800.
Chloroformi, ...	.1350.
Ol. Menth. Pip., ...	.0025.
Tinct. Capsici, ...	.0025.
Acid. Hydrocyanici Dil., . .	.0170.
Alcohol, ...	.3000.
Glycerinæ, ...	.4570.—M."

No dose is stated, but from the amounts I should suppose this to be intended for one dose. I cannot imagine who could have written such a prescription, and I do not wonder at any physician finding fault with it. It certainly violates every rule of correct prescribing, and must, I think, have been (in the journal from which copied) a clumsy attempt to translate grains and parts of grains into metric terms.

The observance of a few simple rules are a wonderful help to correct and easy prescribing:

1. The ingredients should be placed in the order of their strength and importance. If the mixture contains both solids and liquids, place the solids first in this order, and then the liquids, in like order.
2. Write down first all the ingredients intended to be ordered.
3. Determine the number of doses to be given in the prescription, and make the quantities to correspond.
4. If a liquid is ordered, let the vehicle be named last, and by placing after it the term "*ad*," or "*ad q.s.*," let it show how much the entire prescription calls for. In this way there is no necessity of adding up the amounts to see how much they make.

Now for this objectionable R—under these rules. We write down the ingredients in proper order, and determine to make twelve doses, of a dessertspoonful each.

This R is supposed to be an anodyne, for internal administration. The doses in the above copy of some of the ingredients are decidedly homœopathic. We shall give the usual doses, as follows:

R.—Morphiæ Sulph. (dose, 0.01), . .	0	12
Ol. Menth. Pip. (dose, 0.05), . .	0	60
Ac. Hydrocyan. Dil. (dose, 0.10), .	1	20
Chloroformi (dose, 0.30), . . .	3	60
Tr. Cannab. Ind. (dose, 2.00), . .	24	
Tr. Capsici (dose, 2.00), . . .	24	
Glycerinæ (dose, 2.00), . . .	24	
Alcohol, ... ad,	100	00

M. S. Dessertspoonful every 4 hours in water, until relieved.

It is not very often, I believe, that a physician writes as complex a prescription as this one, but when he does, he needs the metric system. A comparison between this and the example given in the paper criticised, will show the difference between a properly and an improperly written metric prescription.

[Obverse.]

METRIC PRESCRIPTION. Grams. Decimal.

R

[Reverse.]

METRIC SYSTEM IN MEDICINE.

Old Style.	Grams.	Decimal.
1 grain or 1 minim equals............	0	06
15 grains or 15 minims equal.........	1	00
1 dram or 1 fluidram equals	4	00
1 ounce or 1 fluidounce equals......	32	00

The Cubic Centimeter (C. C.) may be considered identical with the gram for water or aqueous solutions.

Liquids lighter or heavier than water should either be weighed or a proper allowance be made.

Being a pioneer in the metric line in my own city some four years ago, I anticipated trouble from the pharmacists in connection with my prescriptions. But few of them were familiar with the system, and at first there was some grumbling; but when they learned how simple it is, and obtained the weights and measures, there was no more trouble. Now I do not believe there is a pharmacist in the District of Columbia but prides himself on being able to compound "metric prescriptions." I enclose the form of prescription blank which I have always used. The reverse contains brief but ample directions for converting the metric terms into apothecaries' weights, for the benefit of such druggists who may not have metric weights.

This letter is in a measure an advocacy of the metric system, but space does not allow of any extended argument to prove its superiority. I will, therefore, close by stating briefly some of the reasons for its adoption generally:

1. Its simplicity—

   One unit of length = the *meter*.
   One unit of capacity = the *liter*.
   One unit of weight = the *gram*.
   One unit of cubic measure = the *ster*.
   One unit of sq. measure = the *are*.

   The divisions and multiples of these units are by tens. At present there are over seventy arbitrary units in use in the United States.
2. Its substitution for our present system of weights and measures would save an immense amount of time and labor in all forms of business. *It would save one year of school life for every child.* In Appleton's *Cyclopædia*, under article weights and measures of the United States, over seventy units are given as in use, and they are utterly independent of any systematic relation to each other. Think of having to multiply by 1728 to find how many cubic inches are in 1883 cubic feet! Yet this is but one item of but one of the miserable tables that all our school children are obliged to memorize. And not that only, but these heterogeneous tables must be applied to all the examples in arithmetic to be worked out during all the years the unfortunate juvenile is at school.
3. The metric system is the cosmopolitan system. It is legalized by twenty-three nations of the civilized world, and is in exclusive use in thirteen nations. It is legalized in the United States by special Act of Congress passed in 1866. The English foot is only in use in Great Britain, Russia, and the United States.
4. It is used by scientists in all countries.
5. It is used exclusively by the U. S. Coast Survey, the U. S. Marine Hospital Service, and the U. S. Navy. Also by a large number of physicians, especially in the north and northwestern sections of our country.

Other arguments might easily be adduced, but as this is not intended to be an exhaustive article, I rest here.

Objections to introduction of the metric system in the United States.

1. It revolutionizes existing weights and measures.
2. It is difficult, I might say well-nigh impossible for established physicians to forget the old system.

As to the first of these, each person must weigh the arguments *pro* and *con* and decide for himself. In my opinion, the "game is worth the candle."

As to the second objection, older physicians should not be expected to make the change, unless, indeed, they be teachers. But all students should be taught, and should learn the new system exclusively.

In this way a revolution may be accomplished without doing violence to any one's principles.

NEWS ITEMS.

BERLIN.

(*From our Special Correspondent.*)

The Cholera Commission.—Fortunately the good wishes which accompanied the Cholera Commission have been, to a great extent, fulfilled earlier than could have been anticipated.

Dr. Koch's first report, sent to the Secretary of State for the Home Department, gives an account of the excellent results obtained in a few weeks. The negative statement, that infectious germs were absent in the blood and in the large glandular organs of ten individuals who died from genuine cholera, would be alone of the greatest importance. A still greater step is the discovery of a certain species of rod-shaped organisms, unexceptionally present in the intestinal walls of the same individuals; and the fact that this species—which does not exist in other infectious diseases—is apparently quite the same as that which was found by Koch in cholera intestines sent to him from India last year, makes it but little doubtful that the bacilli in question are specific to cholera. Only the last link of the chain is still wanting, since it has not yet been possible to reproduce the disease by inoculation. The intended expedition to India, where the cholera is still prevalent, will show if Koch was right in assuming that the failure of his inoculation experiments was only due to a certain immunity generally gained by man and animals at the end of an epidemic.

The short additional remarks concerning researches made on bilious typhoid, dysentery, and Egyptian eye disease, open a fair perspective for the successful activity of our Commission.

The Wilms Memorial.—A colossal bust of the late Dr. Robert Wilms was erected October 30th, on the place opposite to the large hospital, at the Protestant Sisterhood, called Bethanieu, where the deceased had worked as a chief-surgeon since his twenty-eighth year.

Museum of Hygiene.—The hygienic exhibition has come to a close at the proposed term. The committee has resolved to retain the most instructive objects, with the permission of the exhibitors; this collection is intended to constitute the basis of a museum of hygiene similar to the Parkes's Museum in London.

Yellow Fever at Havana.—Sanitary Inspector Burgess in his abstract of Bills of Health issued to vessels bound to the United States from Havana, reports as follows: November 6, inspected and disinfected Spanish brig "Nuevitas" bound to Charleston, S. C., she has been 100 days in port at Havana, 20 of them at an infected wharf; Spanish bark "Habana" for New Orleans, 37 days in port, 29 of them at an infected wharf, has had one yellow fever case on shore and another on board just shipped—vessel disinfected before leaving; Spanish brig "Eugenia" for New Orleans, 50 days in port, 30 at an infected wharf, shipped a new crew, vessel was disinfected; Nov. 7—Spanish bark "D. Petronila" for New Orleans, 40 days in port, 20 at an infected wharf, suspicious fever occurred on board while in port, vessel disinfected; Nov. 8—Am. stmr. "Saratoga" for New York, and Am. stmr. "Morgan" for New Orleans, both healthy; Am. schr. "L. A. Edwards" for Pensacola, with a suspicious case of fever, supposed to be yellow fever, she was 20 days in port, 13 at an infected wharf where a suspicious case was sent to hospital. Nov. 9—Spanish bark "Trinidad" for Pensacola, 40 days in port, 20 at suspicious wharf, had suspicious sickness on board, was disinfected; Am. bark "Alice" for New York, 29 days in port, 12 at suspicious wharf, had five cases of yellow fever on board while at wharf, was disinfected; British stmr. "Texas" for New Orleans, healthy except several children with measles. Nov. 10—Am. stmr. "City of Merida" for New York, healthy; Am. schr. "W. Blackford" for Key West, 8 days in port, 4 at suspicious wharf.

There were 19 deaths from yellow fever for the week ending November 10th.

The Quarantine Fleet of four barges and a steamboat which has been anchored in the Mississippi River for two or three years past (late the property of the National Board of Health), was advertised and sold at New Orleans last week, by direction of the Secretary of the Treasury.

Why a Doctor's License was Revoked.—Dr. "Frank" B. Smith has begun a suit for $50,000 against Dr. John H. Rauch, Secretary of the Illinois Board of Health, whose name, he declares, was signed to a circular revoking his (Dr. Smith's) license for alleged unprofessional conduct. This conduct, the plaintiff says, consisted in his advertising his presence when he was a delegate to a health convention at Peoria.

Health in Michigan.—Reports to the State Board of Health, for the week ending November 10, 1883, indicate that measles, bronchitis, diarrhœa, tonsillitis, dysentery, puerperal fever, and diphtheria, have increased in area of prevalence.

Including reports by regular observers and others, diphtheria was reported present during the week ending November 10, and since, at nineteen places; scarlet fever at thirty-two places; and measles at nine places.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM NOVEMBER 12 TO NOVEMBER 19, 1883.

Bache, Dallas, *Major and Surgeon.*—Ordered to report in person to the Commanding General, Department of the East, for assignment to duty.—*Par. 10, S. O. 259, A. G. O.*, November 12, 1883.

Appel, D. M., *Captain and Assistant Surgeon.*—Granted two months' leave of absence.—*S. O. 68, Division of the Atlantic*, November 16, 1883.

Gardiner, J. de B. W., *Captain and Assistant Surgeon.*—Relieved from duty at Fort Huachuca, and assigned to duty as Post Surgeon at Fort Bowie, A. T.—*Par. 1, S. O. 104, Department of Arizona*, November 8, 1883.

Cochran, J. J., *First Lieutenant and Assistant Surgeon.*—Assigned to duty at Fort Bayard, N. M.—*Par. 5, S. O. 236, Department of the Missouri*, November 15, 1883.

Egan, Peter R., *First Lieutenant and Assistant Surgeon.*—Upon being relieved from duty at Fort Bowie, A. T., to proceed without delay to Fort Huachuca and report to the Commanding Officer at that post for duty.—*Par. 1, S. O. 104, Department of Arizona*, November 8, 1883.

Wilson, George F., *First Lieutenant and Assistant Surgeon.*—To report in person to Lieutenant Schwatka, Third Cavalry, Aid-de-camp, for temporary duty in connection with the completion of report of recent expedition to Alaska.—*Par. 3, S. O. 156, Department of the Columbia*, November 9, 1883.

ORIGINAL LECTURES.

CHRONIC LEAD-POISONING.

A Clinical Lecture delivered at the Philadelphia Hospital, September 19, 1883.

BY JAMES TYSON, M.D.,

PROFESSOR OF GENERAL PATHOLOGY AND MORBID ANATOMY IN THE UNIVERSITY OF PENNSYLVANIA; ONE OF THE PHYSICIANS TO THE HOSPITAL, ETC.

GENTLEMEN: The patient whom I show you to-day presents, on superficial examination, nothing unusual in his appearance except anæmia, which is, however, less marked than it has been. This symptom is a part of the condition of which he is suffering, but the following history prepared by the resident physician, Dr. Culpepper, describes some more striking symptoms due to the same cause:

M. B., laborer, admitted August 3, 1883. He is 35 years old, born in Ireland; father died of phthisis; other family history good. He denies having had venereal disease, but is somewhat intemperate. He began to work in a white-lead works in April a year ago, and after two months was seized with abdominal cramps, and had to give up work. He recovered in two weeks, and then worked in a coal yard until May of the present year, when he again returned to the lead-works. One month later he was again seized with cramps, but persisted at his work until about a month before his admission to the house, when he was again compelled to give up. During this month he suffered from cramps in his fingers, toes, and abdomen, noticed that his legs and feet were swollen, and heard from his friends that he had had five epileptoid fits, although he has had none since his admission. He also noted an inability to straighten his wrists and fingers.

When admitted, he was suffering from abdominal colic, particularly on the left side, together with great and obstinate constipation. He had also a blue line on his gums. He was first treated with sulphuric acid, and afterwards with iodide of potassium in small doses. He has improved considerably, but still suffers from intermittent colicky pains, although his bowels appear to be tolerably regular.

It is scarcely necessary to say that our patient is a victim to lead-poisoning, but let us discuss the symptoms on which we base our diagnosis, and, if necessary, complete the picture of the disease by pointing out others which belong to it, but are not here present.

First, the *anæmia*, which, as stated, is less marked than it has been. This symptom is a very constant one in lead-poisoning, and its higher degrees are attended by a sallowness which early gave rise to the term *icterus saturninus*; but it must be remembered that this is not caused by bile pigment. In more serious cases, too, the impaired nutrition results in an emaciation which is sometimes extreme. Along with the anæmia are frequently noted a sweetish taste, with fetid breath, and loss of appetite.

The next symptom, which has been most striking in this case, and from which alone, in connection with the history of exposure, one may often diagnosticate lead-poisoning, is *colic*. Indeed this symptom, with the next to be considered, constipation, is often the sole manifestation of the disease, so that the term lead-colic has come to be recognized in medical terminology. It will be noted that in this case the colic was worse in the left side. It is more frequent in the region of the umbilicus, and is often relieved by pressure. It varies greatly in degree, being sometimes a simple, grumbling pain, at others of frightful severity, the patient writhing in the paroxysm, which, as a rule, does not last long, but is soon followed by another; but it may continue for hours or until relief is afforded by treatment. It is probably due to powerful contractions of the muscular wall of the intestine, by which the nerve-filaments distributed through it are compressed. Unlike flatulent colic the abdomen is not distended, but flat, and may even be retracted, sometimes so much so that it is said that the vertebræ may even be discerned through the abdominal walls. Still, distention of the abdomen is occasionally present. The pulse during the attacks of colic is often strikingly slowed, having been noted as slow as thirty per minute.

Constipation has been alluded to. It is very common, even more constantly present than the colic. And yet it is not invariable, and may even be substituted by diarrhœa.

It will be remembered that our patient suffered also with *cramps* in his fingers and toes, as well as with colic. This is a well-recognized symptom of lead-poisoning. Nor are these cramps confined to the fingers and toes. Groups of muscles anywhere, and especially flexor muscles, as of the arms and legs (the latter most frequently), become involved. In addition to these painful cramps, which, like the colic, are intermittent, there are pains in the neighborhood of the joints. The sum of these painful joints and muscles has received the name *arthralgia saturnina*. They are quite frequent, occurring, according to the statistics of Tanquerel, in 755 out of 2151 cases.

Our patient's history also contains a note of swelling of the legs. *Œdema* is a condition sometimes met with in lead-poisoning, but usually in the more advanced stages of the cachexia. It is impossible in this instance to decide whether the swelling was that of œdema or not.

I have called your attention to the *blue line* on the patient's gums. It is a very characteristic symptom, and appears at the border of contact of the gums with the teeth, or just above it. As a rule, it is easily recognized when present. It is caused by the presence of sulphuret of lead, produced by the action of sulphuretted hydrogen upon the lead in the tissue of the gums. Hence the line is more common and more distinct on the gums of those who take no care of the mouth, and in whom sulphuretted hydrogen is generated in the decomposition of food. Such has been the case with our patient. This line often remains after all other symptoms have subsided, and although it is not invariably present, its disappearance may be considered a pretty sure sign that the harmfulness of the lead has been suspended.

Another symptom of great importance is *muscular paralysis*. This, in contrast with the muscular cramp, is more likely to involve extensor muscles than flexors, and especially those of the wrist, giving rise to the very characteristic symptom known as "drop-wrist," which, in Tanquerel's experience, occurred in 107 out of 2151 cases. Our patient appears to be free from it now, but there was evidently loss of power at one time in the extensors of the wrists and fingers, shown by the inability to straighten them. This is what would be expected in a case of comparatively short exposure, like the present; for, usually, it is not until the colic and arthralgia present themselves that the wrist-drop appears. On the other hand, it has been the first symptom observed. It may last but a few days, or it may resist all treatment. It may affect a single muscle, or groups of muscles. It is further characterized by the fact that the muscles affected are subject to rapid atrophy, so that they almost seem to disappear; dislocations of the more movable joints, as the shoulders and phalanges, may occur in consequence. While sensibility is but slightly impaired, electro-muscular contractility rapidly disappears. The muscles cease to respond to the faradic current, while the reaction to galvanism is unchanged, or slightly increased at first. Tremor of the paralyzed muscles is often observed.

Another set of symptoms of lead-poisoning, not uncommon, suggested by, if not actually present in, the case before us, are those due to involvement of the central nervous system. You will remember that he had convulsive seizures, which were considered by his friends as epileptic. Nevertheless, I can scarcely conceive that such involvement has taken place; for the symptoms developed by neurotic changes are not so prompt to disappear. Occurring usually only in those who are peculiarly exposed, they come on in from eight days to fifty years, the majority showing themselves, according to Tanquerel, within the first nine months. The most frequent mode of manifestation is in eclampsia, as in the case of our own patient. But there may be headache or amaurosis, apathy, stupor, or the opposite condition of maniacal excitement, or melancholia and hallucinations.

A frequent complication of lead-poisoning, more especially where it has been present for some time, is *interstitial nephritis*, and its resulting morbid product —the contracted kidney, as shown by the presence of a small degree of albuminuria and tube-casts; and as this is the form of kidney disease in which uræmic convulsions are most frequent, it is evident that these must be distinguished from the convulsions just referred to as a part of the saturnine encephalopathy. Hence, an examination of the urine in every case of lead-poisoning should be early made in the study of the case. In this case the urine was examined with negative results.

In consideration of the evident *etiology* of lead-poisoning, we need only pause to enumerate a few of the many ways in which the intoxication may be brought about. That house-painters and workers in white-lead factories are frequent victims to lead-poisoning, goes without saying. That we, in the cities, who receive our immediate water supply through leaden pipes, do not more frequently acquire the disease, is, at first thought, more surprising. But this, too, is easily explained. It is the very impurities of our drinking waters which save us. Almost all drinking-waters contain sulphate of lime, the sulphuric acid of which combines with the superficial layer of lead and forms an insoluble coating of sulphate of lead. Should it happen, however, that water of unusual purity, as rain water, is stored in lead-lined tanks, or even painted tanks, it not rarely happens that families are poisoned thereby. Among the recognized causes is the use of cosmetics and hair-dyes containing lead, and even the use of vegetables canned in tin vessels. A very interesting case of lead-poisoning from this source was published in a recent issue of The Medical News (Sept. 8th), by Dr. Wm. Magruder. All grades of what is known as tin, which is really iron coated with a layer of tin, contain a small quantity of lead; and the more inferior the tin the larger the quantity of lead. Now certain conditions favor the solution of this lead. Thus, if any of the vegetable acids, as acetic, tartaric, or citric, be present, they may dissolve the lead and thus form soluble salts, which are readily absorbed. Of course, such solution is favored by prolonged action of the acids; hence old canned vegetables are more dangerous than those recently canned, and it would be a wise measure to insist that canned fruits and vegetables should be stamped with the date of the canning. The solder used in closing the cans may also be a cause of poisoning from this source; when it is considered, however, how enormous is the consumption of canned fruits and vegetables, and how few the cases of lead-poisoning traceable to it, it is evident that even moderate precautions may suffice to remove the danger altogether.

Among the more rare causes of lead-poisoning mentioned by Naunyn in his article on lead-poisoning, in Ziemssen's *Cyclopedia*, have been the result of cooking in badly glazed crockeryware, drinking beer drawn through lead pipes, or beer and wine from bottles which have been washed with shot, of which some have been left behind, the use of snuff packed in spurious tin-foil containing lead, and from sleeping on mattresses, the hair in which was dyed black by some lead-containing substance; and one, a most incredible case, is that of a proof-reader who was poisoned after many year's reading of printed proof. Notwithstanding the solubility of the acetate of lead so much used in medicine. it is very rare that poisoning has resulted from its administration, and there need be no fear of using it for the purposes to which it is adapted until at least a couple of drachms have been given.

It has always been an interesting question, how lead in the system operated to produce its peculiar effects. That the lead itself lodges in the tissues, is easy of demonstration, and analysts have gone so far as to determine the exact quantity in the different tissues of animals poisoned by lead; which, by the way, is surprisingly small, the largest amount found being a quarter of one per cent. in the bones, while that in the muscles was but .002 to .003 of one per cent. It was formerly the custom to ascribe the phenomena of lead-poisoning partly to the direct action of lead in the tissues; the cramps and the palsy to the presence of lead in the muscular fasciculi; the colic to the lead in the unstriped muscular fibre-cells, and the nervous symptoms to the lead in the nerve-centres. In part, too, these phenomena were ascribed to the anæmia of the tissues due to the contraction of the arterioles induced by the presence of lead in the muscular coat. More recently, however, the soundness of these views has been shaken by some experiments of Heubel, and the tendency appears to be to ascribe the phenomena of lead-poisoning to neuroses which are undoubtedly central in the case of the encephalopathic phenomena, and which are probably central in that of the peripheral symptoms. On this supposition, the phenomena of lead-poisoning have been compared to those of chronic alcoholism, which are ascribed to effects upon the nerve-centres due to the long-continued circulation through them of blood charged with alcohol.

The *morbid anatomy* of lead-poisoning may be quickly disposed of, for, so far as studied, it has none which is essential to it. That is, although we find the paralyzed muscles in a state of fatty metamorphosis, yet this alteration is secondary. If it be true, as is now claimed, that the phenomena of the disease are due to alterations in the central nervous system, the microscope should discover changes which we would expect to be primarily of an interstitial character, but nothing bearing upon this has been reported, so far as I know, until quite recently,[1] when Moies published the results of some experiments upon guinea-pigs, which he dosed with acetate of lead until they died with symptoms of plumbism. On post-mortem examination, in addition to granular and fatty changes in the surface and glandular epithelium of the alimentary canal, infiltration of the adventitia and muscular coats with leucocytes which were undergoing degeneration, hemorrhages, and superficial ulcerations, *scleroses of the ganglia with atrophy of their cells and nerve-fibres* were noted; also overgrowth of the connective tissue of the gastro-intestinal wall, kidneys, liver and *central nervous system*. Here, again, the question arises as to which of these results is primary. Moies is inclined to regard the protoplasmic changes as the first event, and the connective-tissue hyperplasia the result of this, while he considers that the resulting sclerosis causes further atrophy of the active protoplasmic elements, including the muscular fibres.

[1] Virchow's Archiv, xc. p. 455. Dec. 1882, and Centralblatt f. d. med. Wiss , 1883, p. 358. See also abstract in Med. Times and Gaz., Sept. 6, 1883, p. 269.

As to *prognosis*, it depends largely upon the degree of saturation of the system with lead. As a rule, therefore, persons who respond most quickly to the action of the poison are those who most promptly recover, provided, of course, they are removed from the influence of the lead; for such persons, too, being most susceptible, are in great danger from prolonged exposure. We are enabled to infer something of the prognosis from the symptoms which are present. If the attack be ushered in by a colic, and there be no other symptoms except constipation, we may confidently expect our patient to recover completely. If there be arthralgia and palsy, the prospect is less certain; still less so if there be atrophy; and least of all if there be encephalopathia, when complete recovery is hopeless. So, too, I have never known a case of contracted kidney due to lead-poisoning, to pass away. No favorable prognosis should be given where the patient is unable to remove himself from the cause. It must be remembered, too, that relapses occur, often at long intervals, even when the patient is removed from exposure, and that the primary disease has been known to make its appearance a long time after exposure.

Treatment.—Much may be done to guard against the occurrence of lead-poisoning by proper precautions on the part of those exposed to it. Thus, those employed in lead-works may do much to protect themselves, or rather their employers may do it for them. Thus, such persons should keep themselves scrupulously clean by frequent hot baths and frequent changes of clothing, which should never be allowed to become saturated with lead. Mehu recommends that hypochlorite of sodium be added to the hot baths. It is made by mixing in two and a half gallons of water thirteen ounces of chlorinated lime with sodium carbonate. Sulphur baths were recommended by Todd, it being thought that sulphur has the power of neutralizing lead by forming insoluble compounds with it. From two to four ounces of sulphuret of potassium are mixed in from twenty to thirty gallons of water. Above all, the employés in lead-works should not be allowed to eat their meals in the lead-factory, as the metal is often introduced with the food Finally, the ventilation of the factory should be of the best. Experience has shown that much may be done to arrest the dangers of lead-works by such precautions. The same remarks with regard to cleanliness, bathing, and change of clothing, apply to painters, and indeed to all who have to do with lead in any shape or degree. It is evident that lead-lined and painted cisterns should never be used in houses; that cosmetics and hair dyes are dangerous, and that care should be taken in the selection of canned vegetables which may have been too long canned.

The curative measures may be divided into those for the immediate relief of urgent symptoms and the removal of the lead from the system. It is scarcely necessary to say that the patient should be promptly removed from the influence of the lead. The extreme pain of a lead colic requires to be relieved by the hot-bath or poultice, and the opiate, of which the best mode of administration is by the hypodermic syringe, one-quarter or one-third of a grain of sulphate of morphia being required for the purpose. Identical treatment is required for the arthralgia. The accompanying constipation is best relieved by sulphate of magnesium, the sulphuric acid of which, on theoretical grounds, at least, aids in rendering inoperative the lead which has entered the system, by forming an insoluble sulphate.

These more urgent symptoms being relieved, measures directed to the elimination of the lead should be taken. The hot baths already referred to may be used for this purpose, as well as for prophylaxis, and purgatives and diuretics may aid in the elimination. The iodide of potassium is the remedy most relied upon to eliminate the lead from the system. It is believed that after its absorption into the system the lead becomes intimately united with the albumen of the tissues, forming an insoluble compound; that the iodide of potassium, after its absorption, combines with the lead, and forms a soluble iodide of lead, which is dissolved out, reënters the circulation, and is passed out with the urine and feces. It is evident that elimination by these channels will be encouraged by purgatives and diuretics. It is even suggested that acute lead-poisoning may be produced by the liberation of the soluble lead salt into the blood in this way. Hence, caution is suggested in the use of the iodide. Practically, I can scarcely conceive this to occur with such doses as are ordinarily given. Our patient is taking ten grains three times daily, which, after a while, will be reduced to five, but this dose will be kept up indefinitely. Remember that iodide of potassium is more efficient when given fasting and freely diluted.

For the paralyzed muscles, faradaic electricity is indicated, and should be daily administered, both to resist the tendency to atrophy and to overcome it.

That restorative and blood-making remedies, in the shape of nutritious, easily assimilable food and iron, should also be given to antagonize the cachexia which is always a part of plumbism, is evident. In view of the nervous lesions which may be at the bottom of the phenomena, we should expect strychnia to be a valuable adjunct to our treatment, and it is generally so considered. It should be given in full doses, $\frac{1}{30}$th of a grain three times a day, and increased to a $\frac{1}{20}$th, which should be kept up. Ergot is said to have been useful in increasing the power of the muscles involved in the palsy.

A CASE OF GASTROSTOMY FOR CARCINOMA OF THE ŒSOPHAGUS,

WITH A BRIEF ANALYSIS OF THE RESULTS OF 137 CASES OF A SIMILAR NATURE.

BY SAMUEL W. GROSS, M.D.,
PROFESSOR OF THE PRINCIPLES OF SURGERY AND CLINICAL SURGERY IN THE JEFFERSON MEDICAL COLLEGE OF PHILADELPHIA.

ON the 7th of February, 1882, a shoemaker, 64 years of age, presented himself at the surgical clinic of the Jefferson Medical College Hospital on account of difficulty of deglutition. Five months previously, in swallowing solid food, he first noticed trouble, which rapidly increased, so that at the expiration of four weeks he was able to take only fluid nourishment in the form of milk, soups, and oatmeal gruel. For the past month his sole diet was milk, to which he occasionally added a little whiskey, but only when he felt very weak, on account of the pain which it excited. The amount of milk that he drank during this period averaged about two pints a day. At times it occasioned suffering and a sense of constriction in the chest, and was now and then ejected.

The man was pale, debilitated, emaciated, and weighed only eighty pounds. Exploration with a bougie detected an obstruction, situated at eleven inches and a half from the level of the incisor teeth, through which instruments could not be passed. From the absence of a history pointing to cicatricial stricture, I diagnosticated carcinomatous obstruction of the œsophagus at the point at which it is crossed by the left bronchus. In view of his increasing prostration and the outlook of death from starvation, I explained to him that gastrostomy might prolong his life, but at the same time fully impressed upon him the risks of the procedure. He at once expressed a wish to take the chance offered him, so that he was placed in a ward and his rectum prepared for the reception of nourishment.

With the assistance of my father, Professor S. D. Gross, and Professor Brinton, Dr. Hearn, Dr. Allis, Dr. Packard, and Dr. Nancrede, I did the first step of the operation under chloroform, which was preferred on account of its less liability to provoke vomiting than ether, and with strict antiseptic precautions, on the 9th of February. An incision, two inches and a half long, was made half an inch below and parallel with the eighth and ninth left costal cartilages down to the peritoneum, and bleeding arrested with hot-water and one carbolized pure silk ligature. On incising the peritoneum to the same extent as the outer wound, the stomach at once filled the opening, its omental attachment being fully in view. The centre of the exposed portion having been grasped with tenaculum forceps, two silver wires were then passed, so as to penetrate the muscular coat, at the distance of six lines from each other, their object being to steady the organ during the succeeding steps of the operation and during the puncture to be made in its second stage. Eight silver sutures were next inserted through the entire thickness of the edges of the central portion of the wound and through the muscular wall of the stomach, through which perfect apposition of the peritoneal surfaces was ensured, when the remainder of the incision was closed with ordinary stitches. The usual carbolized gauze dressing was then applied, the operation having required one hour for its completion.

The patient reacted well. On the evening before the operation the pulse was 100, the respiration 24, and the temperature 101°. On the following evening the pulse was 96, the respiration 34, and the temperature 101.2°. The dressings were removed on the second day and reapplied, the condition of the parts being excellent. On my regular visit at 11 A.M., Feb. 13th, I found him to be in a most critical state. The thermograph of the previous evening indicated pulse 115, respiration 30, and temperature 101.2°; and of that morning, pulse 118, respiration 30, and temperature 99.3°. I was informed that at 4 A.M. there was low, muttering delirium, with panting and feeble respiration. Up to the time of my visit, nourishment had been administered with great regularity by the rectum, the articles having been milk, beef juice with pepsin and dilute hydrochloric acid, eggs, and scraped beef and pancreas, which alternated with one another, and to which a little brandy was occasionally added. I now administered brandy and milk by the mouth, and soon afterwards opened the stomach by a small puncture, through which beef juice and brandy were poured through a funnel into the organ. The man, however, continued to sink, and died at 3 P.M., or ninety-nine hours after the operation.

At the post-mortem examination, the attachment of the stomach to the wall of the abdomen was found to be firm. There was no peritonitis. The liver was hobnailed, and the large vessels of the belly and thorax were extensively calcified. The œsophagus was occupied by an ulcerated epithelioma two inches long, the centre of which was crossed by the left bronchus. The post-œsophageal lymphatic glands were carcinomatous, and the ulcer of the neoplasm had extended into the mass of glands, through which the obstruction had assumed a sigmoid configuration. The tube itself was dilated above the seat of the disease.

This is another case of gastrostomy in which the operation was too long delayed. Even if I had seen the patient when the low delirium indicated approaching collapse, I doubt whether the administration of food by the mouth or by the stomach would have been of any avail. In a case of a similar nature, I would not wait so long for the completion of the second step of the operation, but would open the stomach at the end of forty-eight hours, when the adhesions would be sufficiently firm to resist the peristaltic movements of the organ. Indeed, when the case is urgent, rectal alimentation may with propriety be supplemented by feeding by the mouth, provided small quantities of proper food, such as koumiss, be administered, after the expiration of twenty-four hours, since there is sufficient post-mortem evidence of firm adhesion at a far earlier period than one would imagine. Thus, in the case of Berger, the union was solid in nineteen hours; in the cases of Croly and Le Fort in twenty-four hours; and in that of Reeves, in thirty hours. In studying the records of the 64 fatal cases from exhaustion, I am satisfied, when the operation of Howse is practised—an operation in which the stomach is not opened until its fixation is presumed to be firm—that some lives might have been saved by feeding by the mouth or through the stomach sooner than was done. The post-mortem evidence in regard to adhesion in the cases just referred to is, therefore, most valuable for future guidance in this direction. In another class of cases, the operation of Howse is inapplicable; there can be no delay whatever, and the stomach must be opened at one sitting.

As gastrostomy for carcinoma is merely a palliative operation, its designs being to relieve the pangs of hunger and thirst and to prolong life, its statistics merely indicate the chances of survival. Its mortality is by no means inconsiderable, as would naturally be expected when the exhaustion from deficient alimentation and the changes produced in other organs by secondary growths are taken into consideration. I have collected the details of 137 operations, which will be made the subject of a future and more complete paper, of which 31 perished as the result of the procedure—17 from peritonitis, 9 from pleurisy, bronchitis, and pneumonia, 4 from gangrene of the stomach, and 1 from uræmia—the mortality being, therefore, 22.6 per cent. 64 cases died of exhaustion, at varying periods up to the expiration of one month, but of these, 37 succumbed within forty-eight hours, so that shock doubtless was a factor in these examples. If we regard all of the 37 as having been due to shock, 137 operations afford 68 deaths, or a mortality of 50 per cent. Be this as it may, 95 died within a month, and 42 survived longer than a month.

The success of gastrostomy is progressively improving. Up to January 8, 1879, Petit[2] had collected 46 cases, of which 7, or 1 in every 6.57, lived for upwards of a month. Up to the middle of 1883, Alsberg[1] had collated 93 cases, with 29 survivals, or 1 in every 3.20, after one month. Both Petit and Alsberg, however, include in their statistics examples of cicatricial structure, which yield better results than when the operation is done for carcinoma. Of the 137 cases which I have analyzed, 42, or 1 in every 3.26, lived for upwards of a month, and as they were all examples of carcinoma, it is evident that the results are growing better and better. Of the 42, 17 died subsequently, 3 in two months, 3 in two months and a half, 3 in three months, 2 in four months, 1 in five months, 1 in six months, 1 in six months and a half, 1 in seven months, and 2 in eight months, and of the remainder, 9 were living, respectively at the end of two months, two months and a half, three months and a half, four, five, six, and seven months, and twelve months and nine days, while another made a rapid recovery and gave birth to a healthy living child.

The case that was still alive upwards of one year is so remarkable that it is worthy of more than passing notice, particularly as I am able to add some facts to the original report.

On the 18th of February, 1882, Mr. Walter Whitehead,[3] of Manchester, excised the tongue, close to its base, of a man, forty years of age, on account of carcinoma, and opened the trachea, on the following day, for impending suffocation. On the 8th of March, the pharynx being blocked by the growth, and starvation being threatened, the first step of gastrostomy was performed, and the stomach was opened on the 19th. In answer to a letter inquiring into the sequel of the case, Mr. Whitehead wrote me, under the date of March 28, 1883: "I have to inform you that he is still alive. The glands—submaxillary, cervical, and sublingual—are very much enlarged, but painless. He can swallow fairly well and has discontinued the use of the gastric fistule. He suffers very little inconvenience from his condition, and, although he cannot live much longer, he is emphatic in his assertion that since the operation he has suffered no pain, whereas beforehand his life was one incessant period of unbearable suffering."

While not strictly a case of carcinoma of the œsophagus, it was substantially the same thing, as it interfered with deglutition, and threatened life from inanition. The man had gained nearly a stone in weight in four months, and was able to articulate with remarkable distinctness. Such a result must be regarded as a surgical triumph, and speaks more in favor of gastrostomy than would any arguments that could be made for it.

1112 Walnut Street, November 24, 1883.

AN EASY METHOD OF STAINING BACILLUS TUBERCULOSIS.

By I. BERMANN, M.D.,
of Baltimore, Md.
Surgeon to the Baltimore Eye, Ear, and Throat Charity Hospital.

The examination of secreta and excreta for bacilli is growing to be of such importance that a simple method, which will put such examinations within reach of every medical practitioner familiar with the use of the microscope, is greatly to be desired. My own experience, and that of friends who have talked with me on this subject, leads me to believe that the methods commonly employed do not always give satisfactory results. In many cases where the bacteria were undoubtedly present, the methods of Koch, Ehrlich, and others have failed to reveal them, although the examinations were made strictly in accordance with their directions. Weigert has lately published (*Deutsche medicinische Wochenschrift*, June, 1883, No. 24) a method which gives very good results. My own method, however, which is a modification of his, has given me more satisfactory results than any other which I have tried.

I place the sputum between two slides instead of between cover-glasses, and thus obtain easily the thin layer which is so necessary for examination. This is a matter of very great importance, as all the subsequent operations are greatly simplified by the use of the slide instead of the cover-glass.

In order to evaporate the water, I heat two flat dinner plates over the alcohol lamp or Bunsen burner, taking care that one of them is not hot enough to burn the hand. The slide is then placed upon the cooler plate and covered by the hot one, when the water quickly evaporates.

Meanwhile, I get ready four tumblers with clear water and my solution of nitric acid (one part nitric acid to two parts distilled water), and filter one teaspoonful of a two per cent. gentian violet solution into a small watch-glass. This is stirred up with a glass rod which has been dipped into a bottle containing strong water of ammonia (the glass rod should not carry more than one drop of the liquor ammoniæ). With a dropping-tube kept specially for that purpose, a few drops of this staining solution are then transferred to the dried sputum on the glass slide, which has previously been drawn, not too quickly, three times through the flame of a Bunsen burner or alcohol lamp, in order to fasten the sputum to the slide. The slide, with the staining-fluid on it, is then held at some distance over the flame, until evaporation sets in. Then the staining-fluid is poured off, and the slide dipped into a glass of clean water, after which it is at once put into the nitric acid solution. It is left there until the color has disappeared, which takes a few seconds. It is then washed off again in pure water, and should the color reappear in this, it should be once more submitted to the nitric acid bath and washed out again in clean water. A few drops of a saturated vesuvin solution in water are next dropped on the slide and left there for about thirty seconds, then washed off —always in pure water, when the specimen will show a slightly brownish color.

---

[1] Traité de la Gastrostomie, Paris, 1879.

[2] Archiv für klinische Chirurgie, Bd. xxviii. Heft 4, 1883.

[3] British Medical Journal, vol. i., 1882, p. 133.

Four to six drops of absolute alcohol are next poured on the slide, which is then placed slanting, to allow the alcohol to flow off and evaporate. After the slide has thoroughly dried, a few drops of xylol are dropped on it and left to evaporate, when by covering the specimen with a cover-glass, after having put on one drop of Canada balsam dissolved in xylol (dimethyl-benzol), it is ready for examination, *and will keep for any length of time*. A homogeneous immersion lens is very desirable, but not absolutely necessary if one only wants to see the bacilli; but a condenser is indispensable. The bacilli appear violet, while the rest is stained slightly brownish-yellow. The staining solution is prepared by dissolving two parts of gentian violet in one hundred parts of distilled water; and to prevent the solution from spoiling, it is well to add a small quantity—about ten cubic centimetres—of absolute alcohol to one hundred grammes of the solution, which may then be kept until it is wanted.

THE ANTISEPTIC TREATMENT OF A DISCHARGING EAR BY THE DRY METHOD.

By CHARLES A. TODD, M.D.,
PROFESSOR OF DISEASES OF THE EAR AND THROAT, MISSOURI MEDICAL COLLEGE, ST. LOUIS.

The method of aural practice which is the subject of this paper, was first published in the *Transactions of the Missouri State Medical Association*, May, 1880; since which time it has grown in favor, and has taken its place among the established therapeutical procedures. The general practitioner will discover in its extreme simplicity a grand merit, while the specialist cannot fail to be gratified at this invaluable addition to his resources against the serious class of aural disorders in which it is efficacious.

This method of treatment of a discharging ear (suppurative or catarrhal, otitis media or externa, acute or chronic) may be thus summed up: The ear, as a rule, is to be cleansed with absorbent cotton to the absolute exclusion of syringing or other customary methods of washing out the discharge; next, borax or other antiseptic powder (boracic acid, iodoform, etc.) is to be insufflated. Like all other methods of practice, this one must be modified according to circumstances that will be more or less self-evident. An old accumulation of inspissated secretion must necessarily be removed by syringing; a very tender ear in a restless child,—such exceptional cases plainly require exceptional treatment. Also, the presence of polypi, dead bone, narrow fistulæ, and other inaccessible seats of disease; all these represent complications to the proper inflammatory condition, and will require modifications of the above stated rule. But there is a large class of cases, including the great majority of the frequently observed acute and chronic aural inflammations with discharge, that will be properly treated according to the dry method.

Bezold, of Munich (*Arch. f. Ohrenheilk.*, June 13, 1879), was the first to insist upon pure antisepsis in the treatment of otorrhea—Listerism introduced into the domain of otology. Bezold's bold departure from established modes of treatment by instillation, he amply justified, and his justification stands. Unfortunately, he did not adopt the full rubric of Listerism, he still used the syringe and ignored the dry method of antiseptic applications. It would take too much space to state in detail the anatomical peculiarities of that remarkable cavity—the tympanum; yet some reference may be excused for the purpose of presenting, in the strongest light, the mischief that the syringe, in aural treatment, is capable of inflicting. The middle ear with its numerous small osseous recesses, its pockets formed by the ossicles and folds of the membrana tympani, to say nothing of the freely communicating mastoid cells, may be regarded as a congeries of small cavities, an arrangement eminently adapted to foster chronic discharge and to frustrate local treatment.

When the ear is syringed, there is always the possibility that the pus may be driven into parts as yet free from disease, parts that, from anatomical reasons just stated, are difficult of access for medical interference. Pus, we know, sometimes is infectious; decomposing pus is irritating. An immediate danger that cannot be overlooked is, that in case of perforation of the petrous or mastoid region, with abscess of the brain, the syringed water may aggravate, or even initiate, cerebral symptoms, and precipitate death. Such abscesses may exist unsuspected; this is well known. Politzer figures such a case in the last edition of his work on the ear. I have found a similar condition at a post-mortem, the cerebral abscess communicating directly through a fistula with the tympanic cavity, the bone demonstrating long-standing disease. Besides these direct risks, syringing is attended by another serious objection, in that it tends to increase the œdema of the parts, or at least cannot be thought to relieve it; the tissues are sodden in the midst of the discharge, and saturated with exudation; this condition is disastrous to rapid recovery. It may be urged that Bezold's saturated boracic acid solution, by osmosis, will deplete the tissues. How far in the end this may be is problematical. Absorbent cotton removes the pus by attraction and not by repulsion, at once avoiding the risk of forcing pus or injected liquids into remote parts, and in no way adding to the existing excess of moisture. Again, syringing, even when done with great care, sometimes causes vertigo. An obvious pathological reason for not syringing is that application of water is likely to hinder cicatrization, by washing off the newly formed epithelial cells. In dermatology, this fact is well recognized, and made the basis of a law. Briefly stated, the reasons for not using the syringe or other like methods in cleansing an ear from discharge are these:

Irritating secretions are likely to be driven into healthy cavities opening into the tympanum.

Direct pressure may be made upon the brain-tissue through a fistula.

The local œdema is encouraged.

Cicatrization is interfered with.

The absorbent cotton may be aided in cleansing the tympanum by forcing out the pus by the air-douche, acting through the Eustachian tube; or, in case this passage is impervious, the secretions may be drawn into the meatus by gentle suction through a rubber tube, one end of which is lightly pressed into that canal; the suction may alternate with equally gentle insufflation. The cotton is best introduced upon the end of a slender probe, a wisp being twirled about the point, so that the soft cotton shall extend well beyond the metal; thus placed, and carefully inserted into the meatus, the cleansing with cotton is more likely to be an agreeable operation to the patient than otherwise. After the ear has been thus cleansed and dried, and the processes of natural repair have been encouraged to the utmost, shall we next proceed to disturb this state of things by dropping aqueous solutions into the ear when special indications do not exist? (Instillation of alcohol is akin to the dry method, provided the alcohol, after a moment's retention, when it has become diluted through osmosis, is removed.)

In order to avoid the introduction of water into the ear, we may resort to the use of powdered drugs or of medicated cotton. It has been recommended that pledgets of medicated cotton be left in contact with the fundus of the ear to secure constant medication and continuous absorption of the secretions; such a procedure would be in exact accord with the antiseptic method in general surgery, with this fatal distinction, however, in the circumstances of application—in the one case, there is a free surface to be covered with the antiseptic dressing; in the other, we have to do with a long and narrow canal. Unless kept under close supervision, such pledgets will become saturated with the secretions, and prevent free discharge, a disastrous result; also, their presence is that of a foreign body.

By the use of powders in the ear, we can secure antisepsis, and local treatment as well, without incurring the evils just described. Borax, boracic acid, and iodoform are antiseptic powders convenient to use. They are to be puffed into the ear in any desirable quantity through an insufflator: Dr. Burnett suggests a quill scoop that is to be slipped into a rubber tube, which is a simple enough arrangement. I use an insufflator of silver, the scoop part fitting into a collar that is permanently attached to the rubber tube with mouthpiece. As to the choice of powders, I prefer the borax for a routine application; it is more readily soluble than boracic acid, and is an energetic fungicide. Dr. Walb, of Bonn (*Centralbl. f. klin. Med.*, 1883, No. 34), states that boracic acid actually encourages the growth of moulds. Besides, it is dispensed in the powder form, while the acid requires to be specially pulverized, a tedious process. As to iodoform, its value is impaired by its pungent odor and little solubility, whereby it clogs the canal if freely used, besides obscuring the field; this last is a serious objection.

The amount of powder to be insufflated at any one time and the frequency must depend upon the case. A small amount of discharge will require only a coating of the fundus in case of tympanic disease, which coating may not entirely dissolve for a day or two; free discharges will require that the canal be well filled daily to insure antisepsis. Of course, the dissolved antiseptic by diffusion will penetrate into the recesses of the tympanum immediately communicating. When the powder remains unchanged day after day, the discharge evidently has ceased; in rare cases, by reason of a very glutinous condition of the diminishing secretion, the powder may become mingled in the scant discharge without entirely dissolving, and the whole will harden together, requiring to be washed out.

To conclude, the dry method, by assisting nature, hastens a cure, and by doing away with repeated syringing and instillations spares both surgeon and patient much inconvenience and loss of time. I repeat, the method is no panacea, only an invaluable addition to our existing therapeutics, and a reform in practice.

CASE OF PROLAPSE OF THE URETHRA.

By R. H. Day, M.D.,
of Baton Rouge, La.

Prolapsus urethræ is an affection but rarely occurring, so uncommon, indeed, that many physicians of long experience and varied practice have never seen a case; hence its literature is scant and but little known.

I saw my first case a few months since, after being for more than half a century engaged in the general practice of medicine; and I confess that I harbored the opinion that no author had ever written of this disease. Under this belief, I wrote to Prof. S. D. Gross of my case, when I was informed by him that he had treated of it in his work on the *Urinary Organs*, and also in his *System of Surgery.*

Upon reference to Prof. Gross's work upon the *Urinary Organs*, I find the following:

> "The mucous membrane of the urethra, like that of the bladder, with which it is continuous, is liable to become inverted and prolapsed at the external orifice of the canal. The affection is extremely rare, and is, for obvious reasons, confined to the female sex. No regular account has yet been published of it, as our data are still too limited and imperfect to enable us to do justice to the subject."

Referring to my library, I find that Prof. Thomas, of New York, in his work on the *Diseases of Women*, also speaks of this affection, and says—

> "This accident which has likewise been described as procidentia and inversio urethræ, consists of prolapse of the urethral mucous membrane, with proliferation of the underlying connective tissue. It is not commonly met with, but at times produces considerable irritation of the urethra and bladder, and leads to an erroneous diagnosis of irritable caruncle. I have met with it only in adults of enfeebled constitution and advanced age; but Guersant, in the *Rêvue de Thérapeutique*, declares that he has seen fifteen cases in little girls between two and twelve years ot age."

In view of the rarity of this disease, and the little that has been written in elucidation of it, I am induced to report my case with the treatment and result.

On Saturday, the eighth of September last, I was requested to visit a colored girl, aged between six and seven years. On entering the house, the mother informed me that on the Sunday night previous, her little daughter was in great pain, and tried to urinate frequently, that suddenly, while straining over the night-vessel, her womb came down, and that she had been losing blood ever since, like a woman having her *courses* on her.

The little girl was seen that night by a physician. What he did I could not learn, but the child got no better, and suffered during the week with painful and frequent micturition, and painful dysenteric stools. I found her with some fever, perhaps of an irritative character. Yet the tenesmus and the character of her stools led me to prescribe a few doses of calomel and Dover's powder, and quinine to antagonize the malarial element that I thought I detected in her case.

Examining the vulva I found a dark-red tumor protruding through the labia, covering the clitoris and occluding the ostium vaginæ. It had a rough appearance, was flattened or slightly depressed in the centre with a sort of fimbriated border, and bled upon the slightest touch. I soon satisfied myself that it was not the uterus; first, from its shape, and secondly, by elevating the lower border I could see the ostium vaginæ. I thought it might be a vascular excrescence surrounding the urethral opening, but its granular and villous surface made me doubt the correctness of this view. At any rate I deemed it best for the present simply to sponge the tumor frequently with cold water, and to relieve her general or systemic symptoms.

On the 10th I visited my patient again, and finding her general health better, I made a more thorough examination of the tumor, and diagnosticated, beyond a doubt to my mind, that it was prolapsus of the mucous membrane of the urethra, and determined upon an operative procedure for its removal.

On the 13th, assisted by Dr. J. W. Dupree, after again exploring the tumor, and both of us being satisfied that the diagnosis was correct, I proceeded to operate. Anæsthetizing our patient with chloroform, Dr. Dupree raised up the everted borders with a pair of dressing forceps, and I passed around its neck, at its narrowest part, a strong, well-waxed silk ligature, and drew it sufficiently tight to produce complete strangulation. I then, with a pair of curved scissors, removed all of the tissue above the ligature, and cauterized the cut surface with the solid nitrate of silver. The ligature was then cut loose and a pledget of absorbent cotton saturated with carbolized oil applied between the labia in contact with the cut-surface, and retained by compress and bandage. The child was kept in bed in a horizontal position, with instructions to reapply the dressings as often as needed.

The next morning I found the little patient suffering great pain from retention of urine. I administered chloroform and drew off a large quantity of urine without any difficulty in introducing the catheter; continued local application, and applied over the vulva and lower part of abdomen a flaxseed poultice. After this there was no further trouble in urinating, and the part rapidly healed. To-day, she continues perfectly well, and upon examination the urethra appears as perfect and natural in appearance as though no operation had been performed.

Now in analyzing this case, there are several questions that naturally and pertinently present themselves.

First, did the protrusion of the urethral mucous membrane suddenly occur on the night of the second of September, as the mother stated? or had the prolapse been progressing for some time previously, unnoticed by the mother, and only discovered on the occasion named, by the sufferings of the child, and perhaps at that time aggravated by the straining efforts induced by her dysenteric condition?

I could not solve these questions satisfactorily to my own mind, though I critically catechized both the mother and the child. If the prolapse previously existed, it was not observed or recognized by either. But it seems almost impossible to conceive that an affection of this kind, and to such an extent, could suddenly take place when we bear in mind the anatomical conformation of the female urethra, and the necessarily limited diameter of its canal, in a child as young as the subject of this accident. It is more reasonable to suppose, that from previous intermittent fever, from which she had suffered during the summer, there was relaxation of all the tissues, and that the urethral mucous membrane, which had been gradually prolapsing unobserved, becoming intensely congested by her bowel complication on the night in question, and was then for the first time discovered.

This view of its origin seems to be justified from the statements of Prof. Thomas, who says: "I have met with it only in adults of enfeebled constitution and advanced age." It is true, that Dr. Thomas does not give the number of his cases, and hence his experience may not be sufficient to justify a positive opinion on this point.

Second, were the operation and its mode of performance, though perfectly successful, the best? This I conceive to be, after all, the most important question to decide. I confess that at the time I was greatly perplexed in my own mind how I should proceed. Then, I had not consulted my authorities, and if I had ever read what their teachings were, I had forgotten them, and was left to reason the thing out for myself upon general principles.

It was clear, since the prolapsed and hypertrophied urethral mucous membrane, forming a considerable tumor, could not be replaced, its removal was the only alternative. Excision and the ligature were the only methods at my command. By excision, the bleeding might be considerable, requiring torsion or ligature to control it, or involving the use of other expedients, thereby consuming much time. Its removal by ligature would obviate these difficulties, and be equally effective and expeditious. I decided upon the ligature, combined with excision, and was successful.

Since the operation and its results, I have consulted the only two authors in my library who treat of this disease, and I am convinced that my mode of operation was theoretically and surgically correct and proper.

The reader, by reference to Dr. Thomas' work on the *Diseases of Women*, pages 119 and 120, will find a corroboration of my procedure in principle, while the plan which I pursued is much more simple and easy of execution in all its details.

Prof. Gross lays down no specific mode, but says:

> "When the disease is obstinate, or has resisted the more ordinary remedies, excision may become necessary, as in the case observed by M. Seruin, already alluded to. Having assured himself, by repeated and careful examinations, that the tumor formed no part of the bladder, but consisted wholly of the mucous membrane of the urethra, he cut it off, without any hesitation, with a bistoury, on a level with the meatus of the tube; a slight hemorrhage ensued, but soon ceased spontaneously, and the cure was as prompt and complete as the operation was easy and simple."

Before I conclude, I will add that, within two weeks of the first case, another was brought under my observation—this, too, in a colored child only fifteen months old—a fine, large child, and in perfect health otherwise. The mother says she has noticed the tumor for several months. The child does not seem to be notably inconvenienced. I made a careful examination, and had no difficulty in detecting its true character.

The meatus urinarius, upon separating the labia, is distinctly seen in the centre of the prolapsed and everted urethral mucous membrane. Laterally, the tumor is slightly compressed, making its longest diameter from the clitoris to the ostium vaginæ. The tumor is small, and gives so little annoyance that I did not feel justified in advising, for the present, its removal. I am trying to effect a cure by astringent applications, and, I think, with diminution of its size.

I am now using a solution of tannic acid in glycerine. I shall watch the case and the results of the treatment, and be governed accordingly, and report the case, if deemed of sufficient interest.

HOSPITAL NOTES.

BELLEVUE HOSPITAL, NEW YORK.

THE TREATMENT OF FRACTURES BY THE PLASTER-OF-PARIS DRESSING.

Reported by J. H. Woodward, M.D., House Surgeon.

Plaster of Paris is most frequently and most successfully used here in the form of the plaster-of-Paris bandage. The bandage should be made of crinoline or cheese-cloth; crinoline will hold more plaster in its meshes, and on that account it is the better material to use. Crinoline (or cheese-cloth) is cut into strips two and a half or three inches wide, and eight or twelve yards long. These strips are rolled up moderately tightly, like the ordinary roller bandage; and while they are being rolled, a thin, even layer of dry plaster of Paris, recently baked, is spread upon the upper surface of the crinoline. The bandage, being thus thoroughly filled with the plaster, is wrapped in a piece of newspaper and placed in a covered tin box, where it can be kept dry until used.

Splints are constructed with this bandage in the manner to be described immediately. For example, simple fractures of the tibia and fibula are often put up within a few hours after admission to the hospital. If the surgeon thinks that there will not be any unusual swelling of the limb, he does not hesitate to apply the immovable splint. In such cases, a very thick layer of ordinary cotton is wrapped about the foot and leg, from the toes to just below the knee. An assistant maintains the bones in good position while the splint is being made. The paper is now removed from the plaster bandage, and it is placed on end in lukewarm water, which is just deep enough to cover the bandage, about a handful of salt having been added to the basinful of water. The bandage is squeezed two or three times to facilitate the entrance of the water into it, and when saturated (*i. e.*, after the lapse of about a minute), it is removed from the water and squeezed as dry as possible. About one foot of it is then unrolled and cut off; the remainder is passed snugly over the layer of cotton, by the figure-of-eight turn, from the toes to just below the knee. The bandage applied thus, should be smoothed with the hands, and dry plaster of Paris may be rubbed into it. A second and a third layer are put on in the same way. Three layers of this bandage make a very firm splint; two layers are quite sufficient for the first splint, if you propose to keep the patient in bed during the first ten days after the receipt of injury. If the limb is considerably swollen, the patient is usually kept in bed until the first splint is loose. Under such circumstances two layers of bandage are sufficient.

Having enveloped the fractured limb in two (or three) layers of the plaster-of-Paris bandage, it is placed upon a soft pillow which is moulded extemporaneously, so that the posterior of the splint will not be flattened or the leg bow backwards. Sand-bags, or some substitute, should be placed beside the leg to keep it quiet and prevent angular deformity, and the foot should be kept flexed upon the leg, either by a sand-bag or some other support. The patient is cautioned to keep very still. This splint, exposed to the air, will harden satisfactorily in from one to three hours.

Unless signs of strangulation of the leg appear, and they must be looked for diligently when this immovable apparatus is applied so early in the case, or the patient complain of unusual pain in the part, the splint may remain upon the leg until it is loose, *i. e.*, for a week or two. It is then cut down with a strong sharp knife; before cutting, nitric acid may be applied along the line of incision to soften the plaster. Having removed the splint and the cotton, you should examine the limb and correct any deformity. The fractured bones should be maintained in good position by an assistant while the second, and usually final, splint is applied. A roller bandage of old blanket, or of thick flannel, should be passed around the limb in a spiral, covering it from the toes to just below the knee. Then three layers of the plaster-of-Paris bandage are applied by the method already described. The bandage should be laid upon the limb smoothly and snugly. If it is put on lightly, the splint will be loose as soon as the plaster is hard; if it is applied tightly, the veins may be strangulated. Wind the bandage on snugly, and the splint will be a success. This splint should be treated, while the plaster is setting, just as described for the first splint. As soon as the plaster is hard the patient may go about on crutches.

It should be stated that all simple fractures are not put up in these splints as soon as admitted. A large number are treated in that manner, but the majority are not. During the period of inflammation, the injured leg is usually kept in the fracture-box and treated with cold or other astringent applications. As soon as the swelling has subsided the immovable apparatus is put on.

Such is the method of using plaster of Paris in ninety-nine per cent. of all the fractures of the tibia and fibula, femur and humerus that present at Bellevue Hospital. Fractures of the femur are not put up in plaster early in the case, however. The immovable splint is seldom carried above the knee-joint in cases of simple fracture of the tibia and fibula; and, although this practice is contrary to an established rule of surgery, it does not seem to be followed by any bad results.

The plaster-of-Paris bandage is used to make gutter splints and fenestrated splints, both of which are employed in the treatment of a variety of injuries and diseases. Wishing to make a fenestrated splint, we apply the plaster-of-Paris bandage according to the method described. The limb is now completely covered by the bandages, and, when the plaster has dried thoroughly, a fenestrum is cut through the splint with a knife at the proper situation. Fenestrated splints constructed in this manner are extensively employed in the treatment of compound fractures, in cases both in which the wound is small enough to be sealed and in those in which it is large enough to require frequent dressing. The edges of the fenestrum may be protected by rubber-tissue, oiled silk, or any other suitable waterproof material. Should it be necessary to cut a very large fenestrum, strips of iron or zinc are included in the splint in that vicinity to increase the strength of the apparatus. Strips of iron or zinc are also frequently included by the plaster splint, even when it is not fenestrated. Gutter splints especially are strengthened in this way where they cross a joint, and the plaster spica for the hip should always be reinforced in front of the hip-joint by an iron band between the layers of bandage.

The plaster-of-Paris bandage is employed also in manufacturing the bracket splint for compound fractures. That apparatus is quite a favorite one with many surgeons, and is used extensively in the hospitals of New York. In order to construct it, select pieces of hoop-iron about one inch wide and as long as the given case requires. These iron bands, three or four in number, are bent upon themselves, so that, when applied to the limb, the iron will stand away from it above and pass back to it below the wound. The site of fracture is thus bridged across by the irons. One layer, or more, of plaster-of-Paris bandage is then laid upon the limb above and below the seat of injury, and over the padding of cotton or the blanket roller. The irons are then fitted accurately to the parts and bound firmly to them by a number of layers of the plaster bandage. The splint made in this fashion is allowed to dry, and the case is dressed at the site of the fracture as often as the surgeon desires.

The plaster-of-Paris bandage is often applied outside of the Lister and other closed antiseptic dressings to maintain the limb in good position, both in compound fracture cases and in cases where joints have been operated upon for various diseases. Two layers of the bandage usually suffice, and furnish a very satisfactory apparatus for such cases.

Bavarian splints are seldom used in New York hospitals; but a splint made of plaster of Paris and cheese-cloth is frequently adopted. The advantage presented by this splint over the roller bandage splint is that it hardens in a few minutes, and hence the limb may be held in position by an assistant during the setting of the plaster. Anterior, posterior, and lateral splints are more readily made by this process than by any other that I have seen tried. But the splints are more apt to be worthless than are those made with the bandage, for reasons to be indicated presently.

In order to construct such a splint, you should proceed in the following manner: Suppose that you wish to make anterior and posterior splints for the foot, leg, and lower half of the thigh. For the anterior splint, cut three layers of cheese-cloth long enough to pass from the toes to the middle of the thigh, and wide enough to cover one-half the circumference of the foot, leg, and thigh. Three more layers of cheese-cloth are cut of the same length as the first, but about an inch and a half narrower. Finally, three layers of cheese-cloth two inches wide, of the same length as the former, are prepared. For the posterior splint, cut five or six layers of cheese-cloth wide enough to cover one-half the circumference of the foot, leg, and thigh, and long enough to extend from the toes to the middle of the thigh. Of course, in measuring these strips, allowance must be made for the increase in circumference of the limb made by the dressing and the padding. Having prepared the cheese-cloth, a plaster-of-Paris cream should be made. To prepare this, take the best plaster that can be obtained, and be sure that it is free from dirt and moisture; into a basinful of quite warm water, in which a handful of salt has been dissolved, stir the plaster slowly until a moderately thick cream is made. The anterior splint should be passed through the cream first. Saturate the wider pieces of the cheese-cloth first, and lay them upon the limb and smooth them down nicely; and then saturate the second three layers of the anterior splint with the plaster cream and apply them to the limb. Finally, saturate the narrower strips with the cream, and lay them upon the median line of the former layers and smooth all down nicely, and add more of the cream to the splint with the hands. If you intend to suspend the limb, iron rings should be passed upon the narrowest strips of cheese-cloth before they are applied to the other layers. The posterior splint is now put through the plaster cream and saturated with it; then it is applied to the posterior surface of the foot, leg, and thigh. These manœuvres must be performed with celerity, or the plaster will begin to set before the next step in the process is taken. Such an accident endangers the value of the splint, which is apt to crack at important points, and be weakened thereby. Having placed the anterior and posterior strips upon the limb, they should be held in proper coaptation and bound upon the limb by plain crinoline bandages, which have been moistened. Of course, any description of bandage may be used instead of the crinoline, but the latter, when dry, is quite firm, on account of the starch contained in it, and is, therefore, better than the ordinary muslin bandages. The limb may be held by assistants for a few minutes until the plaster is dry, or it may be supported on pillows. After the plaster has set, the limb may be supported by slings passed through the iron rings.

This variety of splint is a very excellent one, and is used extensively in the Bellevue Hospital. Now and then, it happens that the plaster will not set; but, if the cream is made of the proper consistency, and of good plaster of Paris, that accident will not occur very often. In mixing the plaster cream, especial care should be taken that it is not made too thick. Instead of cheese-cloth, old blanket, or flannel, or carbolized gauze, or any material which is of coarse texture, may be used in constructing such splints as these. Old blanket is frequently substituted with advantage here, especially when we wish to make a strong posterior splint for the lower extremity.

Such are the methods daily employed in the manufacture of plaster-of-Paris dressings in New York. A very detailed description of the various procedures has been given, because any description of them, to be a reliable guide, must be as specific as possible. The various steps in these processes have been followed by the reporter day after day during the past year, and he has seldom observed the plaster-of-Paris dressing to fail to be satisfactory, when it has been carefully made according to the foregoing plans. And he cannot recall a single instance where harm has resulted to the patient from the immovable apparatus itself.

MEDICAL PROGRESS.

Corrosive Sublimate in Puerperal Antisepsis.—**Paolo Negri** has adopted this agent as an antiseptic at the Maternity at Novare. He finds a solution of one to two thousand sufficiently strong as a rule. During four months at this Maternity, the statistics show not one death among the fifty-one cases; and but very little sickness.

Negri draws the following conclusions:

1. The toxic effects of corrosive sublimate employed in the usual strength, one to fifteen hundred or two thousand, is almost nothing; in one case only, he had slight mercurial exanthema.
2. The solution of the strength of one to two thousand is sufficiently powerful to prevent puerperal sepsis.
3. This solution will completely substitute the two to one hundred solution of carbolic acid generally used.
4. The sublimate has the advantage over carbolic acid of being cheaper, and having no odor; this last consideration being not unimportant in private practice. —*Bull. Gén. de Thérap.*, October 30, 1883.

The Etiology and Pathogenesis of Phthisis.—**Prof. Sormani**, in an article on this subject, draws the following conclusions:

1. Tubercle bacilli are not found in the breath of phthisical persons. 2. The tubercle bacillus is preserved for a long time unaltered in the sputum of phthisical patients, resisting putrefaction and desiccation. 3. This bacillus retains its virulence for a long time, but gradually grows more feeble. 4. Tuberculosis acts, therefore, not as a directly contagious disease, but indirectly, by means of the dried tuberculous sputa, pulverized and suspended in the air. 5. The prophylaxis of phthisis should tend to the prompt destruction of tuberculous sputa, and to the efficacious disinfection of chambers by destroying the infecting tuberculous material. —*Annali Univ. di Med. e Chirurg.*, Sept. 1883.

Myomatous Tumor of the Prostate in a Child Thirteen Months Old.—At the meeting of the St. Louis Medical Society, September 29, 1883, **Dr. Mudd** presented this specimen. The child had been healthy until within a few weeks of the time of its last illness. When Dr. Mudd was called to see the child, it had suffered for several days with retention of urine, passing nothing but a little water at a time; the bladder was very much distended. The child had passed a little water, from time to time, and the mother had not noticed any distention of the bladder. This retention, which came on suddenly, was persistent until death, which occurred about two weeks after he first saw the child. Upon examination of the child before death, by passing the finger into the rectum, he could feel a large tumor presenting anteriorly. The tumor was connected with the bladder, and could be outlined pretty distinctly. He could then determine that it was uniform in its outline, uniform in its consistency, and could feel, after emptying the bladder, by bimanual palpation, the outline of the tumor very distinctly. Upon making the post-mortem examination, he found that the bladder was about as might be expected in a child of thirteen months; but there was a tumor springing apparently from the prostate gland, that was as large as a small lemon, and which presented upon the mucous surface of the bladder—it was a hypertrophy of the middle lobe of the gland, so as completely to occlude the passage of urine. From the microscopic examination, which was made by Dr. Luedeking, it appears that the character of the tumor is a hyperplastic myoma of the prostate gland. The structure of the prostate gland seems to have been lost in the hypertrophy of the muscular tissue — the muscular tissue is non-striated, such as is found in the bladder. It is the opinion of Dr. Luedeking, that the hyperplastic growth may have been developed as an intra-uterine growth. As could be seen upon examination of the specimen, the mass of the tumor would not interfere at all with micturition, the interference coming only from the projection of the third lobe. It is very distinct, and projects as little nodules, cutting off the passage of the water. It is remarkable, from the fact that it comes from so small a child—remarkable by presenting no characteristics of malignancy; simply presenting a hypertrophy of the muscular tissue.

As to the cause of death, he found that the pelvis of the kidney was involved in the inflammatory action, probably from the obstruction to the outflow of urine; the calices of the kidney structure also were involved. He supposed that death occurred from disturbance of the kidney and retention of urine. The appearance of the tumor is very much such as will be found described by Paget as a hypertrophy of the gland in old persons. No such appearance was observed in the child.—*St. Louis Medical and Surgical Journal*, November, 1883.

Laryngeal Chorea.—**M. Blachez** read a paper on this subject at the meeting of the Académie de Médecine, on October 16th. From his researches on this subject it appears that laryngeal chorea is less rare than is generally supposed. He has seen two cases of the affection in children. The first child, lymphatic and born of an arthritic mother, was taken with a slight laryngitis with spasmodic cough, which presented, every few days, very peculiar characters. There were no choreic phenomena on the part of the limbs; all the movements were regular. Bromide of potassium, valerian, and belladonna, completely failed; chloral alone gave a decisive and rapid result. Two very intense febrile movements came on, and the affection disappeared.

The second child, lympho-anæmic, was taken during the course of a slight bronchitis, with paroxysms characterized by a peculiar piercing cry, somewhat resembling that of a toy goat. The cry came on eight or ten times in a few minutes, and the paroxysms several times during the day. They never came on during sleep. The child was nervous, always agitated, but had no true choreic movements. Large doses of bromide of potassium completely broke up the attacks.

It appears to M. Blachez, then, that bromide of potassium and chloral are to be particularly recommended in laryngeal chorea. He based his diagnosis on the hereditary arthritic antecedents of the two children, on the absence of multiple and varied nervous phenomena, on the integrity of the psychical functions, and on the absolute suspension of the paroxysms during sleep.—*L'Union Méd.*, October 18, 1883.

The Iodoform Treatment of Ruptured Perineum.—The short confinement to bed, and the absence of purulent secretion with iodoform dressings, have induced Behm to follow this method of treating ruptures of the perineum.

The instruments and the wound are first disinfected by means of carbolic acid solution, the lips of the wound are trimmed and bleeding stopped by most careful pressure with wadding pads. If primary union is wished for, he only puts a thin layer of iodoform in the wound; in two cases, in which too much iodoform was used, primary union did not take place.

Two complete, and twenty-eight incomplete ruptures were treated in this manner: Of the first two, one healed without trouble, while the other, dressed thirty-six hours after delivery, after the rectum and bladder were emptied, healed only incompletely, with a recto-vaginal fistula. Of the twenty-eight incomplete ruptures, twenty-three healed by primary union. Behm has had no cases of iodoform intoxication.—*Centralbl. f. Gynäkologie*, August 18, 1883.

Cubitus Valgus.—Under this name L. von Lesser describes a deformity which is somewhat similar to that producing genu valgum. It consists in the production of an obtuse angle, opening posteriorly during forced extension of the forearm on the arm. At the fold of the elbow it makes a projection anteriorly. Posteriorly there also exists an obtuse angle, the summit of which corresponds to the epicondyle, this angle being equally apparent in pronation of the forearm. The olecranon is so closely drawn to the epicondyle that the ulnar nerve is pressed upon in its groove, and in prolonged extension the patient experiences, in the little finger, sensations peculiar to pressure on that nerve. The epitrochlea is situated in a higher plane than is the epicondyle. In forced extension the head of the radius is found pressed posteriorly into a position of subluxation, and its cup is easily felt below the exaggerated projection of the epicondyloid muscles.—*Virchow's Archiv*, Bd. xcii. Heft. i.

Phosphorus in the Treatment of Osteomalacia.—Busch has recently reported two cases of osteomalacia treated by phosphorus. The first was that of a woman, æt. 30 years, who seemed to be in excellent health. The objective symptoms were limited to the bones of the pelvis, which appeared to be involved on both sides. The symphysis pubis projected forward, and the horizontal rami of the pubes were markedly incurvated. The woman was unable to walk, and could only move from the bed to a chair with extreme difficulty. Busch prescribed absolute rest in the horizontal position for three months, giving at the same time Wegner's phosphorus pills. After five months' treatment the patient could go up and down stairs without difficulty. At this time she was lost sight of.

The second patient was a woman, æt. 50 years, who complained of violent pain in the right arm, at the point of insertion of the deltoid. Osteitis was diagnosticated, and treated by the ordinary means. There was no amelioration of the symptoms, and she came under Busch's care. She was extremely emaciated, could not walk, and presented many deformities: kyphosis ot the spine in the dorsal region, and lordosis of the cervical portion of the vertebral column; the head seemed forced down between the shoulders; the thorax was deformed, the thighs curved, and the pelvis presented the characteristic deformities of osteomalacia. She was put on Wegner's phosphorus pills, and took them for eighteen months. At the end of that time the bones were quite firm, and she could walk without pain.

The formula for Wegner's pills is as follows:

Phosphorus,	grs. iv.
Simple Syrup,	f℥ij ♏xx.

Mix and add—

Powdered Liquorice,	ʒijss.
Powdered Gum Arabic,	℈iv.
Powdered Gum Tragacanth,	ʒss.

Make 250 pills. S. 2 pills a day.

This dose may be increased.—*Progrès Méd.*, October 27, 1883.

Neuralgic Ciliary Pain Cured by Stretching the Nasal Nerve.—Mr. John Garey reports the following case, coming under the care of Mr. Henry E. Clark, at the Glasgow Eye Infirmary.

M. C., æt. 49, presented himself on April 3, 1883, suffering from acute irido-cyclitis in right eye, with considerable muddiness of the vitreous. He stated that he had received a blow on this eye two years previously. He was ordered to have ext. bellad. applied over the supraorbital region, the eye was bandaged, and a purgative administered; he was instructed to bathe the eye frequently with the compound lotion used in this institution. On his return the following week he complained of very severe supraorbital pain, extending as far as the crown of the head; the pupil did not yield to the action of atropine, and the ciliary region was very sensitive to the touch. He was ordered to take one grain of calomel and half a grain of opium every night at bedtime. Three days later, the pain not having appreciably diminished by this treatment, the artificial leech was applied over the right temple, and a small quantity of blood abstracted; from this he experienced considerable relief, but it proved to be only temporary in character, and in a few days the pain returned with all its former intensity. It had now certain neuralgic features, and was distinctly intermittent, commencing generally about five o'clock in the morning and disappearing about two in the afternoon. He was put on phosphorus pills (B. P.), $\frac{1}{30}$th grain every six hours, and under this treatment the pain soon disappeared, and he was sent to Dunoon Convalescent Home. While there he for a time continued well, but on catching a slight cold, the affection became lighted up afresh, and he was compelled to return before the expiration of his term there to undergo further treatment. We administered full doses of bromide of potassium, and kept him at rest in bed, but with no lessening of the pain; free phosphorus was again tried, and persevered in for twelve days, but it appeared entirely to have lost its influence. Mr. Clark now suggested stretching the nasal nerve, and the patient being willing to submit to anything that offered a chance of relief, the operation was performed on August 1st, without the aid of an anæsthetic. An incision about one inch in length was made in the upper eyelid, running obliquely downwards and inwards, from the level of the pulley of the superior oblique nearly to the inner canthus The orbital periosteum being exposed, a strabismus hook was carried backwards close to the bone, and after one or two abortive attempts the nerve was caught in the hook and drawn forwards. It was fully exposed, so as to make quite sure that the right structure was being pulled, and pretty firm traction was made on it in the axis of the inner wall of the orbit. This part of the operation caused most excruciating pain to the patient. The wound was brought together with sutures, and dressed with boracic lint; it healed kindly in the course of a few days, and he was dismissed on August 6th, the neuralgic pain having entirely disappeared. Since that time he has had no return of the neuralgia, and the eye retains a fair perception of light, but the pupil being almost closed, it will be necessary to perform an iridectomy at a later date.

The connection of the nasal nerve with the nutrition of the eyeball has so long been recognized, that we can quite understand that some change will be produced in the nutrition by the elongation of that nerve, but we are as much in want of anything like a plausible theory of the exact mechanism by which such change is brought about in this instance as in other cases of nerve-stretching. That the operation is attended with much improvement of the condition of the patient is evidenced, not by this case alone, but by numerous others very similar in their nature, and it seems to be especially effective where the pain is very acute and very persistent.—*Glasgow Med. Journ.*, Nov. 1883.

Ectopia Cordis.—M. Marey read a report, at the meeting of the Académie de Médecine, on October 16th, of a case of ectopia of the heart observed in a woman under Prof. Tarnier's care.

The woman presented a congenital division of the sternum and diaphragm, with eventration and congenital hernia. The bifid condition of the sternum enabled the examiner to see the ventricles under the skin; their greater axis was almost vertical. The right was more accessible; the flaccidity of the skin enabled him to seize the ventricular mass in the hands and to compréss the aorta.

By auscultation a systolic souffle could be heard, which appeared to correspond to a narrowing of the root of the aorta; in other respects the functional action of the heart appeared to be normal. Inspection alone of the heart's movements would seem to show that the sudden ventricular diastole caused the heart beats, but the placing of the finger on the ventricle showed that the pulsation takes place during the ventricular systole. The registration of the pulsations of the heart showed that the ventricles are synchronous as to their action, except when irregularities of their rhythm were produced; that the pulsation coincided with the diminution of the volume of the ventricles, and consequently with the time of the ventricular systole.—*L' Union Méd.*, October 18, 1883.

A Case of Wandering Liver.—Dr. Felix Schwarz reported a case before the k. k. Gesellschaft der Aerzte, in Vienna, on June 8th. He believed that he was supported in his diagnosis by the symptoms of the case, which are:

1. When the liver is entirely sunken downward—the absolute liver-dulness begins, while the thorax is in the position of expiration, in the right mammary line at the upper border of the seventh rib, and reaches four inches beyond the free border of the ribs. In inspiration absolute liver-dulness begins in the right mammary line at the free border of the ribs; percussion is somewhat tympanitic in the sixth intercostal space; there is a clear tympanitic note in the fifth interspace, and from the fifth upward there is normal pulmonary resonance. Between the border of the ribs and the left lobe of the liver, during inspiration, is a furrow one inch wide, running toward the left hypochondrium, which gives a dull tympanitic percussion.

2. The smooth upper surface, the sharp border, and the longitudinal fissure of the liver can be easily felt in the mesogastrium.

3. On the liver being replaced the liver-dulness begins at the fifth rib, and extends a little over one inch below the free border of the ribs in the right mammary line. In the right parasternal line it extends three inches beyond the free edge of the ribs, in contrast with five inches in the displaced state.

4. The liver is movable, not only upward, but to the right and left. When the patient lies on the left side the liver falls toward that side, and the greater part of the right lobe can be felt in the scrobiculum cordis. Finally the liver can be forced into the right hypochondrium without much opposition on the part of the organ. The fifth symptom, relaxation of the abdominal walls, did not exist in Schwarz's case; on the contrary, the standing posture made the walls so tense that an examination could only be made in the horizontal position.

There are fifteen cases of wandering liver reported in literature, thirteen in females, and two insufficiently described cases in males.—*Wien. Med. Presse*, No. 24, 1883.

Parenchymatous Injections in Uterine Affections.—Dr. Adrian Schuecking describes the following method of making parenchymatous injections into the uterine tissue:

After having introduced a speculum into the vagina, and fixed the neck of the uterus, he forces into one of the lips of the cervix a long syringe-needle. Before and after the injection, the cervix is washed with a disinfecting solution. He has never seen any undesirable consequences after this procedure. The slight hemorrhage caused by the needle he regards as rather advantageous than otherwise; in fact, more useful than scarification.

Schücking thinks that parenchymatous injections should be substituted, in gynecology, for the subcutaneous method, being more convenient and efficacious. Immediately after the injection, the cervix is seen to become pale, and diminished in size. There can be no doubt of the absorption of the injected medicine, for one patient stated that the distinct metallic taste was perceived as soon as when the substance was given hypodermatically.

Thus far Schücking has used parenchymatous injections in the following affections:

1. Uterine fibroma—four cases—while the action of ergotine given hypodermatically seemed to be doubtful, after about twenty parenchymatous injections, he constantly noticed either a diminution of the hemorrhage or in the size of the tumor, or both.

2. Incomplete puerperal involution causing prolapse and retroflexion of the uterus. By injecting, three times a week, half a syringeful of an aqueous solution of Fowler's solution (1–3), he has seen the uterus regain its normal position after about fourteen injections.

3. Erosions with hypertrophy of the cervical glands—eight cases—interstitial injections of tincture of iodine, combined with touching the cervix with pure acetic acid, caused much more rapid recoveries than when the acetic acid alone was used.

4. One case of exudation into the broad ligaments.—*Berlin. klin. Woch.*, July 2, 1883.

THE ORIGIN OF VACCINIA.—M. WARLOMONT, of Brussels, read a paper on this subject before the Académie de Médeciné, on October 16, drawing the following conclusions: 1. Neither horses, cows, nor any other animals can be considered as vaccinogenous. Neither horses nor cows can directly give rise to horsepox and cowpox; either must have previously received the originating germ. 2. The original cause of vaccinia, in its relation to the cow and horse, is nothing else than variola; introduced into the organisms of these animals, it there undergoes an attenuation resulting in vaccinia. 3. This attenuation is less in the case of horses than of cows; consequently, horsepox more nearly approaches the character of variola. 4. The horse is, therefore, less fitted for the culture of vaccinia. 5. Artificial variolic or vaccinial impregnation in the horse by inoculation or intra-cutaneous injection, seems to be produced very much as in the case of the cow, and immunity should be the result of this impregnation.—*L' Union Méd.*, October 18, 1883.

INTRAPULMONARY INJECTIONS IN BRONCHIECTASIS.—DR. O. SEIFERT has made intrathoracic injections of ♏ xxx of a three per cent. carbolic solution, in cases of two patients affected with bronchiectasis. In the first case inhalations of spirits of turpentine, perchloride of iron, tannin, and carbolic acid had been tried without any good result. After each injection it was evident that the expectoration had completely lost its fetid odor and had diminished in quantity.

The second patient died in the hospital. Seifert made a post-mortem examination with the view of noting the traces left by the injections. On a level with the site of the last injection, made two days before death, there was found, on the pulmonary pleura, a spot of hemorrhagic infiltration with a central point corresponding to the prick of the instrument. The traces of the other three injections made on the sixth and fourth days before death were only shown by a slight pleural pigmentation. It is evident, therefore, that no injurious effects follow from these punctures. They are only very slightly painful, only cause cough when thrown into moderately large cavities, and cause no rise of temperature.—*Berlin. klin. Woch.*, June 11, 1883.

POISONING BY COAL GAS.—In connection with the recent Hygienic Exhibition at Berlin, popular lectures were given from time to time by various eminent men upon important matters of public health. One of the last so delivered was by PROF. PETTENKOFER, who chose for his subject coal-gas poisoning. After pointing out that the products of the burning of gas were no more noxious than the exhalations of human beings, and that really gas illumination did not consume so much oxygen as an equivalent number of wax candles would do, he passed to his main thesis, which was the poisonous action of the gas itself. The escape of gas in a house can be readily and at once detected by its peculiar odor, but it is otherwise when the escape takes place in the ground from breakage of the mains, whence it finds its way into the basements of houses. The evil effects of such escape had been exemplified in Italy, in Cologne, and in Breslau, and he believed that such cases were far more frequent than is supposed. The poisonous property of coal gas depends upon its containing carbonic oxide (viz., ten per cent.), the other constituents, although irrespirable, not acting as direct poisons. From Grube's researches it is evident that the danger of this gas depends not so much upon long exposure to a mixture of air and carbonic oxide, as upon the amount of the latter contained in the air. Air containing a proportion of five parts of carbonic oxide in ten thousand can be breathed for hours and even days by men and animals without any injury to health; whilst a proportion of seven or eight in ten thousand causes appreciable discomfort; of twenty in ten thousand, difficulty of breathing, weakness and uncertainty in gait; twice that proportion leads to stupefaction, and higher proportions to extreme and fatal effects, referable to the nervous system. The occurrence of cases of illness directly attributed to the entrance of gas into houses from the mains has been found to increase in the winter months, a fact partly explained by the more frequent breakage of the pipes in that season, and also perhaps by the closing of windows and artificial heating of rooms, inviting the accumulation and entrance of the gas from without. Gas thus filtered through the soil may be quite odorless, at any rate until it has collected in large amount; and herein lies the danger to the dwellers in the basement of a house. On the earliest occurrence of symptoms such as headache, the windows should be thrown open, and if on their closure the symptoms reappear, it may be suspected that there is an escape of gas near the house. The mains should be examined and the defects repaired without delay; but Professor Pettenkofer urged that it would be well that the police should warn all the inhabitants of houses in the vicinity to see that their rooms were kept thoroughly ventilated. For when the gas remains in the soil it may again find its way into houses when the rooms are artificially heated in the cold season. In conclusion, he remarked that he had chosen this subject for his lecture to show how important it was in hygienic inquiry to pay attention to minutiæ; and he urged that every university should have attached to it a hygienic institute, such as Munich and Leipsic possessed, and as Göttingen was about to have.—*Lancet*, November 10, 1883.

CYSTICERCUS OF THE BREAST.—M. GUERMONPREZ publishes an interesting case of this rare effection in the *Lyon Médical*, of September 16th.

In his *Thèse d'Agregation*, Paris, 1878 (Des tumeurs kystiques de la mamelle), M. Richelot has distinguished glandular cysts, which he calls independent, that is to say, which are developed either at the circumference of, or in the glandular tissue, but which are developed in the mammary glands in the same manner as in the other places.

The patient whose case came under the observation of M. Guermonprez, was twenty-nine years of age, and presented a fluctuating tumor at the upper and internal part of the left breast. Into the inflammatory swelling puncture was made by means of a bistoury in the central part, which caused three different materials to flow out: first a copious amount of thick serum, then a cyst, and finally a considerable amount of pus. The operation was performed on March 25th, and the woman was completely well about the last of April.

The cyst was provided with a single wall, very thin, and could be stretched out on a table, like an incompletely filled bladder. When stretched out it formed a sort of disk, thediameter of which was about one and a half inches; its volume was six cubic centimetres. The color of the pouch and its contents was a greenish-yellow. The surface, generally opalescent, showed at one point a single spot of milky-whiteness with diffuse borders which gradually blended with the rest of the mass. This part, examined by a magnifying glass, showed a vermiform organ, the various parts of which were more or less sheathed in one another. These were separated by methodical compression and teasing. Under the microscope it was easy to recognize all the characters of the cysticercus.—*L' Union Méd.*, October 18, 1883.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

Communications are invited from all parts of the world. Original articles contributed exclusively to The Medical News will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

Subscription Price, including Postage,

Per Annum, in Advance, ... $5.00.
Single Copies, ... 10 cents.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

Address, HENRY C. LEA'S SON & CO.,
Nos. 706 & 708 Sansom Street,
Philadelphia, Pa.

SATURDAY, DECEMBER 1, 1883.

WIRING THE FRACTURED PATELLA.

In *The Lancet* for November 3, 1883, Mr. Lister gives the details of seven cases of fractured patella, in which he was uniformly successful in securing union and a good use of the joint, by approximating the fragments with stout silver wire. The operation is done briefly as follows: A longitudinal incision is made over the patella; firm or soft coagula, or fibrous or ligamentous tissue, are removed; the fragments are freshened, and pierced obliquely with an ordinary bradawl, without penetrating the cartilage; a drain is inserted into the joint; the ends of the wire are secured with a twist, and the latter hammered down upon the bone, with a view to its permanent retention; and the limb, enveloped in an antiseptic dressing, is placed in the trough of Gooch's splint.

Mr. Lister claims that the mode of treatment which he recommends "restores the joint to practically a perfectly natural condition, provided that no disaster occurs," and he warmly urges that it should be pressed upon the patient, if strict antiseptic precautions be carried out, through which accidents will be prevented. He, moreover, states that "we are morally certain that we do not subject the patient to risk," because, "if there is in the whole body a situation which is well adapted for antiseptic treatment, it is this." "I believe," he adds, "that if we use the means that we have now at our disposal, we may say, with a safe conscience, if we use them aright, that we do not subject the patient to anything like so great a risk as people used to be subjected to, not many years ago, when they had fatty tumors removed in general hospitals."

So far as the personal experience of Mr. Lister warrants him in speaking, his successes justify the emphatic language that he employs; but, as we shall show presently, a more extended record of antiseptic suturing of the patella does not confirm his positive assertions. Dogmatism is all very well in its way, but surgeons who occupy the high rank that Mr. Lister does should be very careful in their efforts to inculcate doctrines which are based upon a too limited test. Had he studied the reports of cases in the hands of other surgeons, we feel convinced that he would have been more guarded in his expressions, and would never have penned the words, "Antiseptic treatment converts serious evil into complete safety." It will not do to put forward the excuse for the failures that antiseptic measures were not properly employed, as the operators mentioned in the succeeding paragraphs, in connection with the bad results, are too well known to be accused of negligence.

Antiseptic suturing of the patella has now been done 49 times; the surgeons having been Lister in 7 cases, Koenig in 4 cases, Trendelenburg in 3 cases, Cameron, Jessop, Rose, Rosenbach, Wheelhouse, and Schede, each in 2 cases, and Amphlett, Bell, Bull, Dicken, Fowler, Goering, Hartwich, Holmes, Langenbeck, Langenbuch, Lauenstein, Metzler, Poncet, Sabine, Schneider, Henry Smith, Socin, Teale, Timme, Uhde, Van der Meulen, Wahl, and Wyeth, each in 1 case.

In the single cases of Bull, Dicken, Von Langenbeck, and Wyeth, in Schede's 2 cases, and in 2 of Koenig's, the joint suppurated. Of these 8 examples, that of Bull died of exhaustion on the fourteenth day; that of Von Langenbeck died of pyæmia, after amputation of the thigh, on the sixteenth day; and the case of Wyeth recovered after amputation of the thigh; while the remainder got well with stiff joints, the upper fragment having died in Koenig's fourth case.

In addition to these accidents, there was partial necrosis of the lower fragment in the case of Wahl, and the patient of Fowler perished of carbolic acid poisoning in thirty-one hours.

The results of the operation show, therefore, 16.3 per cent. of suppuration of the knee-joint; 6.12 per cent. of deaths; 4 per cent. of necrosis of the fragments; and 4 per cent. of amputation of the thigh; results which completely negative the dogmatic assertion of Mr. Lister that, "Antiseptic treatment converts serious evil into complete safety." In favor of the operation it must, however, be said that the large majority recovered with bony union and with excellent use of the joint.

From the remarks of Mr. Lister, one would naturally infer that Dr. Cameron, of Glasgow, took the initiative in suturing the broken patella, in 1877. It was, however, first done by Dr. John Rhea Barton, of this city, more than fifty years ago, and repeated by McClellan in 1838, by Cooper, of San Francisco, in 1861, and by Logan, of Sacramento, in 1864. A fourth operation, before the introduction of antiseptic surgery, was performed by Gunn, of Chicago. Of the four, those of Barton and Gunn perished.

HYSTERICAL FEVER.

Dr. Briand, in a recent number of the *Gazette Hebdomadaire*, maintains, with Gubler, Rigál, Dieulafoy, and others, that the term hysterical fever should be applied to certain conditions of actual fever which cannot be referred to any other cause than the hysterical affection itself. Three forms are described: 1. The slow continued fever of Briquet, characterized sometimes by a simple acceleration of the pulse, *without elevation of temperature*, sometimes by a temperature rise, either without other phenomena or accompanied by headache, thirst, and other symptoms. 2. A shorter form, always the result of a more or less active disturbance of the nervous system by terror, fear, chagrin, and like causes, occurs in well-marked neuropathic subjects. Examples of this variety have been described by Graves, Briquet, and Bouchut; and the following typical case is related: A young girl after intense fright, was seized with severe fever which lasted ten days, and in which the temperature reached 103.1° F. Sudden defervescence ushered in a series of phenomena characteristic of hysteria. 3. The febrile phenomena sometimes assume the intermittent form. In three examples of this variety, Briand observed respectively temperatures of 100.6° F., of 100° F., and of 100.2° F., and in a single case reported by Charcot, the temperature attained 101.3° F.

On the other hand, M. Henry Pinard, in a thesis presented this year to the Paris Faculty, without denying absolutely the occurrence of a true hysterical fever, describes the so-called intermittent variety as a pseudo-fever, at the same time declaring that the first and second of the above forms have no existence whatever as direct manifestations of hysteria.

This view, in which we concur, accords more closely than the other with the known facts concerning hysteria. That febrile phenomena should occasionally occur as secondary to hysterical outbreaks, in consequence of violent and prolonged muscular effort, or of local injuries, is altogether probable. That intercurrent affections, such as enteric or intermittent fever occurring in hysterical subjects, present peculiar modifications is well known. But that febrile conditions resembling these affections are the direct outcome of hysteria is far from being established. A much greater collection of closely observed cases, in which accidental and intercurrent febrile manifestations have been rigidly excluded, than has yet been made, would be needed to give any sanction of right to the use of the term, hysterical fever.

THE REMOVAL OF NEOPLASMS OF THE BLADDER.

In The Medical News for August 11, 1883, we directed attention to the operative treatment of tumors of the bladder, and showed that, in view of the dangerous condition to which the subjects are reduced, their removal was perfectly justifiable. We also protested against the exclusive use of the forceps, as recommended by a distinguished London specialist, which are not only almost worthless except for pedunculated growths, but the resort to which is attended with the risk of lacerating the bladder. For these reasons we advised the employment of the sharp spoon, with which the base of the neoplasm can be successfully attacked.

In *The Lancet* for October 6, 13, and 20, will be found a series of papers from the pen of Mr. Walter Whitehead, of Manchester, in which the details of six cases are given, which confirm the views we expressed in regard to scraping away vesical neoplasms. In five the spoon was employed, and all the patients, of whom four were males and two were females, recovered from the immediate effects of the operation. Four recovered completely, while two died, each at the expiration of three months. In one the growth had been completely removed, and the bladder was perfectly healthy; while in the second case, in which the papillated surface of an epithelioma behind the pubes was scraped away with the fingernail, there was no return of spontaneous hemorrhage.

THE MICROCOCCUS OF SCARLET FEVER.

M. Pohn-Pincus, in the *Gazette Médicale de Paris* of Sept. 29, states his belief that he has discovered, in the desquamating epidermis of scarlet fever, micrococci which are the germs of this disease. He demonstrates them by partially detaching with scissors a lamella of the epidermis, but so that it shall be still adherent by a great part of its periphery. He then applies to the under surface of the detached portion a few drops of a saturated alcoholic solution of methyl-violet. In a few minutes he scrapes off, with the aid of a cataract needle, some little fragments of tissue, and immerses them for a short time in distilled water; subsequently he places them upon a glass slide, teases them out as finely as possible with needles, and warms the object glass until the preparation is dry. He then adds a drop of oil of cloves, and covers the whole with Canada balsam.

The micrococci will be stained violet. M. Pohn-Pincus says their dimensions are very small, but measurements are not given. They are united in small groups and are found in the depressions upon the borders of the detached cells. No attempt has yet been made to cultivate these micro-organisms or to inoculate them.

PREVENTIVE INOCULATION OF SCARLATINA WITH SCARLATINAL VIRUS DERIVED FROM A HORSE.

In the *Gazette Médicale de Paris* of Sept. 29th, M. Stickler reports the result of some inoculations with nasal mucus of a horse suffering with an affection which was believed to be identical with human scarlatina.

M. Stickler inserted about six drops of this mucus under the skin of four rabbits and a dog. Twenty-four hours later, these animals presented a decidedly confluent scarlatiniform exanthem, which terminated in four days in a lamelliform desquamation. This eruption was accompanied with fever, anorexia, and redness of the nasal mucous membrane, which was also the seat of an abundant secretion. In the neighborhood of the inoculation, the glands were engorged. At the end of eight days the animals had recovered. The daily examination of the blood showed an increased number of leucocytes, and, on the third day, were noted little rounded distinct granules adherent to the white globules; these had disappeared on the sixth day. Seven days later, he injected under the skin of the same animals blood from a case of confluent scarlatina, and the inoculation was followed by no results.

Again, he inoculated with the same nasal mucus twelve children who had never had scarlet fever. In all of these children a punctiform eruption appeared within twenty-four hours at the point of inoculations, accompanied with fever and enlargement of neighboring glands. The eruption lasted six days, and terminated in desquamation. After an interval of a few days, he inoculated the same children with some drops of scarlatinal blood, with absolutely negative results.

M. Stickler concludes from these experiments that the subcutaneous injection of scarlatinal virus derived from a horse is not followed by harmful results; that inoculation of this virus in man is followed by a circumscribed eruption like that observed in mild scarlet fever; and that this inoculation confers an immunity against scarlatina.

CREASOTE IN PULMONARY AFFECTIONS.

In the *Journal de Thérapeutique* for September 25, 1883, Dr. Reuss publishes some remarkable statistics, proving the great value of creasote in phthisis, and in acute affections of the respiratory organs after the active symptoms have subsided. In chronic bronchitis, in humid catarrh, and in the after-stage of acute bronchitis, he has had the most fortunate results, but his statistics show that in phthisis the most surprising success has been obtained. Thus, in his last series of 60 cases of tuberculosis, there were 25 cases of apparent cure, 20 of these being in the first stage and 5 in the second, but none in the third. The improved were 20 in number, and of these 3 were in the first stage, and 17 in the second stage of the disease. He cites, in the course of the paper, several cases in illustration of his statistical data.

Creasote is administered in pill with balsam of tolu. He gives it for months without interruption in the dose of 40 to 50 centigrammes a day, or 5 to 8 grains. He conjoins the use of tonic medicines and arsenic, the latter especially being very useful, but attributes the disappearance of the pulmonary diseases to the creasote, maintaining that there is a regression, merely, of tuberculosis—an apparent cure—and that the patient is liable to relapses.

What is the mode of action? Dr. Reuss is disposed to attribute the curative effect of his combination of creasote and balsam of tolu to the cicatrizing and desiccating effect of the former and the balsamic and respiratory properties of the latter. If, however, phthisis is a parasitic disease, the effect of creasote may be referred to its action on the microbe of tubercle.

A NEW SYMPTOM OF FATTY INFILTRATION OF THE LIVER.

Lepine and Eymonnet have recently communicated to the Society of Medical Sciences, of Lyons, a new symptom of fatty degeneration of the liver. If urine be freed from its phosphates by a magnesian mixture or baryta, evaporated, and the residue ignited with nitrate of potassium and treated with acidulated water, the solution will contain traces of phosphoric acid. This is derived from the glycerin-phosphoric acid contained in normal urine, and is a constituent of lecithin. In several cases of fatty liver, these observers found this secondary phosphoric acid increased five to tenfold, which is in accord with the fact that a considerable quantity of lecithin, as much as three per cent., is found in fatty liver.

THE NEW SURGEON-GENERAL U. S. ARMY.

After an unusually long delay The President has appointed as Surgeon-General U. S. Army, to fill the vacancy created by the death of General Crane, Dr. Robert Murray, the Senior Medical Officer of the Corps.

Dr. Murray is a native of Maryland, and having been born in August, 1822, has yet a little over two and a half years to serve before reaching sixty-four years, the age of compulsory retirement. He was appointed Assistant Surgeon U. S. Army in 1846, and after a few months' service at Fort Geatint, Michigan, was transferred to California, where he served successively at Los Angelos, Monterey, and Camp Far West, until the fall of 1850. He then served at Fort Independence, Boston, and in New York City, until April, 1854, when he went to California. He was commissioned Surgeon United States Army, June, 1860. During the war he was Medical Director and Purveyor of the Department of the Cumberland until 1862, and then Medical Purveyor at Philadelphia until 1865, Medical Purveyor Military Division of the Pacific, San Francisco. Lieutenant-Colonel and Assistant Medical Purveyor U. S. Army, July, 1866. Was brevetted Lieutenant-Colonel and Colonel U. S. Army, for faithful and meritorious services during the war. Medical Purveyor at San Francisco, Cal., September 30, 1865 (commissioned Assistant Medical Purveyor, U. S. Army, July 28, 1866), to March 13, 1877. On duty at San Francisco, Cal., examining quality and condition of medical supplies at Purveying Depot, and awaiting orders March 13, 1877, to January 2, 1878.

Medical Director, Division of the Missouri, January 2, 1878 to September 4, 1882. Medical Director, Division of the Atlantic and Department of the East, September 7, 1882, to present date.

This appointment creates a vacancy in the office of Assistant Surgeon-General, which by regular promotion, will be filled by the appointment of Col. Charles Sutherland, Surgeon U. S. A.

POISONOUS PAPERS IN THE KINDERGARTEN.

IN the issue of THE MEDICAL NEWS for March 24th we called attention to the danger arising from the use of arsenical papers in the kindergarten. We are gratified to learn as the result of this, and of the consequent agitation of the matter, both here and in Boston, that these kindergarten papers can now be had free from all poisonous properties.

The trouble seems to be further back than the manufacturers of the papers, and exists with the color-makers. Colors even guaranteed by the makers to be free from arsenic were found to be largely made up of that poison, and many colors heretofore harmless are now being made from arsenic. Both greens and reds, and even blues, purples, and other colors are now very frequently arsenical to such an extent as to be very dangerous.

So true is this of wall papers, that we would advise having all such papers tested by a competent chemist before having them hung.

We are very glad to learn that through the efforts of one of the makers of kindergarten papers, Messrs. Milton Bradley & Co., of Springfield, Mass., all their poisonous papers have been replaced by harmless ones. They guarantee them absolutely pure, and analyses made by Prof. Henry Leffman have demonstrated the correctness of their statements. In this city these papers can be had of the Friends' Book Association, 1020 Arch Street. We strongly advise kindergartens not to use papers that have not been previously tested and found free from arsenic. This is a matter which concerns every parent, and we trust that the daily press will call attention to the risks run by kindergarten children from this cause, and the ready method by which they may be avoided.

MEDICAL REFORM.

THE practical tendency of New Code medical reform is illustrated in the contribution to the columns of a New York contemporary, of a letter from a Thompsonian "Professor" of Cincinnati, who advocates a State Board of Examiners, and a high standard of acquirement. The medical college in which this botanical or steam doctor exercises his professorial privileges, is a "chartered institution" and as legal as the best of them, and is surpassed by none in the liberality of its teachings and in the elasticity of its requirements for graduation. They are for reform in the Physio-Medical College of Cincinnati. They are opposed to all restrictions on consultations, and hence approve of the New York Code, and that free trade in medicine which is limited only to chartered institutions and legalized practitioners. They favor a State Board of Examiners in the interests of a higher medical education, and, secure in the learning of the Thompsonian school, they simply require as a condition of their acceptance of the proposed scheme that the Examiners shall be representative men of the steam system. They, too, wish that the requirements for admission to the medical profession be of the loftiest description—that those who aspire to begin the study shall be able to read the Constitution, cipher as far as the "rule of three," and translate *E Pluribus Unum*, and that those admitted to graduation shall have attended a six week's term in the Physio-Medical College, in the course of which they learn the "sanative" virtues of lobelia, the composition of "number six," and the horrors of "calamy" and "old-school" physic.

The "Physio-Medicalists" are for the New Code and reform. They have taken the field against old-school fanaticism and intolerance. They have taken their stand by the side of our New York contemporary and reform. The world is tired of old physic, and clamors for the new—the Physio-Medical comes to the front. The effete institutions under "allopathic" control must conform to the spirit of the age, and adopt the steam-box, lobelia, and "number six!"

The Medical Record takes exception at the figures put forth by the Central Organization of the New York State Medical Association to uphold the National Code of Ethics, and endeavors to throw discredit upon them. Then, assuming a reversal of the figures to be correct, it asks "will a minority of the profession continue to try and force upon the majority the enactment of a disciplinary by-law, which accomplished nothing but to lower the physician in public esteem?"

REVIEWS.

A MANUAL OF AUSCULTATION AND PERCUSSION; EMBRACING THE PHYSICAL DIAGNOSIS OF DISEASES OF THE LUNGS AND HEART, AND OF THORACIC ANEURISM. By AUSTIN FLINT, M.D., etc. Third edition, revised. 8vo. pp. 242. Philadelphia: Henry C. Lea's Son & Co., 1883.

THAT a new edition of this useful little work has so soon come before us, is a hopeful sign of the times. The last generation of practitioners to whom physical diagnosis was a new-fangled art, rests from its labors. To the doctor of to-day, percussion and auscultation are essential, and their acquirement has become a necessary part of his training. To this state of affairs no worker living has contributed so much as Austin Flint. The light kindled by Auenbrugger, and handed on by Piorry, Laennec, Skoda, Wintrich, Williams, he caught and tended till its radiance not only lights up our western world, but is reflected back to the old world whence it came. Out of confusion he has by his analytical method brought clearness, and many signs that at one time served merely as subjects for learned and often pointless discussion, he has made available to the every-day practitioner for the diagnosis of disease. In the present edition the changes are few and for the most part of the nature of further illustration of difficult points. The modes by which pulmonary signs may be reproduced in the lungs removed from the body and by artificial means, are among them.

THE ESSENTIALS OF BANDAGING, ETC. By BERKELEY HILL, M.B., London, F.R.C.S. Fifth Edition. New York: J. H. Vail & Co.

THE first section of this work which treats of the subject of bandaging, is one which probably to the American reader will seem most incomplete, for we notice the absence of many useful and ingenious bandages which are very generally used by surgeons on this side of the Atlantic.

This defect is not so noticeable in the next section which treats of fracture dressings, for here many American methods of treatment are described at length.

The use of plaster of Paris in the treatment of fractures, and the use of Sayre's plaster jacket in Pott's disease of the spine, receive each an extended notice.

The various surgical procedures such as venesection, transfusion, introduction of catheters and bougies, plugging the nares, etc., are clearly and briefly described, and in many cases well illustrated. In discussing the subject of anæsthetics, p. 222, the author makes a statement in regard to the general safety of chloroform from which we must strongly dissent. One of the most interesting and instructive chapters in the work is that treating of surgical landmarks; this of itself would be sufficient to recommend the work to a most favorable notice. The book contains so much valuable information that we can readily understand the favorable reception with which it has met at the hands of the medical profession and students which has necessitated the appearance of this, its fifth edition.

BURR'S INDEX TO MEDICAL SUBJECTS. Adapted to the Special Use of Physicians and Surgeons. Manufactured by the Burr Index Company, Hartford, Conn.

THE *Medical Index*, manufactured by the Burr Index Company, of Hartford, Conn., is by far the most convenient and valuable work of the kind that we have ever seen. The different amounts of spacing under the same letter are most judiciously arranged; all words entered are indexed by the first two letters; and the references are rendered especially easy by notches cut in the edges of the leaves, through which, when the index is opened at any letter of the alphabet, the combinations of each letter appear in full. The projecting alphabet, printed in golden letters on morocco leather, moreover, greatly facilitates the finding of the location of the headings, as it does away with the necessity of turning over the leaves. From the short trial that we have made of it, we have no hesitation in declaring that it admirably fills a need that we have long felt.

SOCIETY PROCEEDINGS.

COLLEGE OF PHYSICIANS OF PHILADELPHIA.

Stated Meeting, November 7, 1883.

THE PRESIDENT, ALFRED STILLÉ, M.D., IN THE CHAIR.

DR. ROBERTS BARTHOLOW read a paper entitled

ENTERIC PARAPLEGIA.

By the term enteric paraplegia, he said, I intend to express the conception of a spinal paralysis, produced by an intestinal disorder. It is a truly reflex paralysis. The fact of the existence of such a malady is denied by many, and indeed most of the reported examples will not bear careful inspection, for it will be found, as I shall show, that they are really cases of ascending neuritis. Eliminating such from the examples of true reflex paraplegia to be found recorded, I intend to place the latter in a special group composed of cases presenting the symptoms of an enteric disease, during the course of which, a motor and sensory paraplegia manifests itself, and pursues a course obviously dependent on the original lesions. The cases I have lately seen occurred in men over sixty years of age, and each one presented a morbid complexus so distinctive and uniform as to entitle it to be regarded as a substantive affection—a pathological entity. Although such cases have been described as examples of reflex paralysis, they have not been adequately differentiated from others similarly classified, but of different nature.

Before attempting the task of analysis and differentiation, I must give a brief outline of three cases, the most recent which have come under my observation.

Case I.—Mr. R., æt. 64, merchant and banker, of very vigorous and robust frame, rather spare and bony in outline, but capable of great endurance, called on me a year ago, amongst other physicians of this city, for relief to an obstinate bowel affection. His story was this: for a year or more previously he had suffered with intestinal indigestion, colicky pains, flatulence, and considerable depression of spirits. Soon after these symptoms were experienced, he began to have pain in the back, with more or less band-like constriction of the abdomen, a feeling of numbness in the feet and legs, a strong sense of fatigue in the inferior extremities, followed by weakness and awkwardness of movements in walking, obstinate constipation, and slowness in the emission of urine. For the relief of these alarming symptoms he consulted an eminent practitioner of this city, who diagnosticated myelitis and advised cups, the moxa, and a pill which probably contained ergot. Without using any of the local applications, Mr. R. took the pills, which had a favorable effect in relieving the flatulence and constipation, but presently dysenteric attacks supervened, and then a remarkable change ensued in the spinal symptoms. Up to this period, the paraplegia had steadily increased, and walking had become exceedingly difficult, but the change in the condition of the intestine, effected a revolution in the state of the spinal functions, and in the course of a few weeks, all the paralytic symptoms had disappeared. Still troubled with intestinal indigestion, Mr. R. finally consulted me amongst others, when I learned the details of the case just given. Very recently I have heard that Mr. R. continues free from the spinal symptoms, and has in the main got rid of his intestinal disorder.

Case II.—Mr. P., a tall, thin, but hardy Quaker farmer, æt. 72. I saw the patient at his home, near Delta, York Co., this State, in consultation with Dr. Hickman, a very intelligent practitioner living there. I learned that the patient some ten years before had experienced a similar attack, but had recovered rather suddenly under the influence of some remedies which were then prescribed. For some years, he remained comparatively free from disorders of digestion. The present attack came on during the past winter; at first there appeared a very considerable disturbance of digestion—acidity, pyrosis, flatulence, and colicky pains. The distress was increased by taking food, and apparently attained its maximum when the alimentary materials entered the intestines. In fact, the symptoms of intestinal indigestion were the most pronounced throughout, and to these were added obstinate constipation, the stool consisting of balls united by masses of mucus, or coated with the same. Very soon after the gastro-intestinal catarrh was established, Mr. P. began to experience numbness of the feet and legs, and an increasing difficulty of locomotion.

At the time of my visit with Dr. Hickman, the patient was nearly entirely disabled. The history of very severe and continuous digestive troubles was repeated. I will, therefore, to occupy as little time as possible, pass on to the objective examination of the paraplegia.

He could not stand without assistance; there was an extreme degree of ataxia; the muscles were so weak that his utmost efforts could not at all hinder slight movement of extension when the legs were flexed on the thigh; the tactile sense was so lowered that the points of the æsthesiometer could not be felt at all; the muscles responded feebly to an induction current; the emission of urine was very slow, and there was much dribbling afterwards, and the bowels were extremely sluggish. There was a feeble knee-jerk.

With attention directed entirely to the digestive trouble, beginning with an exclusive milk diet, in two weeks a marked improvement was manifest in all the symptoms, the paraplegia disappearing. In a letter recently received from Dr. Hickman, I learn, that after a period of very great improvement, Mr. P. began to decline in strength, owing to failure of the functions concerned in nutrition.

Case III.—Mr. McK., of Clearfield Co., about sixty years of age, has had for many years frequent attacks of sick-headache. Within the past year, pronounced symptoms of intestinal indigestion, pain of a colicky character, flatulence, and irregular action of the bowels, etc., have come on; but the symptom which has caused the greatest apprehension, and on account of which, more especially, he has called on me, is an increasing numbness with some diminution of power of the inferior extremities. The tactile, pain, and temperature senses, are not abolished, only slightly impaired, and the tendon reflex is unaffected. A feeling of fatigue, of weight and heaviness is felt in the legs, but locomotion is not as yet much affected. I await further developments in the symptoms referable to the nervous system, but meanwhile treatment is directed to the gastro-intestinal disorder.

Cases similar to those which I have thus briefly outlined, have been recorded by various observers. An admirable example, and one of the first of its kind, was narrated by that eminent clinician, Graves, of Dublin (*Clinical Medicine*, edition by Neligan, vol. i. p. 558). In this case extreme gastric disturbance, with less important intestinal, came on in distinct paroxysms, varying in duration from several days to two or three weeks, and accompanied by complete motor paraplegia. For a time, entire recovery took place, the paralysis disappearing with the cessation of the other symptoms. Finally the attacks grew so frequent as to be almost continuous, and death ensued from exhaustion. The minutest examination failed to disclose a lesion in any organ of the body. With the advance in our means of investigating morbid states, such cases of presumed functional disease of the nervous system are becoming more and more rare. That there is a condition of reflex paraplegia, due to anæmia of the cord, is a postulate I expect to maintain. That there is, however, a so-called reflex paraplegia connected with diseases of the gastro-intestinal and genito-urinary tracts, which is not truly reflex, is another postulate that I believe to be susceptible of demonstration.

There was a period, in England more especially, when the notion of reflex paraplegia secondary to intestinal, renal, and genital disease, was widely entertained. The cases first reported by Stanley (*Medico-Chirurgical Transactions*, vol. xviii. p. 260), Brodie (*Lectures on Urinary Organs*, p. 115), Stokes (*Practice of Medicine, Treatment of Nervous Diseases*), Graves, and others, were supplemented by the striking narratives of Gull (*Guy's Hospital Reports*, various papers). Then Brown-Séquard (*Lectures on Paralysis, etc.*, 1861) gave a scientific explanation of the mechanism, referring the paralysis to vaso-motor action. It must be admitted, nevertheless, that the doctrine of a reflex paralysis has not maintained the position it once had. In no modern work is the subject treated with the extent and gravity befitting an important disease.

The two postulates I purpose to sustain, are:

1. That there is a reflex paraplegia due to a functional disturbance of the intestine—enteric paraplegia.
2. That there is a paraplegia having its initial seat in the end-organs of the nerves distributed to the mucous membrane, thence ascending to the cord by a progressive neuritis.

As respects the first postulate, the cases I have narrated, and many others on record, demonstrate a causal connection between the enteric disorder and the spinal. That the paraplegia is functional is proved by its prompt cessation when the cause is removed. One of the means of determining whether a given paraplegia is due to a myelitis, or to mere anæmia—that is, functional—is the subcutaneous injection of strychnine. At a late meeting of the American Neurological Association, Dr. Jewell, of Chicago, recounted his experiences with considerable doses of strychnine in cases of paraplegia, which improved so remarkably that they must have belonged to the merely functional group. It is in a high degree probable that cases of merely reflex paraplegia—of enteric paraplegia—especially as they occur in aged subjects, are relatively frequent, and happen from a degree of intestinal disturbance that seems a mere accident of the morbid complexus.

What is the mechanism? We are helped in our consideration of this question by physiological data. Kussmaul and Tenner (quoted by Erb), have shown that sufficient loss of blood will cause paraplegia. Tying the abdominal aorta, and its obstruction by disease—of which Gull (*Guy's Hospital Reports*, 1858, p. 311) has given a striking example—embolic blocking of the spinal vessels, as Panum (*Virchow's Archiv*, Band xxv.) has experimentally demonstrated, and large uterine hemorrhage as Moutard-Martin (*L'Union Médicale*, 1852) has shown, have alike stopped the spinal cord functioning. In other words, an insufficient blood supply—an anæmia—is a cause of paraplegia. Brown Séquard in his *Lectures*, published in 1861, maintained the thesis that a strong contraction of the vessels of the cord induced by reflex stimulation is the essential condition in reflex paraplegia. We should not lose sight, in this connection, of the degree of stimulation necessary. A moderate degree of intestinal irritation suffices—for the law of reflex contraction of the vaso-motor fibres may be formulated thus: irritation of the end-organs of the sensory nerves, not too violent and long continued, stimulates the vaso-motor centre in the medulla, and causes a general contraction of the arterioles; but excessive and protracted irritation depresses the vaso-motor centre and relaxes the vessels. It seems probable that an ordinary intestinal indigestion and the stretching of the nerve fibres produced by retained gas, is a degree of irritation sufficient to produce the supposed effect. To the further elucidation of the mechanism of enteric paraplegia, it is necessary to recall the fact that the blood pressure in the vessels of the intra-abdominal organs rises and falls within considerable limits in quite an independent manner, controlled, doubtless by the same ganglia that regulate the calibre of the intra-spinal bloodvessels.

The circulation within the spinal canal is peculiar, in that the veins bear such a disproportionate volume to the arteries, and that the whole vascular supply is in a certain sense a diverticulum. Atheroma of the vessels will contribute to the result of reflex irritation, and hence it is that paraplegia has resulted from endarteritis of the spinal vessels.

The second postulate, is that the paraplegia which succeeds to certain cases of enteric, renal, or genital disease, is due to an ascending neuritis. Chronic dysentery, pyelitis, and vesical catarrh, are affections during the course of which the spinal cord has become diseased. Lesions of continuity involving the terminal nerves in structural changes, are necessary to the production of this effect. The part which ascending neuritis may play in causing anatomical alterations of the spinal cord, is exhaustively shown by Friedreich in his monumental work on progressive muscular atrophy (*Ueber progressive Muskelatrophie, über wahre und falsche Muskelhypertrophie*, Berlin, 1873, Hirschwald). Whether we accept his conclusions or deny them, we cannot withhold the full measure of admiration for his labors. Starting with the theory of an intramuscular neuritis, Friedreich holds that by an extension of this affection upwards, the cord is ultimately reached, and the changes belonging to progressive muscular atrophy are wrought. The intramuscular neuritis admitted, the rest may easily follow. Under the term "Chronic Ascending Neuritis," Dumenil has described the changes in injured nerves which, caused by trauma, proceed from the point of injury up to and involve the cord. Vulpian has especially demonstrated the modifications produced in the spinal cord, by the section of a principal nerve in a member, usually the sciatic (*Archives de Physiologie Normale et Pathologique*, No. 3, 1868, p. 443). The nerves of a limb amputated, as Dickinson has especially shown, undergo degenerative atrophy, and that part of the spinal cord in anatomical connection therewith, also atrophies. Many other observations might be quoted, but these will suffice to show how changes in the cord follow injuries to peripheral nerves.

In paraplegia secondary to ulceration of the mucous membrane, we can readily, I think, conceive of a lesion of the peripheral nerves and an ascending neuritis to which the succeeding changes are due. It follows that such cases require a very different prognosis from those of simple reflex paralysis. The course and termination of the latter are affected by the causal lesions, whilst the former pursue a steadily unfavorable direction from the beginning of the spinal symptoms. The differentiation of reflex from secondary paraplegia is made by attention to the following points:

Reflex paraplegia is sudden in its onset, or, at least, develops quickly; secondary paraplegia is gradual in its evolution; the former is soon complete in all points of its symptomatology; the latter attacks one spinal function at a time. Reflex paraplegia follows the fortunes of the producing malady; secondary paraplegia pursues an independent course, and when the alterations begin in the spinal elements, they proceed in their own way, just as after amputation of a limb, the changes in the cord go on in the associated nerve fibres, or as in Landry's ascending paralysis, the lesions proceed by contiguity of tissue. Reflex paraplegia, of and by itself, never proves fatal, nor does it inflict permanent damage; secondary paraplegia may be the cause of death, and if not fatal, effects lasting mischief.

To this view of reflex paraplegia it may be objected, that extreme variations in the vascular supply must ultimately lead to structural changes. This is certainly possible, but the spinal, like the cerebral circulation, is arranged to permit considerable variations in the amount of blood.

It remains to explain, if an explanation be possible, why intestinal or renal lesions may in one case produce a merely reflex disturbance, and in another, set up an ascending neuritis. There are, probably, two reasons: 1st. The depth and extent of the peripheric lesions. 2d. An inherent susceptibility to degenerative changes in the nervous elements. The first to me has profound significance, and I have already alluded to it. A degree of peripheric irritation not too great, will merely stimulate the vaso-motor centres, and cause anæmia of the cord by tonic contraction of its vessels, but when the lesions of the mucous membrane are of a destructive kind, depression of the trophic centres, as well as of the vaso-motor, ensues. That there is a neuropathic type of constitution, in which the nerve-tissues are peculiarly prone to take on morbid changes is an indisputable fact. When the two influences coincide the result is not doubtful.

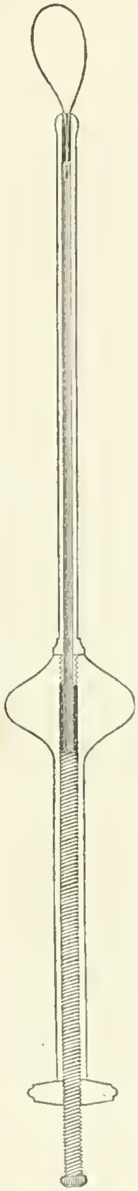
I must, then, conclude that there is a malady which may properly be entitled *Enteric Paraplegia.*

NEW INVENTIONS.

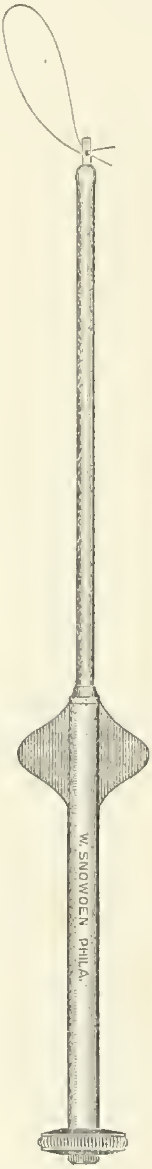
A NEW WIRE SNARE ÉCRASEUR.

By CHAS. E. SAJOUS, M. D.,
INSTRUCTOR IN LARYNGOLOGY IN THE POST-GRADUATE COURSE, JEFFERSON MEDICAL COLLEGE, ETC.

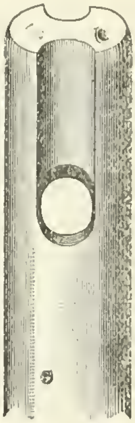
The accompanying cuts represent an instrument which I have had constructed for the extirpation of intra-nasal growths. While possessing all the merits of other wire écraseurs, it has the advantage of being much less complicated, and consequently easier of manipulation. It consists of five pieces: two cylindrical tubes, two rods, and a milled-nut.



Longitudinal section of instrument.



Its external appearanee.



Magnified end of needle-rod.

The two tubes are made of steel and of different sizes. The narrower one, or end-piece, is 4 inches long and $\frac{1}{12}$ inch in diameter, and is threaded at one end to fit tightly in that of the second or larger tube. This is only 3 inches in length and $\frac{1}{6}$ inch in diameter. The two rods are also of different sizes, their diameters allowing their introduction into the tubes, the cavities of which they fill, and along which they can move freely. The end-rod, about the thickness of a crochet-needle, is $\frac{1}{8}$ inch longer than the narrow tube and protrudes through it. Its end is furnished with an egg-shaped needle-eye. The other end is threaded to fit in that of the larger rod, which is also $\frac{1}{8}$ inch longer than the tube containing it, and threaded throughout its entire length for the movement over its surface of a milled-nut. This nut lies in close apposition to the posterior end of the large tube, and when revolved from left to right, causes the rods to descend. Near the middle of the instrument is a ribbed finger-rest to insure the operator a firm hold. Rotation of the rods in the tubes is prevented by a ridge in, and at the end of the larger tube, corresponding with a narrow, flattened, longitudinal surface on the threaded rod.

In other instruments, the wire has to be passed throughout the entire extent of the tubes and attached either to rings, pins, etc., or whatever the inventor may have thought best, a rather lengthly and sometimes difficult procedure, especially if the inside of the instrument be a little rusty. In that introduced in this paper, but a small piece of wire is needed, say two or three inches, as the case may be; this is doubled into a loop, and the ends passed through the eye until they protrude about a quarter of an inch. Traction being then caused by turning the milled-nut, the end of the rod will disappear in the tube, doubling the wire ends on the loop. As shown in the annexed cut, representing the end of rod as seen through a lens, a shallow groove connects the needle-eye with the tip of the rod on each side. When traction is induced, the ends on one side, and the apex of the loop on the other, half fill these grooves, and the pressure exerted by the surrounding tube holds them as tightly as in a vise. The edge of the needle-eye is rounded and smooth so as to avoid a too sharp bend in the wire, which would cause it to break. For operations in the pharyngeal vault, there is a curved end which can be attached to the narrow tube and held there by a self-acting spring.

Besides the simplicity of its construction, this instrument presents advantages which I think it advisable to enumerate:

1st. It is strong as well as light, and its different parts can readily be separated for cleansing.

2d. The wire can be attached in a moment and as rapidly withdrawn.

3d. The loop being close to its point of attachment, it is not liable to twist on its axis.

4th. The loop being at one end, the milled-nut at the other, and the point of support in the centre, it is evenly balanced.

5th. The milled-nut being immovable longitudinally, its rotation does not involve lateral motion of the operator's arm, thereby avoiding pressure of the point of the instrument against the tumor.

While being especially adapted to intra-nasal operations, extirpation of polypi, hypertrophic thickenings of the nasal mucous membrane, adenoid vegetations of the pharyngeal vault, etc., it seems to me that it could be used with advantage in gynecology, aural surgery, and all operations in which an écraseur would be indicated.

NEWS ITEMS.

ST. LOUIS.

(From our Special Correspondent.)

The St. Louis Medical Society and the Ethics of its Members.—The antiseptic spray has been turned on by the Medical Society, and a thorough cleansing process is undertaken, or at least attempted. Erratic brethren exist in the Medical Society of St. Louis as they do in the societies of all other cities, neither more nor less; and though pledged to obey the laws of the Society, as well as the Code of Ethics which governs all, they seek their own path, apart from the trudging masses, for the sake of making a short cut, or of enjoying a more pleasant voyage than they anticipate on the hard high road. The indulgent and kindly spirit which governs the profession, forces them to wink at this proceeding and ignore it unless the independent brother strays too far away.

The unusually cool and pleasant summer which we have enjoyed, has obviated the necessity of the usual vacation which takes place in the meetings of the Society, and fresh in body and mind the fall meetings have been entered upon with unusual activity and interest. Unwillingly, but most necessarily, has the attention of the Society been directed to certain professional irregularities existing here, as they do everywhere, and ignored unless they become so public and excessive as to injure the profession by the odium attached to any one of its members. It is not a local matter merely, as similar conditions exist in many other Societies, and those members of the profession who make an effort in the right direction, taking upon themselves the often unpleasant task of upholding the dignity of their calling, should have the hearty support of their brethren throughout the land.

Certain of the physicians of this city have come into remarkable notoriety of late; and the St. Louis Medical Society was first aroused to action by the doings of a man, indeed, a regular graduate and member of the Society, who has been repeatedly arraigned before the court of criminal correction for the crime of abortion, and who has now been expelled from the Society for other irregular performances. This innocent has sued the committee who recommended his expulsion, for fifty thousand dollars damages, as an appropriate equivalent for the injury done to his character.

MEDICAL ADVERTISING.—The subject of ethics has brought up for consideration minor matters. Thus the circular sent out by an enterprising young member, who some years ago was reprimanded by the Society, and would have been expelled had the opinion not prevailed that no such power was vested in the organization, by reason of a verdict of a court many years ago, which had reinstated a member thus expelled. The gentleman now before the house had issued a circular in recommendation of a new enterprise upon which he had entered; although the circular shown was received by a layman, the author claims to have sent them to the profession only. Urged by the Society, upon recommendation of its committee on ethics, to withdraw said circular, he resigned, and was permitted to do so. His claims of having merely announced his institution to the profession, and the consequent action of the Society, make it appear to those ignorant of the details that he is a sadly persecuted individual. Some of the daily papers have even represented him as such: as an independent man suffering from the restrictions of an antiquated Code. Were the terms of the circular known, which come as near guaranteeing a cure by operation as can well be done, the public and the profession would think otherwise. The gentleman justly claims that he cannot, without advertising, successfully compete with older institutions, forgetful of the fact that such older institutions are the result of the hard work of earnest men throughout long years—perhaps the work of a lifetime, and have by fair means won the esteem of the public, which learns to know the merits of men and institutions without the aid of circulars or daily papers.

Quite a number of gentlemen, seeing the course taken by the Society, followed with their resignations, unwilling to give up the advertisement of their specialties; even that of a member of the committee on ethics was presented, as he seems disinclined that his advertisement for the cure of consumption should come before the Society. All this is advertising *not* accord- to the Code. Other advertisements (in accordance with the Code?) have not been considered, such as those of the schools, or of the professors of colleges, who certify to the harmlessness of "Horse-shoe" tobacco, or the certificates which accompany the recommendations of various medicinal preparations, attested to by men of prominence and otherwise throughout the country, their positions and specialties carefully appended to their names.

This is a question which has been before the profession before, as we may see by the action taken by the American Medical Association in 1868, where a committee was appointed to report on the subject of specialties in medicine, and the propriety of specialists advertising. Four resolutions were then passed: 1. Specialties are legitimate fields of practice. 2. That specialists shall be governed by the same rules of professional etiquette as all other physicians. 3. That it shall not be proper for specialists publicly to advertise themselves as such. 4. That private hand-bills, addressed to members of the medical profession, or cards in medical journals calling attention to themselves as specialists, be declared to be a violation of the Code of Ethics; though it is proper for a physician to announce that his practice is limited to a certain disease or diseases, "that such is simply a note of limitation, but involves no other principle than the notice of the general practitioner, that he limits his business to certain hours of the day; neither would it be regarded as a claim for especial qualifications."

These matters will now assume greater importance and publicity, as specialists and specialties are becoming more numerous; and the beginner or the unsuccessful specialist, jealous of the success of his more able or more fortunate colleague, seeks by public prints or circulars, and cards in the daily papers, to bring himself into that notice which the other has acquired by patient labor of years.

There is, however, a just claim made, by those gentlemen, of equal advertising rights with college officials, whose specialties and positions are most liberally advertised by college circulars and notices in the daily and medical press. But simple Dr. A. advertises his specialty as does the renowned Dr. B., who has the good fortune to be *Professor* of the particular branch. A. pays out of his own pocket for the pleasure, whilst the college settles the bill for B. Colleges might advertise like all other schools; no institution of learning details the names of its teachers, except in its annual announcement, never in standing advertisements. Why is this done by medical schools?

There can be no question as to the wording or meaning of the Code of Ethics of the American Medical Association, which is adhered to by all other associations, or the rules so distinctly laid down by the American Ophthalmological Society, which do not even permit the word "oculist" to be used in connection with any public notice of the physician doing an ophthalmological practice; that his sign must read as plain "M.D.," without limitation or addition. So many are advertising freely without infringing the Code, that it certainly seems unjust that the physician not favored by such accident which permits of this, should be prevented from placing his name with equal publicity before the profession and laity.

It would be well if these questions were pushed to an issue before the St. Louis Medical Society, and if the societies of other cities would bestir themselves, and call to task their offending members, as well as those offending under the semblance of the law. A strict line should be drawn and a law made to govern every member of the regular profession without exception; and all offenders punished, or else they should be exonerated and their action thoroughly justified.

Country practice is the great incentive to advertising, as numbers of the ailing in smaller towns and remote districts coming to the city for relief, are guided by the advertisement which best pleases and suits their fancy. If we have a law such as the Code of Ethics of the American Medical Association, we must obey it; it is the result of thoughtful deliberation of able and honorable men, and that it is pretty nearly correct may be argued from the similarity of the regulations which govern the members of the medical profession in other countries.

As the St. Louis Medical Society has once begun the work, let it go on fearless of consequences; however unpleasant it may be to wound the feelings of a brother practitioner, let right be done; and let the profession elsewhere second these efforts and urge bold action. Let us adhere to the decision of chosen men, whatever it be. It is, as a rule, the restless jealous minority, unwilling to seek success by the slow process of hard work, who are anxious for other and easier means of rising above the surface; and such advertising should be squelched, but the law must apply to all alike.

CHICAGO.

(From our Special Correspondent.)

The Rush Hospital Medical College.—The new hospital building in connection with Rush College is being pushed forward toward completion. It will be ready for occupancy next spring.

The Cook County Hospital.—The two new pavilions of the Cook County Hospital are nearly ready to be occupied. They will accommodate about one hundred and fifty patients.

The Medical Colleges of Chicago show about the usual number of students at this season. The Chicago College has about one hundred and fifty pupils; the Rush about four hundred and twenty-five; the Woman's about ninety; the College of Physicians and Surgeons about one hundred and fifty.

Rush Medical College.—Dr. W. T. Belfield has been appointed a Lecturer on Surgery in Rush College, to take the place of Dr. Roswell Park, who resigned some weeks ago to accept the Professorship of Surgery at Buffalo.

CINCINNATI.

(From our Special Correspondent.)

The Miami Medical College.—Dr. William A. Rothaker has been appointed Lecturer on Pathology in the Miami Medical College, and began a course of lectures there this week. Dr. Rothaker is a young man of more than ordinary ability, and the Miami College is to be congratulated in its choice of one so peculiarly fitted for the position. The lectures that Dr. Rothaker has delivered as pathologist to the Cincinnati Hospital have won for him an enviable reputation, both because of his familiarity with the subject and his ready use of language. Among his literary productions is the text accompanying the *Atlas of Obstetrics and Gynecology*, published in this city a year ago.

Dr. William B. Thornton, one of the oldest practitioners of this city, died recently at his residence on College Hill. In his will he provided substantial endowment for a Thornton professorship in Wabash (Indiana) College.

BALTIMORE.

(From our Special Correspondent.)

The Johns Hopkins Lectures on Municipal Hygiene.—Dr. John S. Billings has been lecturing at the Johns Hopkins University before the students of the University, persons interested in sanitary science, and the administration of cities, and the medical profession, on Municipal Hygiene. He has already delivered several interesting lectures of his course of twelve. The following is a brief abstract of the chief points discussed in the first four.

Sanitary science is not a perfect science; many of its results can only be said to be probably true, and definite laws are not yet established. But it is much better to know what is likely to promote healthfulness than to be ignorant of the matter. This is the age of cities; they have been growing very rapidly. This has its good and its evil side. The sanitarian and statesman's object is to keep the good and get rid of the evil. This they should try to do, not only on ethical grounds, but also because it is practical—it pays. The sanitarian tries to check unnecessary waste of life, to make men's lives happier and longer, and freer from pain, to increase the productive powers of the citizens, and indirectly to prevent vice and crime, which flourish under the same conditions as disease. He studies the influence of existing conditions upon the life and health of the citizens by means of vital statistics. In collecting vital statistics he finds great trouble for many reasons.

Mortality (*i. e.*, ratio between number of deaths and number of living inhabitants, per thousand) is much greater in cities than in rural districts. In cities it increases with the density. The mortality is not equally distributed among all classes, and is greater among males than among females, greater among colored population than among white, and is greater among the lower classes. In cities it is greatly affected by prevailing occupations, and by emigration and immigration. The birth-rate in cities is greater than in the country. Among the American families in New England, the birth-rate is gradually lowering, so that in some districts the birth-rate does not exceed the death-rate. The construction of life tables showing expectation of life is of great importance. In many places they are, however, very difficult to construct, on account of insufficient data. They should be made for male and female, white and colored population, in the various parts of city and country.

Of late years attempts have been made to study statistically the diseases which cause death, and to classify them. They may be divided into (1) hereditary, (2) physical and chemical (due to weather, climate, soil, etc.), (3) organic and vital, (4) mental and emotional. To the third class belong the bacterian diseases, which are divided into (1) parasitic, (2) contagious, (3) miasmatic, and (4) miasmatico-contagious. The Romans believed that certain diseases were caused by living animals in the human body. This notion was first put into a scientific theory by Pasteur, and it is now known as the "germ" theory. Many have been working in this field; one of the most important results is Pasteur's "attenuation of virus," by means of which a second attack of the same disease can be prevented. Septicæmia and like diseases are now believed to be due to the germs of putrefaction. In this direction, great strides have been made, so that the dangers of surgical operations are very greatly diminished. The importance of thorough investigation of this subject is recognized by several European governments, which are spending great sums of money for their prosecution—our government, on the other hand, is still doing nothing.

Water and its Supply.—By water many diseases are conveyed; great care must therefore be exercised in its supply. The old division of water into wholesome, suspicious, and dangerous must be accepted with some modification. Rainwater is not pure, always containing germs which it has washed out of the air. To secure a good supply of pure water is the great problem. In large cities it is practically impossible to preserve wells unpolluted, the vault and the well are often in direct contact, as, for example, the "sulphur" wells of Baltimore and Washington, a few years ago. The danger is due to living organisms present. How much of foreign substances are living, chemistry cannot tell. The biologist can, by observing growth, effects, etc. Dr. Koch found thirty-eight million microdermes (living organisms) in a cubic centimetre of impure water, but in the same quantity of pure distilled water only four. His experiments show that water with more than one hundred and twenty microdermes to the cubic centimetre is unfit for drinking purposes. The chemist can do two things: (1) determine any gross pollution, and (2), by making periodical examinations of a given supply, detect any change from its normal condition, which can then be investigated. All attempts to pollute the water supply above the city should be prevented. When none but suspicious water is available to a city, it can be greatly purified by filtration, especially through spongy iron, which destroys the vitality of germs. Waste of water, caused chiefly by leaky fittings and bad faucets, is a great drain on water supply, much greater than one would think. Manchester, Liverpool, and Glasgow require all fittings to be examined, and by an ingenious method discover all leaks, which are speedily repaired. By these means these cities have sufficient water, while otherwise they would be in great want.

LONDON.

(*From our Special Correspondent.*)

The Debate on Prof. Lister's Address.—The debate before the Medical Society of London, on Monday, November 5, proved to be of considerable interest, and the hour of adjournment was overstepped by another hour to allow of the full discussion of this remarkable subject, but more especially to hear what Prof. Lister had to say in answer to the objections made against his theory and practice. Mr. Bryant was the first to speak, and in an able though rather discursive manner, he apparently made out a strong case against Prof. Lister's teachings. Of the value of antiseptic surgery, Mr. Bryant had no doubt, but on the evening in question he joined issue with Prof. Lister on at least three points. He complained of the too confident expressions used by him. He did not think the operation was called for or justifiable in most cases of simple recent fracture of the patella. And lastly, he contended that strict Listerism was not necessary in order to be perfectly in accord with the grand principles of antiseptic surgery. Readers of Prof. Lister's address will not fail to see that the charges brought against the language of the address, referred to such phrases as "morally certain that septic influences could be avoided"—"convert serious risk into absolute safety and certainty." Mr. Bryant said, indeed, he thought that Prof. Lister did not really intend these statements to be so absolute, for in another part of the paper allusions were made to certain "disasters that might occur." He considered the operation unjustifiable because the results of the old-fashioned treatment were in his experience quite satisfactory. It is true that in many instances there was separation for more than half an inch, but the utility of the limb was by no means impaired.

Besides Mr. Bryant the discussion was joined in by Messrs. Adams, Bloxam, Gant, Henry Morris, William Rose, G. R. Turner, Morrant Baker, Edmund Owen, and others. Most of these gentlemen concurred in the views expressed by Mr. Bryant. Messrs. Bloxam and Rose were exceptions, however, and both these gentlemen had performed the Listerian operation three times with remarkably good results. Perhaps, the speech by Mr. Henry Morris told best of all against Mr. Lister. Mr. Morris made much of the statement, probably used only figuratively by Mr. Lister, to the effect that a first year's student could perform the operation, so simple were the procedures. Stress was also laid by Mr. Morris on the friability of the bone forming the patella. This was proved not only by the primary accident, but also by the fact, vouched for also by Mr. Bryant, that refracture takes place not through the seat of ligamentous union, but through the bone and generally the lower fragment. Mr. Morris thought that antiseptic principles were the main ones, and drew a distinction between Listerism and other modes of attaining the ends of antiseptic treatment.

But to our minds, in his reply, Mr. Lister was not only fully equal to the occasion, but actually came off almost more than conqueror. He ventured to say that even Mr. Bryant would be surprised to see the records of his (Mr. Lister's) death-book. He had operated on numbers of cases of ununited fractures of the femur and for loose cartilages of the joints without a single death or disaster; and in "a multitude" of cases of disease of the knee-joint with similarly good results. Answering Mr. Bryant, he would say that the disasters to which allusion had been made, were to be feared in the hands of those who did not carry out the strict antiseptic precautions, and he repudiated the notion that he feared such disasters in his own hands. He did not mean to say that he would encourage every surgeon to operate in cases of simple recent fractures. Far from it. But he did believe that with due care and proper precautions such operations might be made so free from risk that the operator might feel "morally certain that no septic influences should be introduced." The phrase "convert serious risk into absolute safety," had reference not to the condition of the patient, but to the prevention of all those diseases which come from the outside. For Mr. Lister, no separation could possibly be made between Listerism and antiseptic surgery; the one was coextensive with the other, and he denied that he had advocated any single stereotyped mode of procedure. He spoke well of corrosive sublimate, iodine, eucalyptus, salicylic wool, and other dressings. Mr. Lister also objected that the results of the old treatment of fractured patella were all that could be desired. His experience, indeed, led him to the opposite conclusion.

BERLIN.

(*From our Special Correspondent.*)

Anatomical Teaching at the Berlin University.—The lecture catalogue of this University is just out, but it does not exhibit the important changes recently made in the anatomical department. C. B. Reichert, the venerable successor of Johannes Müller, has at last consented to become restricted to the administration of the Anatomical Museum, in response to the combined efforts of the press, the government, and his own colleagues. German professors, as is known, are unremovable, and sometimes make a too prolonged use or rather abuse of this right. Long enough it was an open secret, that Reichert, otherwise so well merited, belonged to this category, and it was the unanimous opinion that the anatomical instruction at our largest university during the last ten years was in a very bad condition, and it threatened to become of serious detriment to the whole profession.

There is no doubt that Prof. Waldeyer, of Strassburg, who has been recently elected as a second lecturer in anatomy, will soon restore the diminished reputation of the anatomical chair. We are informed that he has appointed Dr. Hans Virchow, the son of the great pathologist, to be his second prosector (the first being Prof. R. Hartmarn, the anthropologist).

Discovery of the Mantle of the Fish-brain.—Nevertheless, Reichert's studies on the normal and comparative anatomy of the brain will not be forgotten. A pupil and former assistant of his, Dr. Rabl Rückhardt, who meanwhile acknowledges to have found it difficult enough to get over the detrimental influence of a school, whose leader indulged in the negation of every modern progress, has lately made a very important discovery. Until now, it seemed almost impossible to state a proper correspondence between the different parts of the brain of teleostian fishes. There existed unsettled controversies with regard to the interpretation of almost every region, particularly the lobi optici and what used to be called the hemispheres. The researches of some modern investigators, far from throwing light into this dark domain of comparative anatomy, only further complicated the question.

But lately Prof. Fritsch declared the "tectum loborum oysticorum" to be homologous to the pallium (mantle) of the higher vertebrates, being unable to find it in the apparently solid hemispheres. Now, Dr. Rabl Rückhardt has discovered this pallium *in loco*, reduced to a thin epithelial layer, covering the hemispheres. Between them there exists a cavity, being the second ventricle, not yet separated by a fissura pallii; consequently the two large ganglionic bodies forming the floor of this cavity, and formerly taken for hemispheres, must now be regarded as corpora striata. Rhinencephalon (olfactory bulbs), corpora striata, and epithelial layer constitute, together, the "cerebrum," and the reduction of what represented the seat of the highest intellectual powers in other vertebrates to a simple epithelial membrane, justifies our looking on the fish-brain as on "an idiotic reflectory engine, so much beneath the brain of higher animals as a simple epithelium is beneath the complicated nervous tissue of the cortex." The proofs of the homologies drawn by Dr. Rückhardt are derived partly from the embryology of salmonides, partly from a series of microscopic sections of the brains of adult fishes, together with the cranium, by means of imbedding the latter in celloidine (collodion), which keeps the very thinnest membrane in its original position. A hundred years' controversy is thus brought to a satisfactory conclusion.

The Dubois Reymond Jubilee.—On the 22d of October, E. Dubois Reymond, the well-known physiologist and philosophical essayist, celebrated the twenty-fifth anniversary of his nomination as a professor under the general sympathy of his friends, pupils, and colleagues.

New Quarantine Regulations at Pensacola.—At a meeting of the Board of Health of Escambia County, Florida, on the 10th of November, it was

Resolved, That from and after the 15th day of May, and until the 1st day of November, A.D. 1884, no vessels from Havana, Vera Cruz, Rio de Janeiro, or other points where yellow fever has actually appeared, shall be permitted to dischhrge ballast or receive cargo in the Port of Pensacola.

That all vessels sailing from other ports of the West India Islands, Central and South American States, and points subject to infectious or contagious diseases, and arriving in the Port of Pensacola, on and after the 1st day of May, and before the 15th day of November, A.D. 1884, shall discharge their ballast in quarantine, be fumigated and cleansed, and remain in quarantine at least ten days after fumigation, and may then be released by the quarantine physician, approved by this Board.

That vessels from Havana, Vera Cruz, Rio de Janeiro, and Aspinwall, and all vessels having unclean ballast on board, arriving in this port, between the 1st day of November, 1883, and the 15th day of May, 1884, shall discharge their ballast, either under water, below low water mark, or must discharge their ballast at quarantine station, subject to the orders of the officer in charge of that station.

Yellow Fever at Havana.—Sanitary Inspector Burgess, of the Marine-Hospital Service at Havana, reports that there were eighteen deaths from yellow fever in that city during the week which ended on the 15th inst., and that the number of cases in the city and harbor was about seventy-five. He adds: "At no time during this year has so large a proportion of the sailing vessels in the harbor suffered from yellow fever as are now suffering from it."

Cholera Quarantine Raised in China.—The State Department is in receipt of a letter from the United States Legation, dated Japan, Tokei, 20th October, 1883, announcing that, as the cholera epidemic at Swatow has almost died out, the enforcement of quarantine against that point has been discontinued.

Successful Treatment of Cholera.—Our Consul at Port Louis, Mauritius, transmits to the State Department an account of the successful treatment of cholera in that vicinity by Mr. T. Edward Fyers. "It shows that Mr. Fyers, although not a physician, saved by the following simple treatment one hundred and forty-nine persons out of one hundred and fifty, who were attacked by the disease. On the first appearance of an attack, or as soon as possible afterward, there was administered an emetic of 30 grains of ipecacuanha and 2 grains of tartar emetic. After the emetic had acted copious doses of warm water were given to clear the stomach. In case either vomiting or purging continued, the usual doses of diluted sulphuric acid were sure to stop it." The patient, Mr. Fyers recommends, should not be allowed to eat anything until the tone of the stomach has been restored.

University of Pennsylvania.—It is reported that the University of Pennsylvania is about to receive a legacy of $250,000, for the endowment of a training-school for nurses.

College of Physicians and Surgeons of Chicago.—Dr. Frank O. Stockton, of Newark, N. J., has been elected to the professorship of diseases of the nose and throat in this institution.

The New York Polyclinic, we are informed, opens the second session of six weeks of its second year, 1883–84, with a class of sixty physicians.

The success of the first year was demonstrated in the fact that the class numbered one hundred and sixty-one.

There can be no truer sign of progress in medicine in America than is evident in the earnestness with which practitioners are seeking clinical and advanced study in the various schools for graduates.

The Library of the Surgeon-General's Office.—The additions to the library during the past year, include 3912 volumes, and about 5000 pamphlets; making the total number in the collection about 60,000 volumes and 68,700 pamphlets.

Dr. David W. Yandell, of Louisville, has been recently elected an Honorary Member of the Medical Society of London.

Unveiling a Bust of Dr. Sims.—At the recent twenty-ninth anniversary of the founding of the Woman's Hospital in the State of New York by the late Dr. J. Marion Sims, appropriate exercises were held in the endowed ward of the building, at Fourth Avenue and Forty-ninth Street. A marble bust of the late Dr. Sims was presented to the Hospital by Mrs. Russell Sage. She paid a glowing tribute to the founder, and spoke of his warm attachment to the Hospital, which was the first of its kind in the world, and which, through his efforts, had achieved such success. After the unveiling of the bust, which was from the chisel of Dubois, of Paris, there were addresses by Dr. T. Addis Emmet and the Rev. Dr. O. H. Tiffany.

A British Tribute to Dr. Marion Sims.—In commenting on the great professional services of Dr. Sims, the *British Medical Journal* says: His achievements are written in imperishable letters in the annals of modern surgical practice; and there are thousands now living, and succeeding thousands in generations yet unborn will have reason to rise up and call him "blessed." The greatest success which any surgeon of genius can hope to achieve, is to be able to definitely and largely add to the power of surgery to save life, to relieve misery, and to effect cure. This success Marion Sims attained in a degree which few can hope to attain.

Sir Prescott Hewett, Bart., recently retired from the active practice of his profession. This step, however, we are glad to learn, was not due in any way to failing health.

Professor Burdon-Sanderson.—A Royal Society Medal has been presented to Prof. J. S. Burdon-Sanderson, for the eminent services which he has rendered to physiology and pathology, especially for his investigation of the relations of micro-organisms to disease, and for his researches on the electric phenomena of plants.

Professor Pajot has been recently recommended by the Faculté de Médecine, to fill the Chair of Clinical Midwifery made vacant by the death of Prof. Depaul.

Tubercular Disease of Lung.—The question of tubercular disease of the lung (especially with regard to heredity, contagiousness, and curability), and also of the relation of pneumonia to phthisis, is about to be presented to the Committee for Collective Investigation of Disease in Berlin.

Centenary of the Vienna General Hospital.—Next year will be completed the centenary of this great hospital, which has so long been the pride and envy of the world, and around which the memory of so many famous men lingers. In anticipation of this event, a most interesting work (*Die Medicin in Wien während der letzten 100 Jahre*) has been written by Dr. Puschmann, the Professor of the History of Medicine at the Vienna University, in which he reviews the whole progress of medical education at Vienna from the time (1744) when, at the instance of Maria Theresa, the illustrious Van Swieten—friend and pupil of Boerhaave—left his native place, Leyden, to establish himself in the Austrian capital.

Monument to Pinel.—Paris will shortly possess a monument of the great alienist physician Pinel, the Ministry des Beaux-Arts and the Municipal Council of Paris having responded to a proposal put forward by the Medico-Psychological Society. M. Ludovic Durand is the sculptor of the monument, which represents Pinel, standing, holding in his hand the chains which he has just struck off from a young girl who crouches at his feet. The monument will shortly be erected in the Place Pinel, a small open space close behind the great Hospital de la Salpêtrière.—*Lancet*, November 3, 1883.

The International Medical Congress, Copenhagen, 1884.—The following are the provisional programmes for several of the sections of the next International Medical Congress, to be held in Copenhagen, in August, 1884:

Laryngology.—1. Treatment of goitre. 2. Syphilitic affections of the larynx, their forms and frequency. 3. The prognostic signification of the different local manifestations of tuberculosis of the larynx. 4. The local treatment of diphtheria. 5. Medicated inhalations in diseases of the air passages. 6. Pathogenesis and treatment of spasm of the glottis. 7. The operative removal of foreign bodies and neoplasms of the air passages. 8. Treatment of nasal polypi—evulsion—galvano-cautery. 9. Paralyses of the larynx. 10. Methodical education of the voice.

Otology.—1. Operative opening of the mastoid process. 2. Nervous diseases of the ear. 3. Dissection of the organ of hearing, with special reference to its pathological alterations. 4. The importance of aural disease in determining fitness for military service. 5. The different kinds of subjective noises and their treatment. 6. Treatment of chronic catarrh of the naso-pharyngeal cavity. 7. The bearing of bacterology in otology. 8. Prophylaxis of chronic diseases of the ear after eruptive fevers. 9. Diagnosis of the intracranial complications of suppurative inflammation of the middle ear. 10. The importance of otology in general medicine.

Section of Psychiatry and Neurology—Psychiatry.—1. Statistics of mental diseases and psychiatric institutions of Northern countries. 2. Proposal for the conformity of annual reports of different insane asylums of different countries. 3. The rôle of colonies in the treatment of the insane. 4. The value of exercises in the treatment of mental diseases. 5. The rôle of schools in the production of mental diseases. 6. The temperature of the body during the primary stages of mental diseases. 7. Mental alienation in infancy. 8. Perversity of sexual instinct. 9. The psychical troubles which replace epileptic attacks. 10. The rôle of syphilis in general paralysis. 11. The anatomical characteristics of the heads of idiots. 12. What method should be employed to break up the use of morphine, and what are the best conditions for treatment?

Neurology.—1. The effect of lesions of the peripheral nerves in the production of the anatomical alterations in the central nervous organs. 2. The secondary degenerations in the brain and spinal cord. 3. The troubles of speech of central origin. 4. The visual troubles of cortical origin. 5. Cortical epilepsy. 6. Vaso-motor and trophic neuroses. 7. The value of peripheral organic affections (especially the sexual organs) in the production of functional nerve troubles, especially hysteria. 8. Amyotrophic lateral sclerosis or progressive amyotrophic bulbar paralysis, especially as regards the constancy of anatomical lesions, and its difference or identity with progressive muscular atrophy (Aran-Duchenne). 9. The curability of tabes dorsalis. 10. The rôle of syphilis in the etiology of tabes dorsalis. 11. Is the paralysis of Landry a particular disease, or only a symptom which may be produced by different pathological processes? 12. The value of nerve tension as a method of cure.

Section of Obstetrics and Gynecology.—1. The antiseptic method in laparotomy (Mikulicz). 2. Anæsthesia in laparotomy. 3. Early ovariotomy (Knowsley Thornton). 4. The treatment of fibromyomata of the uterus by laparotomy (Kœberlé). 5. Castration in fibromyoma of the uterus. 6. Castration in mental and nervous diseases (Regar). 7. Vaginal extirpation of the cancerous uterus (Schröder). 8. Dilatation of the uterus. 9. The operative treatment of prolapse of the uterus and the vagina. 10. Ovulation and menstruation. 11. The operative treatment of extra-uterine pregnancy (Litzmann). 12. International nomenclature in obstetrics (A. Simpson). 13. The albuminuria of pregnant women (Hälbertsma). 14. The treatment of abortion (Gaillard Thomas). 15. The management of delivery (Stadtfeldt). 16. Obstetrical anæsthesia. 17. Treatment of rupture of the uterus during labor. 18. Treatment of neglected shoulder presentation. 19. The Cæsarean operation and the substitutes for it (P. Müller). 20. Statistics of puerperal fever in Denmark, Norway, and Sweden.

A GOVERNMENT INSPECTION OF CATTLE AND DEAD MEAT DESIRED.—The convention called by the Commissioner of Agriculture to consider the contagious diseases of domestic animals met in Chicago on the 15th instant. In the absence of the Commissioner of Agriculture, Dr. Loring, the meeting was opened by Professor Morrow, of the Illinois Industrial College, and Senator Williams, of Kentucky, was made permanent chairman.

Elaborate papers were read by Professor Law, Dr. Salmon, of the Department of Agriculture, Dr. Parsons, Territorial Veterinarian of Wyoming, Dr. Gadsden, of Pennsylvania, and Mr. Saunders. All the grazing sections of the country from Wyoming to New Jersey were represented. The only disease which was deemed an appropriate subject for national legislation was the lung-plague among cattle. It was universally denied that any vestige of the disease exists west of the Alleghanies, and it was admitted that it does exist in parts of New Jersey, New York, Pennsylvania, Virginia, and Maryland. In all the papers and discussions the necessity of stamping out the plague was insisted on, not only to protect the herds of the West from infection, but to remove all suspicion, so that no discrimination can be reasonably made against them in foreign countries. The State law being inadequate, there was an evident determination among the leading breeders and grazers to insist upon action by the Federal Government in the matter of destroying the disease, and, since this is the only authority recognized abroad, it was also argued that a thorough inspection of all cattle and dead meat exported should be made, and a certificate of soundness given by the officers of the National Government.

The Swine Breeders' Association also recommended Government inspection of exported hog products.

SANITARY CONVENTION AT IONIA, MICHIGAN.—Arrangements have been made by a local committee of citizens of Ionia, acting with a committee of the State Board of Health, for a sanitary convention which will be held in Ionia, December 13 and 14, 1883.

At each session of the convention there will be addresses or papers on subjects of general interest pertaining to public health, each paper to be followed by a discussion of the subject treated.

Among the subjects which it is expected will be presented and discussed, are the following:

Sewerage; Ventilation; Present and Future Water-Supply of Ionia; Contagious and Infectious Diseases; Foods and their Adulterations; School Hygiene; Ice from Impure Sources; Poisonous Wall-paper; Best Method of Disposal of the Dead; Disposal of Waste Matter.

HEALTH IN MICHIGAN.—Reports to the State Board of Health, for the week ending November 17, 1883, indicate that whooping-cough, typhoid fever, and intermittent fever have increased, and that typho-malarial fever, dysentery, measles, and remittent fever have decreased in area of prevalence.

Including reports by regular observers and others, diphtheria was reported present during the week ending November 17, and since, at nineteen places; scarlet fever at twenty-four places; and measles at five places.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM NOVEMBER 19 TO NOVEMBER 26, 1883.

MOORE, JOHN, *Lieutenant-Colonel.*—Relieved from duty as Medical Director, Department of the Columbia.—*S. O. 29, Department of the Columbia*, November 8, 1883.

BACHE, DALLAS, *Major and Surgeon.*—Assigned to duty at Fort Adams, R. I.—*Par. 5, S. O. 215, Department of the East*, November 19, 1883.

BROOKE, JAMES, *Major and Surgeon.*—Relieved from duty at Angel Island, California, and assigned to duty as Post Surgeon, Presidio of San Francisco, California.—*Par. 1, S. O. 162, Department of California*, November 14, 1883.

HORTON, SAMUEL M., *Major and Surgeon.*—Leave of absence granted October 20, 1883, extended three months.—*Par. 7, S. O. 266, A. G. O.*, November 20, 1883.

TOWN, F. L., *Major and Surgeon.*—Until further orders, to perform the duties of Medical Director, Department of the Columbia.—*S. O., 29 Department of the Columbia*, November 8, 1883.

WILLIAMS, JOHN W., *Major and Surgeon.*—Granted leave of absence for one month, on surgeon's certificate of disability, with permission to leave the limits of the Department.—*Par. 5, S. O. 157, Department of the Columbia*, November 12, 1883.

MUNN, CURTIS E., *Captain and Assistant Surgeon.*—Assigned to duty at Fort Warren, Massachusetts.—*Par. 4, S. O. 216, Department of the East*, November 20, 1883.

WINNE, CHARLES K., *Captain and Assistant Surgeon.*—Relieved from duty at Fort Winfield Scott, California, and assigned to duty as Post Surgeon, Angel Island, California.—*Par. 1, S. O. 162, Department of California*, November 14, 1883.

APPEL, A. H., *First Lieutenant and Assistant Surgeon.*—Relieved from duty at Fort Warren, Massachusetts, and assigned to duty at Madison Barracks, N. Y.—*Par. 4, S. O. 217, Department of the East*, November 21, 1883.

RICHARD CHARLES, *First Lieutenant and Assistant Surgeon.*—Relieved from duty at Fort Adams, R. I.—*Par. 3, S. O. 216, Department of the East*, November 20, 1883.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

VOL. XLIII. SATURDAY, DECEMBER 8, 1883. NO. 23.

ORIGINAL LECTURES.

BONE LESIONS DEPENDENT UPON NERVOUS DISEASE.

A Clinical Lecture delivered at the Hospital of the University of Pennsylvania.

BY HORATIO C. WOOD, M.D.,
PROFESSOR OF NERVOUS DISEASES IN THE UNIVERSITY OF PENNSYLVANIA.

GENTLEMEN: I shall to-day present to you a subject which I think has never before been lectured on in this institution, and will therefore have at least the charm of novelty. I see this patient for the first time, but I am informed that he has upon his right foot a large growth which has been of slow development. He has been sent from the Orthopædic Dispensary for an opinion; and the question which has to be determined, is whether this tumor, which is evidently bony in its nature, is the result of disease originating in and confined to the bone, or whether it is the evidence of trophic changes in the bone due to disease of the nerve-centres.

In order to give you an intelligent idea of the ground upon which the opinion that I shall formulate is based, it seems necessary to discuss briefly the whole question in regard to the trophic changes in the bones which follow diseases of the nervous system. I shall therefore leave the consideration of this individual case for a moment, and discuss the nature of the changes in the bony tissues which follow, or are connected with, diseases of the nervous system. Prominent among these changes are the alterations which are found to take place in general paralysis of the insane, and which probably are also present in other forms of insanity. Many years ago, it was noted that the bones of insane patients were frequently broken, and that not rarely there would be multiple fractures in the same case. These frequently recurring fractures have been brought forward by the opponents of insane asylums as evidences of cruel and rough handling on the part of attendants, but we now know that there is often a tendency of the bones to fracture upon the least exposure to force. Under certain circumstances, the bones of persons suffering from general paralysis, and probably the bones of those suffering from other forms of insanity become enlarged and readily fracture. When broken, these bones unite easily and with great rapidity, and with the formation of an excess of callus, so that there may be a large tumor at the seat of the fracture. After death in these cases, it will be found that the bones are notably enlarged; that they are so soft as to be readily cut with a knife; and that there exudes from the cut surface a pink or reddish sanguinolent juice, which, when placed under the microscope, is found to contain large quantities of nuclei and imperfectly developed cells. If a section of such a bone is made, it is shown to be more porous than normal, and the microscope reveals great dilation of the Haversian canals, which are filled with a fluid containing embryonic cells. A very curious feature in this form of bone disease is that it attacks almost exclusively the skeleton of the trunk. It is the ribs, the bones of the pelvis or of the vertebral column which are affected.

I have seen one case in which changes in the bones nearly like these occurred in a person supposed to be suffering from chronic alcoholism. I saw the patient just before death, and am unable to say whether the nervous symptoms were those of chronic alcoholism or whether they were the commencing symptoms of a peculiar form of general paralysis. But in this case it was the limbs which were especially attacked.

Again, it has been found that there is a peculiar form of arthritis connected with hemiplegia, and especially when such hemiplegia is dependent upon diseases of the brain in which there are minute foci of softening. In these cases the diagnosis of this form of arthritis is a matter of importance, for I believe that in nine cases out of ten this condition is supposed to be due to rheumatism, and the patient is believed to be suffering from a second disease—acute or subacute rheumatism—supervening on the attack of hemiplegia. In separating the two affections, it will be noted, in the first place, that hemiplegic arthritis comes on in twenty or thirty days after the attack, and just about the time at which late muscular contraction develops in certain cases. In the second place, the inflammation of the joints, at least in the early stage, is limited to the affected side; there are moderate pain and exquisite tenderness in the affected joints, which are much swollen, the swelling usually developing rapidly and being accompanied by distinct œdema with pitting on pressure. The history of such a case differs entirely from that of chronic rheumatism. In rheumatic arthritis there is no tendency to the development of pus, and little or no tendency to the breaking down of bony tissue, the effusion within the joint being serous and remaining so for months. The cartilages may be removed, but the bone beneath the cartilage becomes hard, thickened, and of irregular stellate growth, and has little or no tendency to ulceration and destruction. Frequently osteophytes are found in the effusion. In the joint affected with hemiplegic arthritis, although the process is very slow and the arthritic changes may continue for months and even years, still there is a tendency for the formation of purulent liquids, and a tendency to the destruction, not only of the cartilages, but also of the bone. You will see in this specimen which I hold in my hand, an illustration of the changes of which I am speaking. This elbow-joint was removed from a woman who died in the Philadelphia Hospital several years ago. This patient was completely hemiplegic on the right side, and completely aphasic. When I first saw her, she complained greatly of pain in the leg and arm. The moment the coverings of the bed were lifted, or the limb approached, she would scream and yell with the mere fear of contact; when the joint was touched, the emotional disturbance became uncontrollable. The joints were swollen, very glossy, and hard to the touch. When she first came under observation, the affection was confined to the hemiplegic side, and was evidently not rheumatic. There was no history of rheumatism, and the joints did not present the peculiarities of rheumatic joints. For many months the joints remained in the same condition, and finally the joints of the other side became slightly affected. After death the lesion of the brain was found to be a large hemorrhage in the neighborhood of the claustrum, completely destroying the external capsule; hence the complete hemiplegia and aphasia, and the secondary nutritive lesions. On opening one of the joints, I found that it contained a moderate amount of purulent serum, that the cartilages were almost entirely destroyed, and that the surface of the articulations was largely affected and eroded. After the bones were boiled, the articulating surfaces were found to be exceedingly porous, and in some places part of the bone had been eaten away. Examining the specimen you will note that the bone is very light, and that its shaft has become exceedingly thin, so that there is not only a destruction of the joint, but atrophy of the shaft of the bone.

There is a third class of diseases of the bone appearing in connection with disease of the nervous system, namely, those which are associated with locomotor ataxia. In this form of bone disease, there are two seats of the alterations, the diaphyses being affected in some instances, while in other cases the epiphyses are the parts involved. You will remember that I said that in diseases of the bone dependent upon insanity, the skeleton of the trunk was the part affected. In locomotor ataxia, the trunkal bones escape almost entirely, and it is the long bones of the extremities which are more especially involved; and the diaphyses are most frequently the seat of the alterations. Attention was first called to this condition, as in bone affections of the insane, by the frequent occurrence of fracture in certain cases of locomotor ataxia, the fractures being produced without obvious sufficient cause; for instance, a man would go to cross one leg over the other, and sustain a fracture of the thigh. At first it was said that this was due to irregular muscular contraction; but it is perfectly clear that no irregular muscular contraction in making such a movement could be powerful enough to break a sound bone. Examination of the bones of those suffering from this variety of fracture showed that they had undergone atrophy. In addition to being atrophied, the bones were very hard. In certain cases this atrophy has seemed to be connected with hypertrophy. This condition has been denied by the French school of observers; but one case has been reported in which the femur of one side was atrophied, whilst the same bone on the other side was enormously enlarged. In other cases, it has been said that while the upper portion of the bone was atrophied and hardened, the lower portion has presented the changes met with in general paralysis. Fractures of these atrophied bones heal with great rapidity, and with the formation of an excessive amount of callus, so that a large tumor will be developed at the position of the fracture. The patient may not complain of the fracture, but may consult the physician on account of the appearance of a hard mass upon his leg. This relation is important, for the man before us is supposed to be suffering from locomotor ataxia.

There may be in locomotor ataxia an arthritis, instead of disease attacking the main shaft. The clinical characteristics of this form of arthritis are entirely different from those of hemiplegic arthritis. In some instances the enlargement is sudden. It may develop in the course of ten days, or it may reach its fullest extent in two or three days. Examining such a joint, it will be found to be painless; the swelling is large, is confined to the neighborhood of the joint, and often ends abruptly. When pressed upon, it feels hard, and does not distinctly pit. The joints remain in this condition for a certain length of time, when one of two changes is liable to occur. Sometimes acute inflammation develops, and acute arthritis and osteitis appear. This is, however, rare. Under these circumstances, the joint suddenly becomes hot, painful, and gives the ordinary clinical appearance of acute arthritis. The more usual change is for the swelling gradually to subside; the joint becomes irregular, but the articulating surfaces do not disappear, and it remains as a hard irregular joint. The effusion does not become purulent, and osteophytic growths are frequently found in the liquid.

In the present case, we desire to know whether this man is suffering from a bone disease which represents one of these trophic forms, or from bone disease of another character. I shall first examine the bony lesion. As you see, there is a large swelling at the right ankle-joint, projecting three inches above the dorsum of the foot. There is no pain in this, either by day or by night. I find no difference in the size of the side on the two sides.

When did this come on? A. "I am a plumber, and about two years ago I was sitting on a board, with my right foot under me, working. Pretty soon the foot felt as though it were asleep, and then I had severe pain. I got up, and found the foot all swollen. I broke the buttons off my shoe and took it off; my leg was black up to the knee. This happened in fifteen minutes. The swelling was as hard as it is now. After this, I was laid up for some weeks, the parts being very sore and painful."

It is clearly impossible that a mass as hard as this could have formed in fifteen minutes. This is evidently a bony tumor. The first tumor must have been of some other nature. The original pain and lameness continued in this foot for four or five months, and then gradually disappeared. He can now walk and attend to his work.

It is perfectly possible that this man had a spontaneous fracture within the ankle-joint at the time of the first attack. This is the only way in which I can reconcile this condition with the history which he has given. Probably in suddenly stooping or rising, he fractured the bone. This was followed, as is the case in articular fractures, by intense swelling, due to rapid effusion. This effusion was absorbed, and we now have a tumor, the result of excessive deposition of callus.

The next point to discuss is whether or not this man has locomotor ataxia. If he has not, the explanation of this symmetrical bony tumor which I have given is not correct, and I cannot explain the nature or cause of the excrescence. The tumor, evidently, is not malignant, for it has been there two years, and is painless.

Before referring to the presence or absence of locomotor ataxia, let me say one word in regard to the time at which the lesions of the bones in that disorder appear. They usually develop just before the symptoms of muscular incoördination make their appearance. In other words, the bone lesions are prodromic. There is one lesion of the bones in locomotor ataxia to which I intended to refer, and which I shall bring in here, a little out of its proper place, because it shows the close connection between the stage of sensory irritation and bone affection in locomotor ataxia. A person will have severe trigeminal neuralgia, perhaps associated with anæsthesia of the region supplied by this nerve without any other symptom, when suddenly the teeth will begin to drop out. They come out without any pain, soreness, or any premonitory symptoms whatever. In some reported cases, the teeth have dropped out during sleep, and threatened strangulation has resulted. We know that this is connected with the atrophic changes of locomotor ataxia. It is observed that after the loss of the teeth, the jaw-bone atrophies until it is reduced to a mere shell. Sometimes all of the teeth have been lost at once; in other cases, only a part at a time. Very rarely have both jaws been affected simultaneously. In these cases, the attention has been centred upon the trigeminal neuralgia, and the changes in the bone, being unaccompanied by pain, have gone on unnoticed. There has really been locomotor ataxia developing high up, involving the root of the trigeminal nerve, and causing the atrophic changes which eventually result in the loss of the teeth. This condition has, in the reported cases, come on before the symptoms of incoördination.

This patient says that he has been subject to rheumatism for the past four years, but has not had any swelling of the joints. In the majority of cases, the early stage of locomotor ataxia is diagnosed to be rheumatism. He has shooting pains in the arms and in the legs. These are sometimes so severe as to compel him to go to bed. There are also neuralgic pains around the chest, but no feeling of constriction. The patella reflex is entirely absent on both sides. The muscles react normally to electrical stimuli. He says that he has lost sexual power to a certain extent. He never had a period of sexual excitement. He feels giddy at all times, and cannot walk as well at night as in the daytime. He is able to work at his trade, but not as well as formerly; and he thinks that there has been no failure of the sight. You notice that, in standing, he keeps his legs further apart than is natural, and, in walking, he has a slightly straddling gait. He can stand pretty well with his eyes closed; he can also keep his balance for a short time, while standing on one foot, with his eyes closed, and the symptoms of loss of coördination are therefore not distinct in this patient; but the symptoms of the early stage of locomotor ataxia are present in the form of tearing, shooting, and darting pains in the legs and body; the loss of patella reflex; the presence of giddiness, and the inability to walk well in the dark. In separating these of this character from those of rheumatic pains, the characters which I rely upon are the following: The pains are bilateral instead of unilateral; they are relieved by, instead of being made worse by pressure, or if there be any tenderness, it is only at the moment of pain; they are apparently causeless; and, finally, they are associated with loss of patella reflex. Occasionally in locomotor ataxia, there will be some tenderness of the skin when the attack of neuralgia is at its height.

I believe that this man is suffering from the beginning stage of locomotor ataxia. If I found a bony lesion, like the one here presented, associated with absence of the patella reflex, I should strongly suspect beginning locomotor ataxia, but when we have at the same time neuralgic pains and some symptoms of muscular incoördination, I think that the diagnosis is clear.

ORIGINAL ARTICLES.

A CASE OF OVARIOTOMY, FOLLOWED BY RECOVERY,

WITH SOME REMARKS ON RECENT IMPROVEMENTS IN THIS OPERATION.

By L. S. McMURTRY, A.M., M.D.,
of Danville, Ky.

In order to place within easy reach of the statistician a case presenting some unusual features, and at the same time to illustrate the efficiency of some recent advances in abdominal surgery, the following case of ovarian cystoma, weighing thirty-three pounds, removed by abdominal section, is reported:

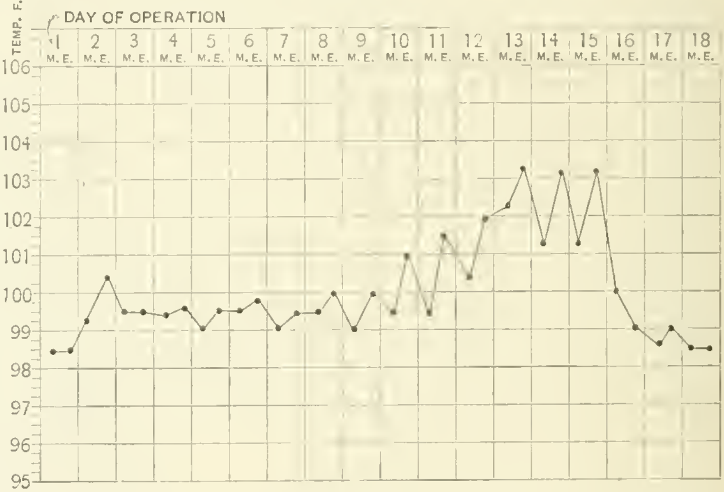
On September 10, 1883, I was called in consultation by my friend Dr. J. M. Meyer to see Mrs. H. S., of Mercer County, with the following history and condition: The patient is twenty-nine years of age, has been married six years, and is without children. About two years ago, she observed an enlargement of the abdomen, and supposed herself to be pregnant, though her menses persisted with regularity and no fœtal movements were felt. At the end of nine months, the tumor had reached in dimensions the extreme limit of pregnancy. It continued to grow, and at the date mentioned had attained occupancy of the pelvis and abdomen from Douglas's cul-de-sac to the diaphragm. The diagnosis of a polycystic tumor of the ovary was established by the usual methods, including exploration of the uterus, analysis of the urine, and chemical and microscopical examination of the contents of the tumor obtained by puncture with the hypodermic syringe. The characteristic wasting and anxious expression of countenance were to be observed, and the patient suffered with dyspnœa and an irritable stomach, both the results of pressure. The pulse ranged from 110 to 120 per minute, and the respiration was correspondingly accelerated.

On September 19th, at twelve o'clock, the operation was performed in the presence of Drs. J. M. Meyer, George Cowan, I. S. Warren, Fayette Dunlap, and Mr. Harry Cowan, a student of medicine, all of this city, and Dr. George Calvert, of Perryville. Drs. Meyer and Cowan kindly took charge of the anæsthetic—ether—and Drs. Warren and Dunlap and Mr. Cowan gave me valued and efficient aid throughout the operation.

The patient occupied a pleasant room in the second story of a delightful country place, where a pure atmosphere prevails, and a good light was had for the operation. On making an incision about five inches in length in the median line, the abdominal muscles were found much thinned by the tension and pressure to which they were subjected. The bleeding from the lips of the abdominal incision was controlled by artery-compressors and pressure with a sponge before opening the peritoneum. On exposing the tumor, two firm patches of parietal adhesions were encountered upon either side of the umbilicus, and introducing my hand into the left hypochondrium, other adhesions to the abdominal wall were separated. Realizing more sensibly the great dimensions of the tumor at this stage of the operation, the incision, which already extended to the symphysis pubis below, was extended more than three inches above, passing to the left of the umbilicus. The tumor, while of an irregular globular shape, was found to project in every direction, filling Douglas's cul-de-sac and the pelvis below, and being snugly adapted to the antero-posterior inclination of the diaphragm above. The periphery of the tumor was an aggregation of many small cysts, which gave the impression of a solid mass, while the interior was occupied by a number of larger cysts.

Plunging a Wells's trocar into the tumor and directing its point in various directions, I was enabled to empty the large cysts, dislodge the tumor from its situation, and turn it out through the incision. As the great cysts were emptied, the increased play of the diaphragm in respiration was observed by all around the table. The pedicle was short, broad, and thick, and situated upon the left side. Finding that one ligature could not safely encompass it, it was secured by Peaslee's chain ligature, so that it was ligatured in four sections. The ligature was of silk furnished me by Messrs. Tiemann & Co., of New York, and bore strong tension without breaking. The tumor was cut away about three-quarters of an inch beyond the ligature. The breadth and thickness of the pedicle were conspicuous at this stage of the operation, the surface of division from the tumor being fully five inches by two inches. The ligatures were cut short and the stump dropped into the abdomen. The right ovary was then examined and found to be in a healthy condition. The toilet of the peritoneum was made with the utmost care. Following the practice of the great master in abdominal surgery, Mr. Lawson Tait, of Birmingham, after sponging out the cavity of the pelvis and of the lumbar region, I filled the cavity of the abdomen with warm distilled water by means of a tube running from a basin held above the table. Holding the divided abdominal walls together with one hand, I moved the intestines with the fingers of the other hand so as to wash them thoroughly. The water was then removed with sponges, and this process twice repeated, when the water came out free from the tinge of blood. After placing five squeezed sponges in the abdominal cavity, I then proceeded to close the wound. After inserting the deep sutures, which were ten in number and of silk, the sponges were removed and the peritoneal surface found quite clean. The lips of the wound being brought evenly and firmly together by the deep sutures, the superficial sutures were inserted, the patient cleansed and placed in bed. The wound was dressed with dry absorbent cotton, adhesive strips applied, the abdomen covered with a thick layer of cotton, all secured by a broad flannel bandage around the body. The operation consumed one hour and a half. The patient was very sick from the ether and vomited a great deal during the operation. During the twelve hours following she suffered severely with nausea and vomiting, and ejected from the stomach at intervals dark fluid commonly described as "coffee-ground" vomit. She reacted, however, promptly, and six hours afterward the pulse was 102, and temperature 99.2°. Small draughts of warm water only were administered, and the nausea and vomiting gradually subsided. More than a pint of healthy urine was drawn with the catheter at 6 P. M. She slept at intervals during the night and on the morning following the operation was cheerful and without pain or nausea, with pulse 94 and temperature 99.5°. Food of every kind was withheld, and only occasional draughts of warm water were given to allay the thirst of which the patient complained.

The history of the next six days is that of continued progress. Beginning with small quantities of chicken-broth on the second day, food was given regularly, and was taken with relish. The temperature remained slightly above the normal, and the pulse ranged between 80 and 90 per minute. On the morning of the seventh day, the wound was examined, and found quite dry, with firm adhesive union. The superficial, and every alternate one of the deep sutures were removed and the dressing replaced. On the following day, the remaining sutures were removed, and the adhesive strips reapplied. On the fifth day after the operation, the patient passed urine without the aid of the catheter, and on the eighth day the bowels acted freely in response to an enema. On the eighth day the patient complained of pain in the vicinity of the pedicle, and exhibited evidences of inflammatory action. The skin was hot, the pulse quickened, and pain, tenderness, and swelling were manifest in the broad ligament of the left side. This was the beginning of a circumscribed inflammation about the stump, which continued several days, and gave some anxiety. The temperature then gradually rose, as shown in the accompanying diagram, until on the evenings of the thirteenth, fourteenth, and fifteenth days it reached 103°; on the sixteenth day it fell to 99°, and was normal after that date.



The treatment of this complication may be appropriately comprehended by the expression "good nursing." The hot vaginal douche was given every three waking hours, and hot cloths were applied to the hypogastrium. During the entire progress of the case no anodyne whatever was administered, with the exception of one-eighth of a grain of morphia on the night of the twelfth day. The pain was at no other time so intense as to necessitate the exhibition of opium, and believing the routine use of this drug after ovariotomy to be harmful by checking the eliminative processes and impairing the nutritive functions, it was withheld. I would not detract from the great value of this remedy in the treatment of inflammatory affections in general and of the abdomen particularly. By allaying pain, producing sleep, checking the early vomiting of peritonitis, and suspending the peristaltic movements of the intestines, its value in peritonitis is simply incalculable. But it should not be used as a prophylactic, and should be held in reserve as long as possible. In the case here reported the pain did not necessitate its use, and no vomiting occurred. Notwithstanding the elevation of temperature the appetite was maintained, and the secretions were not checked. The bowels acted almost daily during the existence of the circumscribed peritonitis, and the skin and kidneys were active in the performance of their functions. On the thirteenth day the menses appeared, and seemed to exert a good influence upon the pelvic inflammation. On the sixteenth day there was a marked improvement in the condition, and the fever and abdominal tenderness and swelling rapidly disappeared.

The exceptionally large stump was the focus of the pelvic inflammation, and it could not reasonably be expected that the repair of such extensive lesions would be without marked local and constitutional disturbance. On the twenty-first day an abdominal belt was placed upon the patient; she was allowed to sit up; and in a short time her recovery was complete. Throughout the entire after-treatment I had the unremitting aid and coöperation of Dr. J. M. Meyer, the attending physician, for whose judicious suggestions and efficient services the most grateful acknowledgments are due.

This case illustrates more than one of the great improvements which have so widely extended the domain of abdominal surgery and reduced the mortality of ovariotomy. It is well known that when, after recovering from the shock of the operation, patients do badly, both the symptoms and the lesions are those of diffuse suppurative peritonitis. It has been pretty well determined of late that this condition is the result of septicæmia instead of injury to the peritoneum by the operation. Hence the great reduction of mortality since operators have bestowed such painstaking care in checking hemorrhage and cleansing the peritoneum. The determination of this fact is at the basis of the recent extension of the field of abdominal section, which now includes intraperitoneal hemorrhage from gunshot and punctured wounds, as well as diseased conditions of the viscera. This knowledge has also dissipated the traditional fear concerning a movement of the bowels after abdominal section, since laxatives are administered when indicated with advantage. In the case detailed above, the bowels were maintained in a soluble condition throughout the entire progress of the case, and with manifest advantage. Mr. Lawson Tait has demonstrated that bad symptoms following ovariotomy are often dissipated by the administration of a purgative in their incipiency. Indeed, regarding the peritoneum an immense lymph-sac, he believes that purgation often acts as a substitute for drainage.[1] These views certainly are worthy of most careful consideration in view of the splendid results which Mr. Tait has achieved.

In considering various methods in ovariotomy the greatest interest has always centred upon the treatment of the pedicle. The intra-peritoneal method is rapidly superseding the use of the clamp, and the prediction made by Dr. Emmett several years ago that "the ligature will become in future the means generally employed for securing the pedicle" seems to be almost verified. The experiments of Spiegelberg and Waldeyer, made in 1868, have removed all theoretical apprehension that the distal portion of the ligatured stump would be thrown off by sloughing into the abdominal cavity, and the splendid results obtained by this method at the hands of varions operators demonstrate its superiority from a practical standpoint. The recent experimental investigations of Mears and Longstreth[1] in this country confirm the results obtained by Spiegelberg and Waldeyer, and demonstrate additional facts of the utmost practical importance.

A SIMPLE OPERATION FOR FACIAL NEURALGIA.

By J. F. HEUSTIS, A.M., M.D.,
PROFESSOR OF SURGERY IN THE MEDICAL COLLEGE OF ALABAMA.

A. E. L., an old gentleman, past seventy, of fine constitution and very healthy in every respect, except being a sufferer from tic douloureux, has consulted me several times in the last year for his complaint, and has taken the various remedies likely to benefit him, with very little relief. As he continued to suffer more and more, I advised him to let me operate on him as the only means of relief. But the neuralgia being general, affecting the branches of both the supra- and infra-orbital nerves, I could not promise him with entire confidence that an operation on the infra-orbital nerve only would be sufficient, although that seemed to be most affected. The pains would dart all over the side of the head and face at the least touch, even of a hair of the head or beard, or from the impression of a breath of air, or even from the movement of the jaws in mastication. His suffering became so great and constant, and the neuralgic attacks so severe from attempts to eat, that he began to run down from sheer exhaustion from want of food and pain.

He was so weak at the time of operation, that it was a very important matter at his advanced age to make the operation as simple as possible, consistently with the hope of permanent relief. Therefore, discarding Carnochan's operation of trephining the antrum and following up the nerve beneath the orbit and removing it; and Langenbeck's slighter one, of dividing the nerve far back in the orbit with a tenotome and drawing it out through the infra-orbital foramen, I merely cut down upon the infra-orbital foramen, and with a fine steel drill, such as dentists use, improvised of piano-wire, drilled out the nerve in its entire length, as far back as the spheno-maxillary fissure. The immediate effect of the operation was to abolish all sensation in the previously sensitive parts, and to enable him to use his jaws without suffering the darting pains he formerly had. And not only was the sensitiveness of the face relieved, but also that of the side of the head, showing that the trouble was in the distribution of the infra-orbital nerve, and that the affection of the branches of the supra-orbital was a reflex one. Barring some swelling of the face, he had no trouble afterwards. The wound soon healed, and he has been able to expose himself to the air, and to eat with impunity, and now, although, nearly two months have elapsed, he remains free from pain and is enjoying excellent health.

REFUSION IN CARBONIC OXIDE POISONING.

BY WM. S. HALSTED, M.D.,
OF NEW YORK.

Read before the New York Surgical Society, November 13, 1883.)

CONTRIBUTIONS to the treatment of cases poisoned by carbonic oxide, the most noxious constituent of coal and illuminating gases, are especially worthy of consideration because of the great frequency of, and mortality from, this form of poisoning. In Adolph Lesser's tables[1] carbonic oxide figures as the most common poison, and the one which yields the highest percentage of cases. Refusion of blood is literally a depletory transfusion, in which the blood withdrawn is returned to the circulation of the loser. Volkmann,[2] in discussing exarticulations at the hip-joint, suggests the feasibility of catching the blood lost, peradventure, in this operation, and returning it to the loser through the divided femoral vein; and Esmarch[3] has, in one instance, endeavored to act in accordance with Volkmann's suggestion, but his patient died while preparations were being made for transfusion. Hueter,[4] in frost gangrene of both feet, transfused centrifugally three hundred and fifty cubic centimetres of the patient's own blood, defibrinated, into the left posterior tibial artery; and believes that he thereby preserved a portion of the frozen part. The right foot, untransfused, underwent an extensive forfeiture. Highmore,[5] evidently not aware that it had already occurred to others to refuse blood, offers "remarks on an overlooked source of blood supply for transfusion in post-partum hemorrhage," and recommends utilizing the blood lost by the mother. Other than these, I know of no hints as to attempts at refusion.

In carbonic oxide poisoning refusion involves an additional factor; viz., the oxygenation of the poisoned blood employed; and is, therefore, an infusion of the purified, defibrinated for the poisoned, entire blood of the individual.

A most radical case of refusion is the following:

On the 15th of last May, Mr. A. S. G., aged 57, a man of medium size and good physique, was found unconscious in a state-room of the steamer "Bristol" by the ticket-taker, who observed a strong smell of gas in the room. He was taken in an ambulance to the Chambers Street Hospital, where he arrived at *9.5 A.M.* The house-surgeon states that, on admission, the patient could not be aroused. Respiration superficial; pulse fairly strong, and eighty-five beats a minute; temperature not taken; skin pale and cold; lips slate-colored; pupils somewhat dilated. Was put in a hot-air bath, and given whiskey hypodermically. At *10.30 A.M.*, when I first saw the patient, he was still comatose. His eyes were partly open, and his pupils equal, slightly contracted, and irresponsive to light; face ashy pale, and surface of body cold. The respirations, twenty-eight a minute, were abdominal, and so superficial that it was almost impossible to count them. Pulse 96, small, and easily compressible; feeble conjunctival and plantar reflexes; other superficial reflexes absent, except cremasteric on left side. Deep reflexes could not be tested because of the rigidity which existed. Both arms were flexed—the right more strongly than the left. *10.50 A.M.* Right radial artery exposed above wrist for about one inch, and two ligatures passed under it. A canula, introduced centripetally into the artery, was held in place by one ligature; the other was used to occlude the vessel peripherally. Through the canula five hundred and twelve cubic centimetres of blood were withdrawn, defibrinated, strained, and kept at a temperature of about 37.5° C. in a transfusive apparatus similar to that which is before you. *11.30 A.M.* Temperature 35.4° C., pulse 92; respiration 22, full and dyspnœic. Superficial reflexes well pronounced; eyes closed; but patient can be made to open them. Rigidity of limbs has, in great measure, disappeared. *11.32 A.M.* Two hundred and eighty-eight cubic centimetres of defibrinated blood, all that could be obtained from the five hundred and twelve cubic centimetres, were refused through the canula in the artery towards the heart—centripetal arterial infusion. At *11.45*, the injection was completed. Temperature 36.6° C., pulse 104, respiration 28, deep and labored. Superficial reflexes possibly exaggerated. The usual post-transfusion rigors lasted for half an hour. *12.35 P.M.* Three hundred cubic centimetres withdrawn, as before, through the canula, defibrinated, and mixed with one hundred and twenty-eight cubic centimetres of defibrinated blood taken from another patient. *1 P.M.* Temperature 38.2° C., pulse 128, respiration 28. *1.5 P.M.* Patient's pallor most striking; one hundred and ninety-two cubic centimetres of the mixed blood infused. The color returned rapidly to his face when from eighty to one hundred cubic centimetres had been injected, the change from a deathly white to a healthy red taking place in a few seconds. *1.13.* Temperature 39.1°, pulse 120, respiration 40. *2.30.* Temperature 39.4°, pulse 140, respiration 40. *5.30.* Temperature 37.8°, pulse 116, respiration 20. Patient has been gradually returning to consciousness since the first venesection, and now attempt to get out of bed.

May 6.—12.15 A.M. Urine voided voluntarily for the first time since admission, it having previously been drawn off with a catheter. *8.30 A.M.* Temperature 37° (normal), pulse 98, respiration 20; patient in good condition, but, mentally, still a little dull. *4.30 P.M.* Patient eats well, and desires to go home.

7th.—Intellect perfectly clear; remembers that the steward lighted the gas in his state-room about 9.30 P. M. the night previous to his poisoning, but that it went out as the door was closed. Undressed himself in the dark, went to bed, and can recall nothing of the night. Has experienced none of the unpleasant after-effects of the poisoning. Allowed to go home about fifty hours after admission.

Oct. 20, five and a half months after the poisoning, interviewed Mr. A. S. G., and ascertained that he has not had a single unpleasant symptom referable to the effect of the gas.

That this patient would have recovered without such active treatment, is not improbable. It is, nevertheless, certain that the bloodletting exerted a most favorable influence, changing almost instantly the entire aspect of the case. The scarcely perceptible respirations became at once conspicuously full; in a few moments the absent superficial reflexes had returned, and the rigid arms relaxed. The body surface grew gradually warmer, and after the first infusion the temperature had risen from 35.4° C. to 36.6° C. (a rise of 3° F.). The pulse and respirations kept pace with the temperature. The first infusion prepared the subject for a second depletion, and contributed to the rise in temperature, and probably to the improved circulation. The second infusion was decidedly indicated, as evidenced by the impression it produced in the patient's color.

In the light of Kühne's[1] experiments on animals, it is a question whether the bloodletting alone would not have rescued all the cases of gas poisoning in the human subject in which a depletory transfusion has been successful. Kühne (*loc. cit.*) found that venesection of itself could save life if the respirations were as much as two in a minute. From twenty-three cases of transfusion for carbonic oxide poisoning of which I have notes, twelve terminated favorably. In two (Casse,[2] Lühe[3]) of the twelve successful cases, very small quantities of blood were transfused, and without any immediate good effects. In one (Hüter[4]) of the remaining two cases attempts at depletion were unsuccessful, only a few drops of blood having been withdrawn. In three cases (Garrigues,[5] Halsted) the venesection exerted a decidedly favorable influence. Three cases (Bodt,[6] Mastus,[7] Lehmann[8]) are narrated in articles to which I have not access, and so cannot arrive at any positive conclusions as to which was the more efficacious agent, the venesection or the transfusion. In one case (König[9]) the venesection (the amount of blood withdrawn is not stated) was attended with slight, and the transfusion with no success. The two remaining cases (Jürgensen,[1] Saltzmann[2]) were apparently benefited by the transfusion, and yet in neither is any reference made to the influence of the depletion, although from one (Jürgensen) four hundred cubic centimetres, and from the other (Saltzmann), one hundred and eighty cubic centimetres of blood were abstracted.

Some, then, of the cases claimed for transfusion seem attributable to the venesection which preceded it; and in no instance has it seemed to me clearly demonstrable that transfusion has saved life where venesection had failed.

A few cases are reported by O. Kahler,[3] P. Martin, and others, of venesection in carboxysmus with good results. And of the several cases which have come under my care, I will cite briefly, in proof of the efficacy of venesection, the most serious one in which depletory transfusion was resorted to.

May 5, 1882, at *10.10 A.M.*, Lillie Kent, a robust girl of seventeen, was admitted to the Chambers Street Hospital, suffering from illuminating-gas poisoning. The night before, on retiring, she is supposed to have blown out the gas in her state-room, on the steamer "Providence." On admission, she is said to have been unconscious, moaning, and much cyanosed. Her respirations were shallow, and her pulse rapid and feeble. Temperature not taken. Whiskey and digitalis were given hypodermically. She was put in a hot-air bath, and hot cloths were applied to the præcordia. Flagellation and the inhalation of ammonia would partially arouse her. Artificial respiration was tried, but with what effect is not stated. She would improve temporarily under the treatment, but when left alone would return to her previous condition.

I saw her about *5 P.M.*, her temperature was 39.1° C.; respiration 40; pulse 120. Advised washing the stomach and large intestine with hot water for the purpose of further stimulation. *9 P.M.* Patient much worse, pulse feeble, more rapid and intermittent; respirations very superficial; conjunctiva insensitive, and all reflexes absent. Mouth frothy; occasional facial twitchings and grinding of the teeth; arms and legs rigid—the flexor muscles overpowering the extensors. *9.5 P.M.*, two hundred and four cubic centimetres of blood withdrawn from left basilic vein. Upon this the condition of the patient improved marvellously; almost instantly her respirations became full, and her pulse strong and less rapid. The rigidity of her limbs disappeared, her reflexes returned, and she could be aroused by shaking or speaking loudly to her. *11 P.M.*, attempted to transfuse entire blood from a

Henrik Densen in Helsingför. Hospital studien, 2. R. I. 25, 26, 1874, reports a fatal case of gas-poisoning, which was interesting from the fact, that decided reaction was observed during a brief menstruation. (Strange that venesection was not suggested to him by this occurrence.) Tauz, in Biel. Schweiz. Corr., Bd. 12, p. 324, 1871.

Behiew apparatus into patient's right cephalic vein, but failed to introduce more than thirty cubic centimetres.

6th.—During the night, nourishment was administered per rectum. At *6 A.M.*, patient answers questions somewhat intelligently, and at *9 A.M.* takes nourishment by the mouth.

7th.—Feels well, but weak.

It is difficult in any case to know precisely how much of the cure should be attributed to the treatment. When, however, a case like the one just narrated, observed sufficiently long to exclude fluctuation, assumes a decidedly more serious aspect, and then is almost instantly on treatment transformed into rapid convalescence, one feels justified in assigning a cause to the effect.

Many apparently severe cases of carbonic oxide poisoning are recorded which have recovered more or less promptly when exposed to fresh air and stimulation. Some, too, where oxygen[1] is believed to have hastened the convalescence. But if, despite these measures, the patient's condition grows constantly worse, death is virtually certain unless venesection be resorted to.

From the hour of her admission until she was bled—eleven hours—Lillie Bent's condition was growing gradually worse, and ultimately became so bad that her case seemed hopeless: this, in a moment, upon venesection, was transformed into one of apparently certain recovery.

The transfusion produced no appreciable effect, as might have been expected from the small amount of blood injected. As additional proof of the value of bleeding in carbonic oxide poisoning, I might allude to the case of her illicit companion, who, occupying the state-room with her, was likewise poisoned. Less seriously affected by the gas, he was venesected while convalescing. Maniacal and confined in a strait-jacket, he was bled about five hundred and twelve cubic centimetres, and thereupon became so rational and docile that it was no longer necessary to restrain him. To cite, as I might, other less serious cases, in which the beneficial effect of bloodletting was less strikingly apparent, would be superfluous.

Why, then, transfuse if venesection accomplishes so much? If, for no other reason, to allow of repeated venesection, the poisoned individual should be bled freely, unless there be decided contraindications, even after, to all appearances, out of danger, in the hope of diminishing the risk of pernicious after-effects.

Although bleeding of itself will probably suffice to save life in almost all cases which occur in practice, it has been demonstrated by Kühne (*loc. cit.*) that animals poisoned beyond hope of rescue by venesection, can be saved by transfusion. In one of his experiments, where respiration had been suspended seven minutes, he was still able to restore life to the animal by the infusion of defibrinated blood. Aside from experimental demonstrations of the value of transfusion in cases beyond recall by means of bleeding, nothing could be theoretically much more enticing than the plausibility of substituting blood corpuscles, capable of taking up oxygen for such as are incapacitated from so doing by reason of the somewhat (stabile) compound which carbonic oxide forms with their hæmoglobin. Thus the much quoted and meritorious experiments of Panum[1] have led his partisans to believe in the possibility of blood substitution, and to regard the blood corpuscles as something which can be taken from one individual and *transplanted* in another.

But Von Ott[2] has shown the falsity of Panum's deductions inasmuch as he could obtain like results, although making use of a fluid which contained no morphological elements.

Von Ott (*loc. cit.*) has demonstrated, furthermore, that blood corpuscles infused into the circulation are short-lived, and that blood, whether entire or defibrinated, for other reasons is not only no better than, but not as good as, a 0.06 per cent. saline solution for transfusion in acute anæmia. One can not, therefore, properly speak of a substitution or transplantation of blood corpuscles by infusion of them into an impoverished circulation.

Fortunately, however, in carbonic oxide poisoning, it is merely necessary to sustain the patient artificially for a brief period, and for this, undoubtedly, the infused corpuscles can serve as oxygen carriers for a sufficiently long time. For the circumstances, as Von Ott's (*loc. cit.*) experiments teach us, that the infused corpuscles do not become integral constituents of the new organism, but rather are destined to a more or less rapid disintegration and elimination, does not prevent them from circulating, and temporarily taking part in the interchange of gases. Clear, then, as are the indications for transfusion auxiliary to venesection in the treatment of the cases under consideration, the extreme difficulty of obtaining blood at all, to say nothing of sufficient quantity, has, up to the present time, classified the operation with the rarer therapeutic procedures. And we might, indeed, in the treatment of these cases content ourselves with bloodletting, were it not that the practicability of refusion removes what has been, perhaps, the greatest obstacle to the performance of transfusion. To the investigations of Hermann,[3] Donders,[4] and Podolinski, I owe the conception of refunding the purified for the poisoned blood of the victim to carbonic oxide poisoning.

Hermann[5] calls attention to the fact that nitrogen monoxide can liberate the carbonic oxide of the carbonoxyhæmoglobin, and forms a stronger combination with hæmoglobin than does carbonic oxide. And subsequently, Donders (*loc. cit.*), Hermann, and Podolinski (*loc. cit.*) find that oxygen, as air, can, in a few minutes, free carbonic oxide from hæmoglobin if passed forcibly and in large quantities through the poisoned blood.

As to the best method of infusing fluids into the circulation, good authorities disagree. Of the four possible methods, centrifugally or centripetally into an artery or vein, the question of centrifugal venous infusion is entertained only to be discarded. Hueter, who gives to Von Graefe the honor of being the first to draw attention to centrifugal arterial infusion, deserves the credit of having introduced it to the profession, and strongly advocated the method.

Landois,[1] too, while contrasting in general arterial with venous transfusion, prefers, from a physiological standpoint, the arterial—be it centripetal or centrifugal.

Cohnheim,[2] on the other hand, expresses himself decidedly against centrifugal arterial transfusion, essentially as follows: One should surely, under no circumstances, inject peripherally into an artery; for the peripheral arterial branches contract with such energy against the foreign blood which is entering them, that it is often necessary, in order to overcome the resistance, to exercise pressure sufficiently forcible to rupture the bloodvessels. The case is very different when one injects centripetally into an artery, and employs no more pressure than is required to overcome the existing arterial tension. The blood infused mingles at once with that which is already present in the artery, and flows without resistance into the first branch above, thence into its arterial and capillary ramifications, and from here on, under normal venous pressure, to the heart.

Kümmel,[3] Schede's assistant, produced gangrene at the hand by the centrifugal infusion of a saline solution into the radial artery, thus giving us a demonstration of a disaster which may attend this method, and which he might have foreseen.

We are then restricted to the choice between centripetal arterial and centripetal venous infusion.

Hüter's[4] arguments for peripheral or centrifugal arterial transfusion, hold good for centripetal arterial infusion. He prefers the arterial to the venous transfusion, because the blood by the former method courses slower and more uniformly to the heart; because the minutest air vesicle is retained in the capillaries, and because the danger of phlebitis is avoided.

Landois (*loc. cit.*) adds to these advantages another, viz., that the capillary system, like a supplementary filter, catches all foreign particles which may be present.

The essential advantages of centripetal arterial transfusion in profund asphyxia, says Landois, can be summed up as follows: 1. Arterial blood is thus most directly dispatched to the nerve centres, in consequence of which the venous blood there contained, is propelled onwards into the veins. 2. The filling of the arterial system rejuvenates the feeble circulation by creating a considerable difference in pressure between the arterial and venous systems.

Cohnheim (*loc. cit.*), too, from his experiments on animals, declares the central or centripetal arterial transfusion to be the least dangerous, and at the same time the most completely effectual procedure.

From a practical standpoint, I am also impelled to advocate centripetal arterial infusion.

Besides the case already narrated, it has been my good fortune to transfuse by this method with most brilliant and unexpected success in two cases; one of acute anæmia, and one of septicæmia.

Joseph Hart, aged eleven years, was admitted to Roosevelt Hospital, September 15, 1882, for a compound comminuted fracture of the tibia and some of the tarsal bones. The ankle-joint was involved in the injury, and the soft parts badly mangled. The wheel of a street car had passed over his leg the night before. Patient is said to have lost much blood, and the clothes in which his leg was wrapped furnished evidence to that effect. The parents would not consent to an amputation, and the boy, although perfectly conscious, and able to give an account of himself, was not in condition for it.

At 8.30 P. M., eleven or twelve hours after admission, the patient was cold and unconscious, and his pulse was so rapid and feeble, that it could not be counted satisfactorily. It was estimated to be about one hundred and eighty per minute. I injected one hundred and ninety-two cubic centimetres of a chlor-natrium solution — ClNa ℥j; H_2O Oj — centripetally into the left radial artery, thereupon the pulse became quite full, and one hundred and thirty-five a minute. The boy returned to consciousness, and his condition seemed to warrant an attempt at amputation—permission to do so having, meanwhile, been obtained. The administration of ether had such a bad effect on the pulse that the operation was deferred, and the leg placed in a hot-water bath. Patient continued to improve, and survived an amputation of the leg performed by Dr. Sands, twenty-five days after admission.

On the 18th of March, 1883, at Ward's Island, I infused defibrinated blood centripetally into the radial artery in a case of septicæmia. The patient, an Italian, about forty years of age, had suffered for several months from a suppurative disease of the ankle and some of the tarsal joints. For about one week prior to the operation he had, almost daily, well-pronounced rigors and a temperature ranging from about 36.1° C. to 40.6° C. He was so feeble that to amputate was deemed inadvisable, even as a last resort. A depletory transfusion was accordingly undertaken. A stout philanthropic German offered to furnish the blood. So plentiful was his subcutaneous fat that not a vein could be seen, although his arm had been carefully constricted below the point at which the basilic vein usually perforates the deep fascia. Dissection for a vein, prolonged until even the would-be donor appeared to be willing to have the search discontinued, failed to discover one. Thereupon the radial artery was exposed without difficulty, although our subject fainted as the incision was being made through the integument, and so necessitated the completion of the operation upon the floor. The Italian was next depleted through his right radial artery until the arterial tension was barely sufficient to throw a jet across the graduated jar into which one hundred and seventy-eight cubic centimetres had been allowed to flow.

[2] Vorlesungen über Allgemeine Pathologie, Bd. i. p. 424.

[3] Centralblatt f. Chirurg., 1882, No. 19.

[4] Langenbeck's Archiv, Bd. xii.

Immediately thereupon one hundred and eighty-six cubic centimetres of defibrinated blood were infused centripetally into the artery. In a few moments, the patient's pulse had fallen to one hundred and twenty, which was eight beats better to the minute than before the administration of ether. The leg was then amputated just below the middle. The patient's pulse was 112 to 114, weak, but regular, and better than before the amputation.

Cardiac stimulants were of course freely administered, slight post-transfusion rigor, and a temperature of 38.8° C. On the following morning, March 18th, the patient's pulse was 110, and temperature normal; since then, uninterrupted convalescence.

It is only just to add that I have once done centripetal arterial infusion in a desperate case of pyæmia, where the fatal termination was probably precipitated by the operation.

If the infusion of defibrinated blood influenced unfavorably the action of the heart, it certainly was, in part, to be explained by the too heroic depletion which preceded it. This unsuccessful attempt should not militate against the method of injecting the blood, but rather against the indication for so doing, or against the manner or extent of the depletion. The main argument of those who prefer centripetal venous to centripetal arterial infusion is that the former is the simpler. If it be true that the latter is, in any degree, the safer method, the simplicity of the former does not deserve to be considered. For surely one would not feel justified in allowing a patient to die because he believed it to be simpler to do nothing than to make an exertion to save life Furthermore, instead of being easier, I am sure that it is often more difficult to discover a vein than to expose the radial artery. It was, for instance, impossible to discover a vein in the stout German referred to in this paper.

Jennings,[1] too, one of the more recent advocates of the intravenous method, without having practised the arterial, had considerable difficulty in finding a vein in one instance; and others testify to the same experience. The dangers of intravenous infusion, such as the introduction of air and small clots, and the overpowering of the heart by a too rapid injection, may be, theoretically easy to avoid, but practically death has frequently been brought about by one or more of these causes. To the centripetal arterial infusion pertain, theoretically, none of the dangers which, practically, in the intravenous method, are far from always to be avoided. And from a practical standpoint my cases, which I believe are the first recorded, induce me to advocate the centripetal arterial method.

HOSPITAL NOTES.

MEMORIAL HOSPITAL, ORANGE, N. J.

(Service of Dr. William Pierson.)

POPLITEAL ANEURISM CURED BY PERSISTENT COMPRESSION.

Reported by John H. Bradshaw,
assistant house surgeon.

Conrad A., age 49; carpenter. History and condition on admission to hospital, July 4, 1883:

A month before admission, patient sustained a fall. He says that, in the erection of a building, he fell through the floor beams; but, straining every muscle, he caught himself in time to be saved from further immediate injury than a severe shock. Two days after this, his attention was called, for the first time, to a lump behind his knee which has increased in size up to the day of entering Memorial Hospital.

Patient is a strong, hearty man, temperate, not subject to any cachexia, and having no history of hereditary disease. Situated in the left popliteal space is a tumor about the size of a goose-egg. This is circumscribed, compressible, and has a marked distensile pulsation.

Pressure on femoral artery lessens the pulsation and size of tumor. Direct pressure upon the swelling diminishes its size. A distinct bruit can be heard.

There is no cardiac trouble. Pulse 72, full and strong. Appetite good. Digestive functions in good order. There are no renal symptoms.

Diagnosis made of sacculated popliteal aneurism, and a trial of the treatment by flexion determined upon. Accordingly, the limb was strongly flexed at the knee and hip, and bound in that position. For twenty-six days this treatment was kept up. During that time, the tumor had diminished in size one-half, had become hard and tense, but still pulsated. The pulsation, however, was very much less than at the start. The tumor had become divided into two—one above and one below the fold of flexion. For most of the time the patient had kept the leg flexed by his own efforts, with no bandage. For a few days during this period, slight œdema of the foot appeared, which passed away after bandaging the leg. The only change in the treatment consisted in the use of a small compress of cloth, upon which the leg was flexed a portion of this time. Full diet was allowed the patient. His appetite had been good, and for most of the time he had wheeled himself about in his chair.

On the twenty-seventh day after being admitted, combined digital and instrumental compression was resolved upon. The instruments used were a conical weight of about seven pounds, suspended from above, and a Signorini tourniquet. Digital compression was made over the femoral artery, as it passes over the pubic bone, and this was supplemented by the tourniquet or weight placed upon the superficial femoral artery. The compression, which was continued for ten hours, was changed in method only as made necessary by discomfort of patient and attendants.

Throughout the entire operation, the aneurism was under constant surveillance, and whenever pulsation was perceived the compression was so adjusted that the throbbing ceased. The pain and discomfort of the operation were borne by the patient without anodyne or hypnotic.

At the end of the ten hours' compression, very little pulsation in the aneurism was to be felt. The tumor was smaller and harder than before the operation. Flexion at once was resumed and continued for twelve days. At the end of this period, a cure not having been accomplished, patient was again subjected to compression, but no weight was used. As before, relays of operators kept up digital compression—this time for twelve hours. The tourniquet was also used. The result was not entirely satisfactory, and after keeping the leg flexed for two weeks more, the same operation was undergone for the third time. The duration of the treatment this time was twelve hours. Four days after, the tumor still pulsating, though feebly, compression was once more tried for half a day. No tourniquet was used this time, but digital compression alone employed. There were relays of operators of about fifteen minutes each. The report of the day following says that the aneurismal tumor was without pulsation, hard, and very small. An elastic bandage was put on the leg, and continued up beyond the tumor, and the patient was permitted to go home for a few days; but the tumor began to pulsate once again.

On September 14, seventy days after entering hospital, patient was called back to hospital, it being thought probable that the Hunterian operation would be a necessity. With no small gratification, the tumor appeared small, hard, and without the slightest tremor of pulsation. On the same day, patient was discharged, cured.

Two months after leaving hospital, patient reports that since date of departure he has never observed any pulsation in tumor, which is very small and difficult to find. He has worn an elastic bandage most of this time. He has returned to his work.

Remarks.—The above case shows a cure resulting from compression persistently employed. Compression in all its forms was tried—flexion, direct compression by compress, digital compression, instrumental compression, and, finally, the rubber-bandage.

The duration of the treatment, although longer than many cases treated by digital compression, had, we think, in this case, not a little to do with the successful issue; for sufficient time was allowed for dilatation of vessels; for the conveyance of collateral circulation; time also was allowed for laminæ formation in the sac, which formation was eventually to close its cavity.

Attention is called to the fact that the patient comprehended the *rationale* of the treatment, and intelligently assisted it in every particular. It is noteworthy that there was an absence of unpleasant symptoms; that no medicine was administered; and that full diet and good health were preserved during the treatment.

MEDICAL PROGRESS.

Pilocarpine in Severe Hiccough.—Dr. Ruhdorfer, in the *Allg. wien. med. Zeit.*, No. 38, 1883, reports a severe case of the above, lasting for three months, and which morphia, given hypodermically, could only check for a few hours or days. It resisted all the usual remedies, such as quinine alone and with extract of belladonna, tincture of castoreum, or tincture of valerian, in water or with aromatics, mustard poultices over the stomach, dry cuppings down the spinal column, chloroform, ether, zinc, bismuth, numerous emetics and purgatives. The patient dragged on for three months under various remedies, morphia being administered whenever a single attack lasted beyond eight hours. At last the attack became overpowering, and the hiccough was so loud that the patient could be heard outside the house, through two doors. She sat up in bed, supported by her parents; there were dyspnœa and cyanosis, the head was jerked in all directions, the pulse was small and frequent, the neck was distended. Remembering a case in the *Revue Médico-Chirurgicale*, Dr. Ruhdorfer injected a solution of pilocarpine hydrochlorate (three centigrammes in a gramme of water; gr. ss–♏xv). The hiccough was at once cured, as if by magic, and has never returned since.—*British Medical Journal*, Nov. 17, 1883.

The Cure of Hydrophobia.—Gingeol has recently made a communication to the Académie de Médecine of Paris on this subject, with the following conclusions: 1. There is reason to believe that clinical experience will verify the opinion as to the good effects of hoang-nan in the treatment of hydrophobia. 2. The oriental practice, which consists in administering the drug per orem, should be rejected on account of the dysphagia and the eventual vomiting. 3. The drug can be better administered by the subcutaneous injection of an aqueous solution—1 to 10—of the alcoholic extract, or an alcoholic acetous preparation, every ♏xv of which represent probably the active principle of three of the pills recommended, and given by Tong-King. 4. The maximum dose of the preparation can not be formally indicated, but must depend upon the indications.—*L'Indipendente*, November 15, 1883.

The Action of Chlorate of Potash.—M. Mering has recently made some experiments on this drug, basing his results on recent researches. He draws the following conclusions:

1. Chlorate of potash traverses the organism for the greater part, without undergoing any alteration.

2. In a mixture of blood and chlorate of potash, methæmoglobine is formed; at the same time a part of the chlorate of potash is reduced.

3. The addition of an alkaline base retards decomposition of the blood; addition of carbonic acid accelerates that decomposition.

4. Chlorate of potash causes more rapid decomposition in non-oxygenated blood than in arterial blood.

5. The deleterious action of chlorate of potash is manifested principally when the salt is absorbed by an empty stomach, and when its elimination is insufficient. —*Gaz. Méd. de Paris*, November 17, 1883.

The Changes in the Spinal Cord after Arsenic, Lead, and Mercury Poisoning.—Dr. N. Popow, after a number of experiments on this subject in the clinical laboratory of Prof. Mierzejewsky, with subsequent microscopic examinations, draws the following conclusions:

1. Arsenic, lead, and mercury, produce marked changes in the cord in acute cases of poisoning, which must be regarded as having the character of acute central myelitis.

2. In proportion, as the cases are protracted, these changes are not merely confined to the gray substance, but invade the white substance of the cord and produce changes similar to those seen in a diffuse myelitis.

3. The peripheral nervous system is completely unchanged by a rapid action of these poisons.

4. The clinical symptoms on the part of the nervous system, observed during rapid poisoning by these substances, *e. g.*, cramps, paralysis, pains, and anæsthesia, are fully explained by the morbid changes found in the spinal cord; and no one of these symptoms can be attributed to an affection of the peripheral nervous system.—*Virchow's Archiv*, Bd. xciii. Heft. ii.

Paracentesis of the Pericardium.—Dr. J. W. Macdonald read the report of this case before the Canada Medical Association.

He was called to see the patient, a married woman, aged 30, on the evening of June 10, 1883. She stated that, three weeks previously, she had been seized with severe pains in the joints, attended with high fever. A day or two afterwards, she complained of pain and violent beating at the heart.

Condition on June 10th: She was unable to lie down with comfort; the face was pale, anxious, and slightly œdematous; the breathing was short and panting; the heart's action tumultuous, and its movements could be perceived through her clothing. On examination of the chest, a dull area was found over the præcordial region, extending from the right edge of the sternum towards the left for about eight inches, and from the seventh intercostal space to the level of the upper margin of the second rib. A loud and distinct to-and-fro murmur at the apex, and a harsh systolic murmur at the base, were the sounds heard on auscultation. The lower lobe of the left lung, posteriorly, was very dull on percussion, and conducted the heart-sounds, so that the murmurs could be very distinctly heard in this situation. Over this area, there was also puerile respiration and increased vocal resonance. A narrow strip, giving normal sounds on percussion, extended down the side from the axilla, and divided the dull areas in the front and back of the left chest. The pulse was small, irregular, and 120 per minute. She was troubled with diarrhœa.

Blisters, iodine, and diuretics were employed, and for a few days the fluid diminished; but the symptoms became aggravated, and the dyspnœa and agony about the heart became unbearable. To use the patient's own words, she felt, "as if the heart was going to burst." She could get no rest except when propped upright, and she frequently fainted. The diarrhœa continued, and, in the hope that it might promote absorption of the effusion, he made no attempt to check it.

On June 18th, he resolved to operate, a point one inch below the nipple, and close to the lower margin of dulness, being fixed upon: first, because no heart-impulse could be felt there; and, second, because it was at the most dependent part of the pericardial cavity. The patient was placed in a semi-recumbent position; chloroform was very cautiously given; and the mamma was held up out of the way. He then made a preliminary incision through the skin, and dissected down carefully between the ribs. No impulse being felt by the finger in the wound, he pushed a moderate-sized aspirating-needle through the remaining tissues; and, feeling that he had entered the cavity, withdrew the stilette. A few drops of greenish-looking fluid escaped; but it appeared impossible to get it to run freely, even after applying the aspirator. Just as he was preparing to enlarge the opening, for the purpose of introducing a tube, the fluid began to run freely; and, on the patient drawing a full breath, it escaped in little jets. After persevering for some time, the cavity was emptied; the dull area over the heart was reduced to its normal size; and the patient, though extremely weak and inclined to faint, was very greatly relieved. The fluid withdrawn measured thirty-two ounces; was of a greenish color, resembling bile; and tended to coagulate on cooling. Shortly after the operation, she could lie down with comfort on either side, and draw a deep breath without inconvenience. The pulse fell to 100, and became more firm and regular.

The patient recovered rapidly.—*British Medical Journal*, October 27, 1883.

ACCESSORY SUPRARENAL CAPSULES IN THE BROAD LIGAMENTS.—MARCHAND has encountered six cases in new-born infants, in which there were accessory suprarenal capsules in the broad ligaments. They were in the form of small yellow bodies, rounded, and situated in the thickness of the broad ligament, near its free border in the vicinity of the ovary. They measured from one to three millimetres in diameter. In one case there were two of these bodies near together. That they are really adrenals is recognized by their histological structure: They are seen, on examination, to be made up of layers of epithelioid cells separated by vessels joining in a common trunk. The pigmentation of the suprarenals, however, is absent. The existence of similar elements may be explained by the vicinity of the suprarenal capsules relatively well developed, and the communication with the embryo of the internal spermatic or ovarian vein.—*Virchow's Archiv*, Bd. xcii. Heft 1.

PORRO OPERATION.—On September 30th, PROF. M. FRARI performed a Porro operation at the Instituto Ostetrico at Padua, on account of rachitic deformity. The patient died of septic peritonitis on the seventh day. The child, well developed, was saved.—*L'Indipendente*, November 15, 1883.

THE HEREDITARY FORM OF DIABETES INSIPIDUS.—At the fifty-sixth session of German naturalists and physicians, DR. WEIL, of Heidelberg, presented the genealogical tree of a family of 91 persons, of whom 70 had come to adult life, and of these 23 were affected with diabetes insipidus. Of the 23 persons, 5 have died, one lived in America, and 17 were examined by Weil. There is no other hereditary disease in the family, the members of it being generally of robust constitution, and often live to a very advanced age. The grandfather lived to the age of eighty-three; one of his daughters to seventy-four; and two others to sixty-six and sixty-five.

Of the seventeen diabetics, five are aged from thirty-nine to sixty-six; two others are twenty and thirty years of age; six are from ten to twenty, and four between two and eight. All are in perfect health except for their insatiable thirst and abundant urinary secretion. The quantity of urine passed in twenty-four hours by the younger members of the family (under thirteen years of age) is between two and two and a half gallons. One, aged 42, passes about five gallons. The appetite of these persons is normal, and the digestion regular. None of them present any nervous or genital troubles. In all those affected by polyuria, the symptoms begin in infancy, attaining their maximum towards the age of twenty years, and then diminish after the sixtieth year. This polyuria persists until death; its duration, then, is undetermined, and its prognosis very favorable, unless complicated by some disease of the general health.

In answer to certain questions, Dr. Weil said that the heart and vessels were perfectly normal, that only one was addicted to alcoholic liquors, and that moderately, and that it was impossible that the affection could be due to imitation, as the disease began in early infancy, and did not affect all the members of the family. None of the subjects had succeeded in conquering the thirst by habit or force of will. One only had been treated; ergot had diminished the thirst and urinary secretion, but the patient felt the worse for it.—*Gazette Méd. de Paris*, October 27, 1883.

TARTAR EMETIC IN EPISTAXIS.—GUEDEVO has published two cases of rebellious epistaxis which were relieved by tartrate of antimony and potash. The usual remedies had been tried in these cases without any good effect, when the following mixture was resorted to: ℞.—Tartrate of antimony and potash, gr. ij; distilled water, f℥iv; simple syrup, fʒvj. Sig. Take a teaspoonful every fifteen minutes until vomiting is produced. After more or less vomiting the hemorrhage ceases.—*L'Indipendente*, November 15, 1883.

THE MEDICAL NEWS.
A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

Communications are invited from all parts of the world. Original articles contributed exclusively to The Medical News will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

Subscription Price, including Postage,
Per Annum, in Advance, ... $5.00.
Single Copies, ... 10 cents.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

Address, HENRY C. LEA'S SON & CO.,
Nos. 706 & 708 Sansom Street,
Philadelphia, Pa.

SATURDAY, DECEMBER 8, 1883.

REPORT OF THE FRENCH CHOLERA COMMISSION.

In our issue of November 10th, we presented the substance of the preliminary report of the German Cholera Commission. At the meeting of the Biological Society of Paris, held upon the same day, M. Straus reported for himself and his co-laborers—Roux, Thuillier, and Nolacq—the results of their researches in Egypt upon the nature of cholera.

Twenty-four autopsies were made—seventeen on men, and seven on women—immediately after death. The Commission confined itself to the study of the intestinal fluid, the walls of the intestines, and the blood. The minute examination of the intestinal walls, stained by methylene blue, showed a large number of micro-organisms (bacilli and micrococci), bacilli resembling those of tuberculosis. But these were not constant, and it was impossible to make any pathogenic studies. Nothing special was found in the mesenteric ganglia, the liver, spleen, or kidneys.

The most important results were obtained from the study of the blood. The dark color and defective coagulation of the blood were immediately conspicuous. Either the globules subsided leaving a clear supernatant serum, or, if coagulation took place, it was slow, and the coagulum was like a soft jelly. Microscopically examined, the red disks were spread out, pale and non-coherent; the white corpuscles were numerous, and very granular. Further, there were seen in the clear spaces between the blood globules, certain small elongated bodies, suggesting those of the acetic ferment, and like those of pig cholera, but less elongated. These were found in the blood of the twenty-four subjects examined, and were particularly abundant in the mesenteric and abdominal veins. The attempts to stain these micro-organisms were unsatisfactory; for not only did they take color badly, but their extreme minuteness made it difficult to distinguish them from the débris of white corpuscles and the precipitated particles of coloring matter. At a temperature of 100.4°, and in tubes of blood, these elements proliferated, sometimes in groups and chains, and always at the bottom of the tube, protected from the action of the air.

The Commission are inclined to consider that they have found in this micro-organism the microbe of cholera; although they admit that the only proof of such view, viz., the successful cultivation or inoculation of the organism, is still wanting. Cultures were attempted with all sorts of culture-fluids, and were alike unsuccessful. Inoculations, subcutaneous and intravenous, the introduction of fluids containing the organisms into the intestinal canal, all failed, in whatever animal employed, including the mouse, which is supposed to be peculiarly disposed to acquire the diseases of man. On the other hand, the Commission feel that failure in these experiments does not exclude the possibility of the microbe in question being that of cholera. The suitable culture may not yet have been found, nor the animals susceptible to the germ. The microbe of malignant pustule resisted for years the most patient researches of the best observers.

Another fact noted by the Commission was the reaction of the blood of choleraics, as determined by testing the serum which separated from the globules when the blood was placed in tubes. This was found to be slightly acid in the majority of cases. And in an autopsy made half an hour after death, the pericardial fluid was also found to be acid, while the blood of subjects dead of other causes presented no such reaction.

A comparison of these results with those of the German Commission reveal wide differences. But ten autopsies were made by the latter. The blood was found free from micro-organisms, which were, however, found in small numbers in the vomited matters, and were numerous in the dejecta. On the other hand, the organism to which most importance was attached—a bacillus resembling in size and shape most nearly that of glanders—was found in the intestinal wall, in which, apparently, nothing distinctive was found by the French Commission. Both Commissions failed in inoculation experiments.

It is evident, from these most diverse results, that our knowledge of pathological mycology and its investigation is still far from that preciseness which will allow us to attach any great value to observations by whomsoever made, and upon whatsoever disease, except, probably, the parasitic skin-diseases, and one or two only of the infectious diseases—malignant pustule and relapsing fever.

WIRING THE FRACTURED PATELLA.

In the issue of The Medical News of last week, we called attention to the treatment of fracture of the patella by wiring the fragments, and analyzed all the cases which had fallen under our notice, with a view to pointing out the dangers of the procedure. Since then we have received the London weeklies of November 17th, from which it appears that important debates upon the subject have been held at the Medical and Clinical Societies of London, with the result of eliciting the opinions of many of the leading surgeons of the great metropolis as to its merits. In France, too, as we learn from the *Gazette Médicale de Paris* for November 17, and the *Union Médicale*, for November 15, the antiseptic suture of the patella was discussed at the Société de Chirurgie. The most comprehensive papers upon the subject are those of Mr. Turner, which was read at the Clinical Society of London, and which may be found in the *British Medical Journal*, for November 17, and of Mr. Macewen, of Glasgow, which is published in the *Lancet* for the same date. In these contributions, and in the discussion at the Société de Chirurgie, are contained 37 cases which were not noticed in our own columns. Our present objects in again calling the attention of our readers to the subject are, first, to add the new cases to those we have already analyzed, in order that they may reach a definite conclusion as to the risks of the procedure, and, secondly, to present the opinions of the gentlemen who took part in the discussions, in favor of or adverse to the method.

The patella has been sutured antiseptically 86 times, the surgeons having been Lister in 7 cases; Bell, Howse, Kœnig, and Macewen, each in 4 cases; Bloxam, Rose, Johnson Smith, Trendelenburg, and Wood, each in 3 cases; Cameron, Davies-Colley, Jessop, Rosenbach, Wheelhouse, and Schede, each in 2 cases, and Amphlett, Beauregard, Bryant, Bull, Cagnoli, Dicken, Fowler, Gœring, Golding-Bird, Hartwick, Holderness, Holmes, Sydney Jones, Langenbeck, Langenbuch, Lauenstein, Lloyd, Lucas-Championnière, MacCormac, Metzler, Parker, Pemberton, Poncet, Pozzi, Pye, Sabine, Schneider, Henry Smith, Socin, Teale, Timme, Turner, Uhde, Van der Meulen, Wahl, and Wyeth, each in 1 case.

In the single cases of Bull, Dicken, Sydney Jones, Holmes, MacCormac, Pye, Turner, Von Langenbeck, and Wyeth, in 1 of Bell's, in 1 of Bloxam's, in 1 of Rose's, and in 1 of Wood's, in Schede's 2 cases, in 2 of Kœnig's, and in the 3 cases of Johnson Smith, the joint suppurated. Of these, the case of Bull died of exhaustion and, probably, pyæmia; that of Wood died of pyæmia; those of MacCormac and Von Langenbeck died of septicæmia and pyæmia, after amputation of the thigh; and the case of Wyeth recovered after amputation of the thigh. The remainder got well with stiff joints. In the case of Wahl, there was partial necrosis of the upper fragment, and in one of Kœnig's, the upper fragment perished. To these ill results must be added the death of Fowler's patient from carbolic acid poisoning.

The statistics of the operation demonstrate, therefore, 23.2 per cent. of suppuration of the knee-joint; 5.8 per cent. of deaths; 2.3 per cent. of necrosis of the fragments; and 3.5 per cent. of amputation of the thigh, results which clearly indicate that the procedure does not warrant the enthusiastic estimate that Mr. Lister has placed upon it, and that it will not replace other safer methods of treatment.

The supporters of the operation are, in addition to Lister, Turner, Royes Bell, Bloxam, Macewen, and Cameron. Adams and Lucas-Championnière approve of it when practised by surgeons who are best experienced in antiseptic measures. Chauvel, Forget, Gilette, Holmes, Heath, Sydney Jones, and Morant Baker think it justifiable in some old cases in which the limb is useless, but they condemn it in recent cases; while Bryant, Gant, Morris, Owen, Verneuil, Le Fort, Richelot, Desprès, and Labbé do not consider it justifiable under any circumstances. Our own view is that it should be restricted to cases in which ordinary measures have failed to secure union, and that it should only be done, under these circumstances, by those who have had a large and successful experience in aseptic surgery.

ADVERTISING DOCTORS.

Doctors who advertise may be classified like objects in natural history. There are doctors who advertise outright and make a merit of it. They are derisively called "quacks," but they are honest quacks, and fly their own flag. There are doctors who advertise indirectly, and obtain any advantage they can in this way, without sacrificing their professional status, and who live within the letter of the Code of Ethics, if they ignore its spirit. There are, still, voluntary and involuntary advertisers—those who deliberately glorify themselves in the public prints, and those who are victims of circumstances, and are displayed in the loudest type without any agency of their own.

In a recent issue of *The Medical Times and Gazette*, of London, a leader devoted to the subject of "Medical Bulletins," declares that the prejudices existing in England "against medical men advertising themselves," may be "doomed to disappear as our institutions become more Americanized." Nothing could be more unjust. The great body of the medical profession in this country is, and has always been, immovably opposed to open or covert advertising on the part of its legitimate members. It is true the offenders have not always been disciplined, especially those who under the guise of official positions have paraded their wares before the secular public; but their conduct has none the less been severely reprobated by the great mass of medical men. There are some kinds of indirect, but quite voluntary, advertising difficult to reach by any tribunal but the common sentiment of the medical profession.

A very opportune illustration of this fact is afforded by the recent action of the Mobile Medical College. Coming into possession of a hospital, the faculty have issued a circular, setting forth the skill of their members and offering gratuitous service to the sick-poor of the State. In this case both the letter and spirit of the National Code are violated—for the claims of special skill made in the public prints, and the offer of gratuitous service, are alike condemned. These professorial advertisers evidently hope for immunity from the usual disciplinary results of such acts, because "the College" is the offender. As it is a fiction of the English law—"the King can do no wrong," so these gentlemen hope that "the College" may occupy before the profession a similar unassailable position. If a Mobile physician may not send broadcast through the State a circular offering his services as a specialist possessed of the highest skill, and agreeing to treat the sick-poor gratuitously (they must write and hear something to their advantage, before coming, however!), why should six or eight medical men, composing a College faculty, be permitted thus to violate the Code and offend the sense of professional fitness?

That form of advertising which we have called indirect, is practised to no small extent. Only a few days ago, in the columns of a New York daily, an eminent New York surgeon appears as the performer of a remarkable surgical operation, which is so described that the hand of a medical reporter can readily be traced. This eminent surgeon will, no doubt, indignantly deny his agency in the matter; but has he not some indiscreet follower, who gathers a precarious subsistence by piping up the achievements of his patron? Very recently, one of the papers of Philadelphia contained a glowing description of a private, special hospital; but the motive for this humanitarian recital was seen in the account of the medical engineer of this establishment, whose remarkable achievements in dermatological science were told in such extravagant phrase that only the insensibility of some pachydermatous animal could support the absurd flattery without collapsing. If such offenders are brought to book, we all know the defence: regret that such an unfortunate publication should have appeared; totally unauthorized; no one feels the impropriety more than the person concerned, etc. All this, and more, when the matter is given to the reporter by some attaché of the advertised great man, who, if he does not approve publicly, is secretly gratified. Much of this indirect advertising is done by reporters, who repay in this kind of cheap notoriety for services rendered.

It must be admitted that there are members of the profession who are advertised quite involuntarily, and pose in attitudes for which they have no liking. A high position, fairly won, may seem a justification for newspaper notice; but every right-minded physician must feel that such cheap applause rather hurts than helps, for through it all lurks the suspicion of contrivance or connivance.

Moral.—In this eager striving for notoriety rather than the just honors of the medical profession, do we not discern the need of maintaining a high standard of ethical requirement? Abate in any respect our regard for the proprieties of professional life, and see the consequences. Remove one stone, and the whole edifice tumbles about our ears. Allow these forms of advertising to obtain a footing of the slightest tolerance, and the newspapers will not have space enough to accommodate the multitude eager to display their wares. What, then, will be the position of the medical profession?

But, says the *Medical Record*, "the triumph of the New Code shows that medical men are growing more liberal as to interpretations of professional conduct, and that of itself is a good sign."

INJECTIONS INTO THE UTERINE TISSUE.

Dr. Schücking proposes to treat certain maladies of the uterus by injecting the medicament directly into the substance of the organ. We believe that this expedient, which he brings forward as new (*Berliner klin. Wochen.*, No. 27, 1883), has been often employed in this country. The advantages of this method are two: it is local; it causes much less pain than subcutaneous injections. The remedies so employed are ergotin, Fowler's or Pearson's solution of arsenic, tincture of iodine, carbolic acid, and some other agents. The principal diseases thus treated, are subinvolution, chronic metritis, fibroids, and some forms of displacement. For the performance of this operation the ordinary hypodermatic syringe suffices, but the needle must have the necessary length to reach through the speculum into the uterus. Only concentrated solutions are suitable, since the tissue of the organ is too compact to admit more than a few minims.

That this method is not a mere fancy, is proved by its employment in this city at the present time. We happen to know that a competent and enterprising female physician is using in this way a solution of carbolic acid, five per cent. in strength, for the relief of uterine cancer. The solution is freely injected into the tissue immediately subjacent the cancerous mass. Too short a time has transpired to permit any opinion as to the ultimate result of this method. It has, however, removed the very severe pain which the poor patients were suffering.

ANTISEPTIC SURGERY.

If additional proof of the value of antiseptic over old methods of managing wounds were needed, it would be found in the results obtained by Professor Bruns, of Tübingen, and published in a recent brochure. Of one hundred and forty-nine amputations performed between 1877 and 1882, only 5.5 per cent. proved fatal. During that period, amputation of the leg was attended with a mortality of 3.2 per cent., and of the thigh of 2.5 per cent. From 1843 to 1863, or in preantiseptic days, the same operations showed, respectively, a mortality of 29.7 and 43.5 per cent.

Equally striking results were obtained by Professor Esmarch, of Kiel, in 92 resections of the knee done between 1857 and 1882, of which a full account may be found in an inaugural dissertation by Dr. Mensing. Of 21 cases treated in accordance with old methods, 14 recovered, and 7, or 33.3 per cent., perished. Of 23 cases managed with Lister's dressing, 21 recovered, and 2, or 8.7 per cent., died. Of 48 cases treated with the antiseptic dressing of Neuber, 47 recovered, and 1, or 2 per cent., perished. In other words, the mortality of antiseptic resections was 4.2 per cent. as against 33.3 per cent. for non-antiseptic operations.

INFECTIOUS NEPHRITIS.

Infectious nephritis is the title given to that form of nephritis which is often found associated with erysipelas of the face. It has, of course, long been known that albuminuria is a frequent accompaniment of erysipelas, and although it has always been looked upon as a rather grave symptom, it formerly had no more stress laid upon it than the albuminuria of other acute diseases, as, for instance, typhoid fever and the eruptive fevers.

Since the discovery by Hueter and Nepveu, in 1868, of a microbe of erysipelas, and its more recent recognition in the blood, in the fluid of the blisters, and in the urine of erysipelatous patients, this albuminuria has been allowed a greater significance. It is now an acknowledged sign of infectious nephritis.

In an inaugural thesis recently published, Dr. Jules Bleehmann has taken up this subject, and, in addition to tracing the history of the urinary symptoms in erysipelas, has added some personal experiences, and has described the lesions and the progress of the erysipelatous nephritis. Throwing aside all other theories which have been suggested, he ascribes the nephritis to the irritant action of the poison germs upon the tissues of the kidney.

That the albuminuria accompanying erysipelas is a part of a nephritic process we satisfied ourselves as far back as 1872. The bloody urine and the epithelial and blood casts could scarcely receive any other interpretation. In view of the recent disposition to ascribe all of the inflammatory processes constituting a part of infectious diseases to a minute organism, it is to be expected that infectious nephritis should be referred to a similar origin. That it may be due to some irritating constituent of the blood in the infectious disease, just as the nephritis of scarlatina is caused by its poison in the circulation, is a very reasonable supposition. But that it is due to a microbe has not, in our judgment, been proved, and so to assert, with the present evidence, is begging the question.

TRANSFUSION OF BLOOD BY HYPODERMATIC INJECTION.

Our Italian *confrères* have manifested much ingenuity in devising methods of transfusion. The most recent contribution made by them to this subject is transfusion hypodermatically. Thus Dr. Paladini has reported a case in which complete success followed the injection under the skin of the abdomen of about 130 grammes or four ounces of blood. The case was one of menorrhagia, the patient losing so much as to faint repeatedly, although recumbent. The husband of the woman furnished the blood. By means of a hypodermatic syringe the blood was drawn from the veins of the donor, and was injected through the canula of a trocar previously introduced, and by means of which a cavity was hollowed out in the connective tissue to receive the blood. The blood-tumor thus formed disappeared in two hours, and neither induration nor abscess was produced. The hemorrhage ceased, the patient took food, and the night following slept tranquilly. The subsequent recovery proceeded without accident.

THE UNSANITARY CONDITION OF CLOSED SUMMER RESORTS.

Great evils result at many summer resorts from the way in which hotels and boarding houses are closed and left. There is generally no attempt at house-cleaning. All manner of trash is left in the cellar; pieces of meat lying on the kitchen range, and unwashed towels in the scullery; fruits and vegetables, partly decayed, are scattered here and there. As a rule, the tenant leaves as soon as he can after evacuation day, and makes no attempt to put the house in sanitary order. So long as this plan is followed, the outside cleaning by city boards of health will not be enough. The house-cleansing and carpet-sweeping company must do its work in the autumn.

REVIEWS.

Epitome of Skin Diseases, with Formulæ, for Students and Practitioners. By the late Tilbury Fox, M.D., F.R.C.P., and by T. Colcott Fox, M.B., M.R.C.P. Third American edition, revised and with additions. By T. Colcott Fox, B.A. (Cantab.), M.B. (Lond.), etc. Duod. pp. 240. Philadelphia: Henry C. Lea's Son & Co., 1883.

For the busy practitioner who cannot give that time to the study of skin diseases which is necessary to master the subject, such manuals as the present have their use. And while we consider this and all similar works little less than pernicious for the medical student, we can cordially recommend Fox's *Epitome* to those graduates whose time as well as knowledge is limited, and who wish a handy manual to lie upon the table for instant reference in the hour of need. Its alphabetical arrangement is suited to this use, for all one has to know is the name of the disease; and here are its description and the appropriate treatment at hand and ready for instant application.

The present edition has been very carefully revised by the surviving author, and a number of new diseases are described, while most of the recent additions to dermal therapeutics find mention; and the formulary at the end of the book has been very considerably augmented.

The Physicians' Visiting List (Lindsay & Blakiston's) for 1884. Thirty-third year of its publication. Philadelphia: P. Blakiston, Son & Co.

That the *Physicians' Visiting List* has reached its thirty-third year of publication is ample evidence of the high favor with which it is regarded by the profession. In its issue for 1884, it retains all the features which in past years have conduced to its popularity. The posological tables have been revised in accordance with the new Pharmacopœia, and there have been added a list of new remedies and a description of Sylvester's method of artificial respiration. This visiting list fully meets the requirements of the busy practitioner.

SOCIETY PROCEEDINGS.

NEW YORK COUNTY MEDICAL SOCIETY.

Adjourned Annual Meeting, November 26, 1883.

The President, David Webster, M.D., in the Chair.

The minutes of the Annual Meeting held October 22d having been read and approved,

the report of the committee on hygiene,

Dr. S. Oakley Van Der Poel, Chairman, which had been postponed from the annual meeting, was read by the Secretary, Dr. W. M. Carpenter.

It consisted of four parts, of which the first was a paper by Edward G. Janeway, entitled,

MORTALITY TABLES AND EPIDEMIC INFLUENCES.

The following extracts embody its more important points: The mortality for the nine months of the year ending on September 30th, has been less than in the corresponding periods of the years 1881 and 1882. It has, however, been somewhat greater, both absolutely and comparatively, as regards increased population, than that of the same period in the years 1878, 1879, and 1880. The work of systematic vaccination was commenced in 1875, and continues at the present time. Previously, spasmodic efforts were made when an epidemic was prevailing. Since that time the corps of the Board of Health charged with this work has performed 119,856 primary and 430,783 re-vaccinations, a total of 550,549. The work was initiated when a very severe epidemic of smallpox had already gained considerable headway. Aided by prompt action in removal, isolation, and disinfection, where the disease has shown itself, as well as by thorough vaccination and watching of the people in the neighborhood of the outbreak, the Board of Health has been able to hold the disease in check on the two occasions when it has since developed. There have been 780 deaths from smallpox since the end of the epidemic in 1877, a period of six years, a number of them in recently arrived immigrants. Without taking into account the fact that the city has trebled its population in the time comprised in this table, the mortality from smallpox is only one-half to one-fourth of what it was in any preceding six years, except between 1866 and 1871. Had the same mortality prevailed as in the years following 1848, instead of 780 deaths in the six years terminating with 1883, we should have read 7500. In other words, 6500 people have been prevented from dying of smallpox. Should some one object to the method of arranging the years, let him do it as he will, and yet he will find ample evidence of a strong disturbing influence operating against the development of smallpox since 1866, the year in which the Health Board was organized, and especially since 1875, the year in which a permanent corps was detailed to do this work constantly, and as vigorously when no epidemic existed as when one was present. Physicians should ever urge on this work, since, when smallpox has only prevailed to the limited extent of the six years just ending, people become careless, and persuasive vaccination by public authority becomes difficult. It is far more essential to keep up thorough vaccination now than to wait for the visitation of another outbreak of the disease, which will find its victims in the careless and obstinate.

We have commented so freely in previous years upon the statistics and their indications, that we shall dwell but briefly upon some facts which we deem of importance to keep before the physicians of this city. The tables show at a glance the fluctuating character of the mortality from measles, scarlet fever, and diphtheria; from which it seems probable that, owing to the moderate number of deaths from scarlet fever this year, we shall witness next year a marked increase of this disease; whereas, for measles, the probability is that there will be a considerable diminution. Diphtheria is on the decline, and from the previous course of the disease it is probable that this diminished mortality may continue for another year or more.

Pneumonia has produced 41 less deaths than last year, but 235 more than in 1881, and 634 more than in 1880. Bronchitis, however, has caused fewer deaths than either in 1881 or 1882. Consumption, on the other hand, caused 35 more deaths in 1882 than in 1881, and 59 more deaths in 1883 than in 1882.

The summer was so comfortable that we find a comparatively moderate mortality from diarrhœal diseases. Yet we observe that the mortality from this class of disorders is 2363 less during the last six of these twelve years, notwithstanding the increase of population by 300,000 during the time comprised. As 1872 was an exceptionally hot and fatal summer, it seems as if an unfair conclusion might be drawn from including it. We can gain a better idea by comparing 1873 and 1881, both comparatively cool summers. In the latter of these years, 16 more deaths occurred than in the former; yet the population had increased 225,000, in round numbers, and should have led us to expect an increase of 730 in the mortality. No one is more aware than the writer of the fallacies liable to occur in comparing vital statistics; yet he feels that, making all due allowance for possible error, a considerable number of lives have been saved by the result of the employment of the summer corps of the Board of Health and of the active charity of New York City.

Mortality for the Three Quarters of the Years.

Typhoid fever has made no very marked change in the past three years. The outbreak of typhus fever which began in 1881 seems terminated, as only 10 deaths have occurred from this cause during the present year. He who looks at the number of deaths which took place from this disease when it gained an entrance in New York in past years will again see the value of an actively interfering agency to prevent the spread of disease. But for the efforts of the Board of Health, the disease would have spread greatly and extended over a number of years. Instead of a mortality of 225 in the outbreak of 1881–1883, there might have been a proportional increase, according to population, over what occurred in 1848 and the following years, when more than 4500 persons died of the disease: the equivalent of which would be over 10,000 for the present time. Judging from the annals of the past, a battle in which 10,000 persons were slain would now be commemorated in history; a battle, in which perhaps more than that number of lives were saved from destruction by pestilence, is a matter not deemed of any special moment. The moral of this is, that the medical profession of New York should see that its Board of Health is properly maintained, aided, and encouraged in its work. At times in the past physicians have, from neglect or concealment, failed to notify the Board of the existence of contagious diseases, with the effect of producing an epidemic in some cases. One case of a contagious disease may seem a little matter; but, as a single spark may cause a great conflagration, so this may be the means of initiating a great epidemic. Smallpox and typhus fever are well under control at present. Let each physician who would be inclined to treat a case of either of these diseases, reflect on the possible consequences should he endeavor to do so without reporting the matter to the Board of Health. In the writer's opinion, he would be more guilty than the man who commits a simple murder. For the sake of a fee or the good-will of a family, he would take the chance of endangering a community.

The second paper was by **Dr. O. D. Pomeroy**, on

SOME POINTS IN THE HYGIENE OF THE EAR.

Some of the points touched upon were the following: To those not in good general condition there was danger of ear trouble in riding fast in the wind, and this danger was increased if the air was damp. Otitis was not infrequently caused by sea bathing, in which it might be due simply to the application of cold water, or to the violent concussion of a wave, or the irritation caused by the entrance of salt water into the nostrils or the mouth. The wearing of cotton in the ears by bathers was recommended. Bathing in the unclean water about New York City, the writer thought, sometimes gave rise to inflammation of the ear. The bad effect of loud and continuous sounds was well shown in boilermakers' deafness, in regard to the exact production of which, however, some discussion was now taking place among otologists. Railroad engineers, ship-caulkers, and telegraph operators, were all more or less subject to ear trouble. Musical sounds, however, never seemed to produce this; monotonous and discordant sounds being required. The discharge of firearms might cause deafness, either by creating such a compression of air as to rupture the membrana tympani, or by the shock to the acoustic nerve, and it was recommended that those exposed to this danger should hold the mouth open. Having spoken of the pernicious effect of compressed air upon the auditory apparatus, the writer passed on to the evils arising from violence to the external ear. Boxing on the ear was a frequent cause of deafness, and pinching and pulling upon it might result in malignant disease where there was a predisposition to it. Sunstroke occasionally impaired the hearing. Syringing with warm water was the best treatment for impacted cerumen.

The next paper was by **Dr. Stephen Smith**, and was on

EMANATIONS OF SEWER GASES.

The very important subject of ventilating sewers, he said, had been altogether too much neglected. In New York the Department of Public Works had adopted a system of doing this, which not only filled the dwellings and schools, but saturated the very streets with the noxious vapors so productive of filth diseases, which everybody desired to avoid as much as possible. Connecting with the sewers was a series of perforations, or man-holes, by means of which the sewer gas escaped, and as it was of a slightly greater specific gravity than the atmosphere, it became a constant source of danger to the public. As an illustration, he mentioned the case of Forty-second Street between Fifth and Sixth Avenues, where he resided. On this block, eight hundred feet in length, there were nine man-holes (or one to every hundred feet), one of them being directly opposite a large club house, and another opposite a church. The air was seldom free from the odor of sewer gas, and in damp or foggy weather the residents were frequently obliged to close their windows on account of it. The street was a great thoroughfare, and those passing through it constantly noticed the odor, but generally supposed that it was brought on the wind from some distant quarter.

What was required for ventilating the sewers was an apparatus which was aspirating. The impure gases should be driven out and diffused through the atmosphere at such a height that they could do no injury, while their place was supplied by fresh air. What Dr. Smith recommended was the use of metallic tubes connecting with the sewers and carried to a sufficient height above the house-tops to secure the above end. Were these adopted, there would always be a downward current of air into the vaults, and if the ventilating shafts were placed only at intervals of one hundred feet, he had no doubt the sewers would be thoroughly ventilated. This was a matter which ought to be regulated by the Board of Health; but when any complaint was made to them of the existing nuisance it was referred to the Department of Public Works as the proper authorities to attend to it.

The fourth paper of the report of the Committee on Hygiene was by the Chairman, DR. VAN DER POEL, on the subject of

DANGERS TO PUBLIC HEALTH FROM THE ERECTION OF HIGH APARTMENT HOUSES.

The growth of the city of New York, he said, constantly excited new interest. Not long since, a law regulating the construction of tenement houses had been passed. It wisely restricted the amount of the lot which could be covered by the building, and also required that every room should be open to the external air. Now the numerous apartment houses which were springing up with such rapidity in every section of the city, called for the most serious attention on the part of the Board of Health. It was true that the same restrictions just mentioned in regard to tenement houses were required in their construction, but another evil had arisen in connection with them, which required new regulations, and this was the enormous height to which they were now being carried. The introduction of elevators did away with many of the objections to this on the score of convenience, but the practice of erecting lofty apartment houses was fraught with serious evils, not only to their occupants, but to all the neighboring property. As long ago as 1869, the authorities of Paris had passed an enactment which required that no house should be more than one and a half times as high as the street on which it was built was wide. Furthermore, it required that even on the widest boulevards no house should be more than five stories in height, exclusive of the mansard. The results of this were most admirable, and Parisian apartment houses were everywhere recognized as the best of their class.

Dr. Van Der Poel then gave several instances in which apartment houses in New York were carried to an enormous height. Thus, one on Madison Avenue was one hundred and twenty-two feet high, or twice as high as the street was wide, and it covered ninety-five per cent. of the lot on which it was built. This matter had already engaged the attention of the insurance companies, as well as of the Fire Department, the authorities of which had declared that it was impossible to save from destruction by fire any portion of a building that was over sixty-five feet high. If the erection of these lofty buildings were to be permitted indefinitely, the streets would be converted simply into narrow chasms.

Having alluded to the disfigurement of the city, from an æsthetic point of view, caused by these enormously high buildings standing beside those of ordinary size, and spoken of the beautiful and regular appearance of the streets of Paris in contrast, he went on to mention some of the evils to which the inmates of such houses were subject. Since the use of apartment houses had come into vogue, no general epidemics had prevailed in New York; but in case of an epidemic of contagious disease occurring, isolation would be practically impossible. In the next place, the apartments on the first three floors of such houses were deprived of sunlight, and must necessarily be more or less unhealthy in consequence. Thirdly, the air-shafts employed to give ventilation were a constant source of danger. As long as the plumbing was new, there might be no trouble; but, later on, it could not be but that miasma would be wafted to all the families on the upper floors. Hence, while the upper apartments were more desirable on the score of getting more air and sunshine, they were the most objectionable on account of this danger. As one line of pipes was usually employed, it was terrible to think what might be the consequence of cholera or typhoid fever breaking out in such an apartment house.

In the next place, he considered the injurious effects of these high buildings upon surrounding property. In the opposite and adjoining streets no sunshine could penetrate, and however clean they might be kept, they would be damp and unhealthy, as the sun's rays were the most important agent in causing rapid oxidation. It was on this account that in Italian cities, when there was far more sunshine than here, the upper stories were, as a rule, preferred. Again, on account of the great height to which these buildings were run up, currents of air were liable to be caused which might cause the chimneys of adjoining houses to smoke, or which might interfere with the ventilation of their sewer pipes. In conclusion, he advocated the passage of a law regulating the height of houses in accordance with the width of the streets on which they are built, as was the case in Paris.

Miscellaneous business being now in order, the Secretary read the

RESIGNATIONS

of Drs. Austin Flint, Jr., William Thurman, James H. Low, M. B. DuBois and J. E. Lay; all of which were, on motion, accepted.

ADDRESS OF THE RETIRING PRESIDENT.

DR. DAVID WEBSTER then delivered his address.

He said that during the year past, the Society had been in a flourishing condition; more scientific papers had been presented than could be read, and the attendance had been much larger than ever before. At the annual meeting last month, there had been an attendance of eight hundred physicians, and, although about two hundred of them were non-members, he believed that it was the largest meeting ever held by any local society on this continent. One hundred and fifty new members had been added to the roll; but there was still room for missionary work, as the membership was not yet quite a thousand, and there were about sixteen hundred unsectarian practitioners in New York. In concluding, he spoke of the distinguished members who had died during the year, among whom were Drs. George M. Beard, John P. P. White, F. D. Lente, Charles Wright, and J. Marion Sims. On motion, the adjourned annual meeting was adjourned; after which there was a

Stated Meeting.

THE PRESIDENT, S. OAKLEY VAN DER POEL, M.D., IN THE CHAIR.

The minutes of the above meeting having been read and approved, Dr. Van Der Poel, the new president, delivered his

INAUGURAL ADDRESS.

In the course of it, he said that the Society, which was not only the largest in the country, but contained some of the best known names in medical literature, was already in good working order. It had reached a point where better than merely ephemeral work should be done, and, he thought that the large number of hospitals in the city afforded a vast amount of rich material for study which had been hitherto practically denied to the mass of the profession, but which might be utilized to advantage through the agency of the Society. By this means the members might be enabled to study practically the relative value of different methods of treatment, the influence of diathesis, the affiliation of various complaints, and other similar topics. The collective investigation of diseases had for some time past been pursued with excellent results in Great Britain, and the British Medical Association had given aid and encouragement to the movement. He had often wondered why the matter had never been undertaken systematically here. It was true that some spasmodic attempts had been made in this direction; but the endeavor had been made to cover too wide a field. Such inquiry ought to be limited in its nature, and addressed to a comparatively few individuals. In England an example of the excellent work that had been accomplished, was furnished by arsenic, our knowledge of the effects of which had been materially increased by this means. He could not too highly recommend the advantage of self-study of disease, and would suggest as a topic which might perhaps be fruitful of good results, the investigation of dyspepsia, an affection which caused an unutterable amount of misery, but killed no one.

He then spoke of the death of Dr. Sims, whose name, he said, was almost a household word on both continents, and appointed Dr. W. Gill Wylie to read a memoir of him at the January meeting.

The paper of the evening, on

CEREBRAL EXHAUSTION,

was read by DR. J. LEONARD CORNING. The affection referred to, he said, was a functional one, but he believed that it was characterized by certain changes in the protoplasm of the brain-cells which, in the present state of our knowledge, we were unable to appreciate. The symptoms, taken in their chronological order, usually occurred somewhat as follows: Restlessness during the day, and sleeplessness at night; pains in the vertex or superciliary region, and sometimes confined to the occiput; disorders of memory; loss of will power; morbid irritability, often characterized by outbursts of unrestrainable anger; disorders of the vaso-motor system (cerebral hyperæmia often alternating with cerebral anæmia); disturbances of the heart's action; unevenness of the pupils; morbid dread of society; morbid fear of various kinds; and, finally, in some instances, hallucinations.

Having alluded to the predisposing and exciting causes, he went on to speak of the treatment. The principal point was to secure rest, by which the further drain upon the nervous system was prevented, and the energies recuperated. A gradually increasing amount of sleep was to be induced by keeping the patient in a darkened room for from ten to fifteen hours during the twenty-four. Whenever the patient awakes, nourishing food is to be administered in fluid form. Alcohol is generally required, and such tonics as cocoa, iron, and phosphorus are recommended, while systematic feeding is of the utmost importance. In the waking hours of the patient, reaction is to be indulged in, and all mental labor is strictly forbidden. The bromides are often of great service temporarily, and are to be given in full doses during the day, so as to insure sleep at night.

DR. PUTZEL said that he could not agree in some points with the writer. As to the circulatory disturbances in cerebral exhaustion, these were often advanced, but no proof of them was given. In the dead-house, these disturbances were not seen unless local disease was present. As to whether hyperæmia or anæmia was present in any given case, the best authorities often differ. The causes of cerebral exhaustion he believed to be heredity, worry, and general anæmia. When there was a hereditary tendency, it was usually found that no treatment was of much value. His general plan of treatment was a tonic and stimulant one, and the tonic he preferred was arsenic. The bromides, he thought, were very injurious in their effects. Often at first, their administration seemed to be followed by benefit, but subsequently they did much harm.

The paper was further discussed by Drs. David Webster, D. B. St. John Roosa, A. Jacobi, and E. Harwood, and Dr. Corning made a few concluding remarks.

The Society then adjourned.

NEW YORK SURGICAL SOCIETY.

Stated Meeting, November 13, 1883.

THE PRESIDENT, THOMAS M. MARKOE, M.D., IN THE CHAIR.

DOUBLE DISLOCATION OF THE PATELLA.

DR. F. LANGE presented a boy eleven years of age, who illustrated dislocation of both patellæ outwards in every attempt to flex the knee-joint. It was difficult to determine whether or not the abnormity was congenital, because it was not noticed until quite late. It had been simply observed that the child was not able to walk as well as other children, that his knees were exceptionally thickened, and became tired easily. Dr. Lange saw the boy about the first of June last, when he was pale, nervous, and sometimes fainted. When he walks he lifts his pelvis, and tries to keep the thighs as perpendicular as possible, thereby avoiding flexion at the knee-joints. The extensor muscles of the thigh are somewhat atrophied. Every time the joints are flexed the patella, which is abnormally small and flat, becomes completely dislocated, and turned so that its internal edge is directed in front, and the condyles of the femur can be easily marked out. There is a strong inward rotation of the femur during flexion. On the other hand he can extend the limbs completely only with difficulty; that is, they are stretched to about a right angle without hindrance, and then he makes a peculiar rotatory movement with the heel on the table and pushes the entire limb in order to complete the extension. If the patella is kept in position, he is unable to flex either joint. The hip-joints were normal. He had been wearing an apparatus, but without improvement. A complete cure probably cannot be obtained.

LIGATION OF THE COMMON ILIAC ARTERY FOR ANEURISM OF THE EXTERNAL ILIAC; OPERATION PERFORMED THROUGH THE PERITONEUM.

DR. LANGE also presented a patient with the following history:

The patient is thirty-seven years old; a musician;

admits having had gonorrhœa, but denies syphilis. He suffered from "ulcers in the throat" about six years ago, and presents still a hyperostosis of the right tibia of probably syphilitic nature.

In July, 1882, he first noticed pain in his left leg about the knee, which appeared quite suddenly and caused transitory intense lameness of the limb. In this way he suffered till January, 1883, being partly in hospitals, partly at home, but never entirely free from a discomfortable feeling or soreness in knee-joint. The joint is said to have been swollen, and was treated for some time by immobilizing dressing. A puncture was also at one time intended, but omitted on account of spontaneous improvement. The patient says that all through that time he had already a small lump, about the size of a pigeon's egg, in the left inguinal region. From January till May, 1883, the patient felt well, but in May he suddenly fell, on account of absolute lameness of the left leg, so that he had to be carried home, where he improved very soon. Such fits, without any pain, were repeated about three times within the next month.

In July, Dr. Lange saw the patient first. Several weeks previous to that he had been subject to severe suffering. The lump in his left groin, which so far had attained about the size of a hen's egg, had increased rapidly without apparent cause. Numbness and feeling of cold had befallen the limb, which became more and more weak, and a more or less severe pain along the anterior aspect of the thigh persisted.

On the 23d of July a pulsating tumor with all the characteristics of an aneurism occupied almost the whole iliac fossa, protruding the abdominal walls above Poupart's ligament. Its upper boundary ran from the anterior superior spinous process towards the umbilicus, ending about an inch below the same in the middle line. The latter formed about its medial outline. A spindle-shaped process of the tumor existed in the direction of the femoral artery below Poupart's ligament. But nowhere could arterial pulsation be detected on the limb, which was cool and had a bluish hue.

Ligation of the common iliac artery was performed as the only remedy worthy of consideration in view of the rapid growth of the tumor within the last few weeks, and I resolved to perform the operation through the peritoneum, on account of the difficulty which must have offered itself in this case to the retroperitoneal and customary way of procedure.

The patient was prepared by rest, diet, laxatives, and internal administration of bismuth, and the operation was performed under strict antiseptic precautions, without any serious difficulty, with the able assistance of Dr. McBurney and the House Surgeon at Bellevue Hospital on the 26th of July.

Dr. Lange decided to make a long incision, and it commenced, as could be seen from the scar, an inch and a half above the umbilicus, and reached downward about six inches. All the intestines were removed from the upper aperture of the pelvis and wrapped between large flat sponges outside of the abdominal cavity. An extra large speculum served as a good retractor and reflector, so that the second act of the operation, the ligation of the artery, was executed with safety and ease. The ligature consisted of silk, and was cut short. It could be ascertained that the artery was lifted from its normal bed by the blood-sac, over the medial aspect of which it could be traced for some distance.

No bad symptoms followed the operation, and the vitality of the limb remained unimpaired, excepting a small cutaneous necrosis on the large toe. The temperature was never very high, and as far as he remembered, only once above 102 F, at the time when the first movements from the bowels took place, and partly perhaps due to a cystitis in consequence of catheterization. The patient was discharged about five weeks after his admission. At that time a slight diminution of the tumor had already taken place, and a faint pulsation in the main arteries could be detected. Dr. Lange did not know whether that was not an error, because he was at a loss to discover any pulsation at this time. The temperature of the limb has become more nearly normal, yet it was somewhat less nourished, and is paler in color than the right one; sensation is normal, but reflex irritability is diminished *vis à vis* to the right side. The pain the patient complained of formerly has ceased, and the tumor has shrunk to the size of a good-sized orange.

COMPOUND COMMINUTED FRACTURE OF THE SKULL; ABSENCE OF BRAIN SYMPTOMS; HEALING BY FIRST INTENTION; RECOVERY.

Dr. Charles McBurney presented a child, five years of age, who received a compound comminuted fracture of the skull on the last day of October. He was operated upon a few hours after the receipt of the injury, under Dr. McBurney's direction, by Dr. Fuller, House Surgeon at Bellevue Hospital. There was marked depression of bone, but there were no brain symptoms. There was a ragged wound, about an inch in length, at the seat of the injury; and the operation was begun by extending this wound about an inch in each direction, when an area of bone about one inch in diameter was removed, made up of many small fragments. The dura mater was not injured. Before and during the operation, the parts were irrigated by bichloride solution, the edges of the wound were trimmed, and the aponeurotic layer, together with the periosteum, was brought together by one deep row of sutures, and the skin layer by another. No drainage-tubes were used. The wound was dressed with iodoform, prepared cotton and gauze, and a starch bandage was applied.

The dressing was not removed until the eighth day after the operation, when the wound was found in the condition of complete union, as then seen. Not a single unfavorable symptom developed during the progress of the case, and no dressing was required after the first was removed.

OSTEO-SARCOMA OF THE LOWER JAW.

Dr. McBurney also presented a colored boy, thirteen years of age, who had a tumor on the side of his face and neck, which was especially notable on account of its size. The tumor was said to have had a growth of nine years, and to have commenced in the lower jaw, from which time—according to the account—it had quite steadily increased in size up to the present date. According to the history, which was exceedingly meagre, the entire tumor was removed about three years ago; but Dr. McBurney had been unable to obtain any of the details of the operation. The growth seemed to involve the lower jaw, and possibly the upper jaw, and considerably narrowed the fauces and cavity of the mouth. Its circumference was twenty-five inches, and it measured eighteen inches from side to side. There had been an average growth of two inches during the last six months.

ARTERIO-VENOUS ANEURISM OF THE COMMON CAROTID ARTERY AND THE INTERNAL JUGULAR VEIN.

Dr. L. A. Stimson presented a patient, twenty-five years of age, who had traumatic communication between the common carotid artery and the internal jugular vein, produced by a stab with a penknife in February, 1882. A profuse hemorrhage occurred at the time of the injury, but it was arrested within two hours, and did not return. At the end of a week, the wound was healed. The neck, however, remained swollen, and in the following June, after a spree, a lump appeared in the throat. The face and neck became swollen; there was some difficulty of breathing; and the patient consulted a physician, who called his attention to a peculiar thrill in the neck. The acute symptoms soon subsided, and in the following August the man resumed work, but soon found that it interfered with his comfort, produced a choking sensation, vertigo, etc., and he abandoned it. Since that time he had consulted several physicians, and had been uniformly advised to have nothing done. He came to Bellevue Hospital complaining of gastric distress, choking sensation, vertigo, dimness of vision in the left eye, and loss of hearing in the left ear. There was considerable exaggeration in his account of all these symptoms. At that time, however, there was a marked thrill over the left side of the neck down to the clavicle, with a loud double sound. Dr. Stimson finally decided to operate, with the intention at first to place two ligatures upon the vessel, but finally decided to apply only one, and that upon the proximal side of the common carotid artery, trusting that the recurrent stream from the distal side of the opening would not be sufficiently strong to give rise to any discomfort. The operation was performed on the eighth day of October. An incision was made so as to expose the artery above the omohyoid muscle; but the tissues overlying the vessel were found so thickened at this point that the incision was prolonged downward, and the artery tied below the muscle; a drainage-tube was introduced, and a dressing applied. The dressing was changed on the fourth day; the drainage-tube was removed; and from that time recovery was rapid. There was no rise of temperature above 100° F., except once, and then only for a few hours, when it sank and remained normal. The thrill, which ceased at the time the ligature was applied, was perceptible at the first dressing, but it was very slight; and it can now be felt, but in very much diminished force as compared with that which was present before the operation was performed.

During the progress of the case, after the operation, two accidents occurred. The first was on the tenth day. The man awoke from sleep with præcordial anxiety and distress, and also distress in breathing, and was very much alarmed. He was quieted with a moderate dose of morphine, went to sleep, and suffered no further inconvenience. Dr. Stimson thought that the symptoms were due to disturbance in the pulmonary circulation, due to transmission of a small embolus detached from the clot. Exactly where it came from, however, he was unable to say. Since that time the patient had had no return of a similar attack, but has had at intervals a peculiar distress which would seem to indicate that probably the explanation given for the first attack was incorrect.

The second accident occurred about the fourteenth day, when he complained in the morning of some loss of power in the right hand, with a moderate amount of dizziness which disappeared in the course of two or three hours. He has not suffered from any inconvenience of a similar character since. Dr. Stimson thought that undoubtedly these symptoms were due to cerebral embolism.

PRIMARY EXCISION OF THE ELBOW-JOINT FOR INJURY OF THE ELBOW.

DR. W. T. BULL presented a patient, forty-eight years of age, who fell three flights from a scaffolding, and received a compound fracture of the ulna, the olecranon being splintered into several pieces, and a vertical fracture or fusion between the condyles of the humerus. He had also a fracture of the ilium on one side. The operation upon the elbow-joint was performed twenty-four hours after the receipt of the injury. All the articular ends were excised, the entire olecranon, the head of the radius, the condyles of the humerus, making in all about two inches of bone, the periosteum being saved as far as possible. The limb was dressed in the right-angled position, and healed, after an attack of cellulitis, in five weeks. Peat and carbolic acid dressings. Eight months after the operation, the patient has now very little power of flexion, but he is able to lift considerable weight with the limb, and the motion of the fingers is satisfactory. He is able to put his hand to his head. While the result was not all that might be desired, Dr. Bull thought that it justified the operation, and that the limb even with its crippled condition was a great improvement on an artificial one.

DR. WEIR suggested that considerable benefit might attend the use of some lateral support for the limb.

AMPUTATION OF THE ENTIRE PENIS FOR EPITHELIOMA.

DR. BULL also presented a patient, æt. 43, who came into the New York Hospital with epitheliomatous ulceration of the penis, for which the entire organ was removed down to the insertion of the corpora cavernosa into the pubic bone, the corpus spongiosum being divided just in front of the bulb. The specimen was presented. It was a rather curious fact that the patient traced his disease to the cicatrix of a chancroid, which had been in existence twenty years before. The growth itself appeared first as a wart, and gradually extended, and he had withstood the ulceration with the suppuration, and the effect produced upon his general system with a great deal of pain for ten years before submitting to the operation. At the time the operation was performed, the ulceration had extended as far back as to within one inch and a half of the root of the penis, but the extremity of the glans was intact. There were induration and enlargement of the inguinal glands upon both sides to the size of a horse-chestnut. In amputating the organ, Dr. Bull followed Demarquay's method. The penis was encircled by two incisions, which started from just above its roots and joined on its lower surface to split the scrotum, and extended as far as the middle of the perineum. The corpus spongiosum was divided in front of the bulb and detached from the corpora cavernosa, and the scrotum on either side dissected back. The attachment of the crura to the pubic arch was divided with scissors. The bleeding was not excessive, and was easily controlled with artery clamps.

The urethra was slit up along its roof and floor, and stitched into the edges of the wound at the peno-scrotal junction. A drainage-tube was inserted at the lower angle of the wound and the edges sutured with catgut. Peat and "bichloride" dressing. Primary union failed, and the wound healed by granulation in six weeks, a catheter was left in the urethra forty-eight hours, at the end of that time a chill occurred and it was withdrawn. A bougie or sound was passed every day for a month, but none has been used for two weeks past. When discharged, a No. 30 sound could be introduced without difficulty, and the same number can be used now.

With regard to the enlarged glands in the groin, Dr. Bull had intended to remove them, but as the operation had already been prolonged and tedious, he decided to postpone their removal until a future date. Since then the induration has *almost* entirely subsided, the improvement in the patient's general condition has been perfectly satisfactory, and began immediately after the operation was performed. He is obliged to urinate in the sitting position. Dr. Bull thought that the wound would have healed more readily had the testicles been removed at the same time amputation of the penis was performed, but the patient declined to part with all his evidence of manhood.

EXCISION OF THE WRIST-JOINT.

Dr. H. B. Sands presented a patient upon whom he had recently performed excision of the wrist-joint. He was a Swiss, forty-three years of age, and a waiter by occupation, who came under Dr. Sands's notice in the early part of last summer, having suffered for nearly a year with symptoms of strumous arthritis of the wrist, the disease having gone on to softening and destruction of the joint, without the formation of abscess. He was treated by immobilizing the joint, but without benefit. The wrist being considerably swollen, very painful, and tender, Dr. Sands decided to perform the operation of excision, which he did on the 31st of July, according to Langenbeck's method, by making a single incision upon the dorsum of the hand and wrist. It was found that the disease involved a great extent of the synovial membrane, which had to be almost entirely cut away. The ulna and radius were separated, so that they could be moved upon each other with crepitus, and before the operation; the bones were softened. The first row was removed by ordinary dissection, the other bones being removed with a sharp spoon; the trapezium, however, and also the pisiform bones being left. The extremities of the ulna and radius were removed, and the bases of all the metacarpal bones, except that of the thumb. A bone drain was inserted, peat dressing applied, and the arm suspended. When the first dressing was removed at the end of twenty-three days, the deep wound was found entirely closed, and there remained only a superficial ulcer which closed at the end of a few weeks. During the operation, the radial artery was divided, but no harm came from the accident. The hand is now beginning to become useful, and the patient has the power of extension and flexion of the fingers to a considerable extent. He can flex the first phalanges at nearly a right angle with the metacarpal bones. Apposition of the index finger with the thumb is easy, the extension of the latter being limited, in consequence of adhesion of the long extensor tendon to its sheath. The patient is free from pain, and is able to move his hand, and to grasp objects with considerable firmness. Passive motion was resorted to after removal of the dressing, and has been kept up steadily since. The operation was tedious, but Dr. Sands believed that Langenbeck's method of excision would be found preferable to that recommended by Lister, in which lateral incisions are practised.

Dr. Stimson remarked that he performed excision of the wrist last summer by the same incision, and found, as Dr. Sands had mentioned, that the removal of the bones was very easily effected.

Dr. Sands said he omitted to state that the power of the hand is very much increased when circular compression is made around the wrist.

ANEURISM BY ANASTOMOSIS OF FACE AND ORBIT—RIGHT SIDE; ELECTROLYSIS PERFORMED ON FACE; LIGATURE OF RIGHT COMMON CAROTID ARTERY.

The President presented a patient whom he first saw with Dr. Damainville, and who had kindly furnished the following history of the case:

Emily C., æt. 43, widow, born in France, had children, all healthy; was born with nævus on right cheek near the eye, which, although quite large, did not seem to grow or pulsate until after her first confinement, sixteen years ago: then it began to grow steadily, extending towards the lip, but giving her no pain. Seven years ago, a Dr. Goodridge or Goodrich—the patient remembers neither the name nor the address of the doctor—probably tied the right superior coronary artery, so far as can be made out from her vague description. Shortly after the operation, whatever it was, the aneurism began to extend upward towards the eye. She did nothing for it, as it gave her no pain, until some time in January, 1883, when, having accidentally struck her head against the bedpost, the tumor began to pain her, and to increase in size.

On February 7, 1883, she came to the French Hospital for treatment. At the time of her admission, her condition was as follows: Tumor well marked, extending from orbit and lid to the lip, elevating the skin to the extent of two inches or more; pulsation very strong, and easily seen from a considerable distance. All bloodvessels on that side of the face enlarged; mucous membrane of mouth and gums so vascular that they bled on the slightest provocation; complains of sense of fulness and throbbing in eye and lip, and says that her vision has never been as good with that eye as with the other. On introducing the finger into the mouth, the pulsations are felt to be very strong and violent.

February 17, 1883, Dr. Charles Bliss performed electrolysis by means of a zinc carbon battery. Eight cells were used, several needles being thrust in various places. Application lasted twenty or twenty-five minutes. This operation was followed by quite an extensive slough at the upper part of the cheek, the wound healing by granulations and leaving a crucial cicatrix. No hemorrhage took place during or after this operation. The pulsations were entirely suppressed when the sloughing occurred, and for some little distance around it, but nowhere else. The other parts of the tumor began to increase very much in size; the lower lid and the upper lip being very much swollen and throbbing violently, thus showing that electrolysis was followed by beneficial results only where it produced sloughing, as stated above.

April 21.—By the advice of Drs. F. H. Hamilton and T. M. Markoe, the right common carotid artery was tied above the omohyoid, the gut ligature being employed. Ether was administered. Simply dry cotton was used as a dressing. Union by first intention occurred, the ligature being absorbed. No bad symptoms followed the operation excepting pain in the right arm and around the clavicle, which prevented her from raising the hand to the head for the purpose of combing her hair, which, after the operation, began to fall off profusely. Immediately after the operation all throbbing ceased in the tumor, except at the inner canthus near the medial line, where a slight pulsation could be detected with the finger; but the improvement was steady and progressive as could be judged from the diminished size of the face, the comparatively free motion of the lower lid, and the feelings of the patient in general.

June 8.—She was discharged from the hospital. Although the pain in right arm had very much diminished, she still had some—enough to impede the motions of the limb. Pulsations in lid and lip suppressed, but quite perceptible at the inner canthus.

September 4.—Called to see me to-day. No pulsations perceptible except at inner canthus. Angular artery seems to be enlarged. Pain in right arm entirely gone. Thinks her vision on that side is very much improved; her hair has ceased falling off. Says that for the first time in a number of years she can chew on that side of her mouth, and can brush her teeth without making the gums bleed. The cicatrix on the neck is very firm, slightly painful on pressure or when the weather is about to change. Cicatrix on the face where electrolysis was performed is hardly perceptible; says she feels strong, and has not been as well in years. In fact, the benefit resulting from the operation is greater than usual, and her present condition is as satisfactory as could be desired.

Dr. Wm. S. Halstead then read a paper on

REFUSION IN CARBONIC OXIDE POISONING.

(See page 622.)

Dr. R. F. Weir remarked that last spring his attention was called to the frequency with which coal-gas poisoning occurred in the past few years, and also to the fact that the greater number were due to gas made by the water process, in which carbonic oxide exists in the proportion of about twenty-five to thirty per cent.; whereas in ordinary coal gas, made after the old method, it exists in the proportion of only two to six per cent. The danger, therefore, from leakage, unburnt gas, etc., in the use of water gas, is apparently very great, and should be known more generally than it now is. Coal or naphtha gas is much safer.

THE PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, November 21, 1883.

The President, William M. Welch, M.D., in the Chair.

Dr. J. C. Wilson presented a

NOTE ON PARALDEHYDE AS A HYPNOTIC.

He stated that he had found the medicinal dose to be from thirty minims to two fluidrachms, and a drachm to be the average dose for an adult under ordinary circumstances. It is to most patients disagreeable, and must be administered with a considerable draught of water. The taste and odor are ethereal and penetrating. Patients complain of this taste several hours after taking it, and it may be recognized by its odor in the breath. It is probably eliminated unchanged by way of the lungs. Paraldehyde acts upon the cerebral hemispheres, inducing rather speedy drowsiness without preliminary excitement. "A lethal dose suspends the functions of the medulla and the respiratory centre, and the action of the heart ceases after the respiration." One observer (Brown) noted a slight depressant effect upon the heart in a single instance. It is stated that neither nausea, depression, headache, constipation, nor any unpleasant after-effects have followed its administration. Several of his own cases complained of the disagreeable after-taste already alluded to, and one or two of nausea.

Paraldehyde has been prescribed as a hypnotic, by the Italian physicians who have used it, in the various conditions calling for such a remedy, but they have found it especially serviceable in the sleeplessness of dementia paralytica, hysteria, and in other forms of disorder of the nervous system.

Dr. Wilson has prescribed it in nine cases, with a view to its influence as a pure hypnotic. In one hysterical patient it acted well for a short time, but lost its effect, and was discontinued. In a patient who could not sleep, after having acquired the habit of watching an invalid at night, it procured prompt and refreshing sleep. In a lady rendered sleepless by a sudden and appalling bereavement, it caused sleep, but was abandoned on account of the nausea which followed its administration. A gentleman who had sleeplessness and great mental depression, after a debauch, and who failed to sleep for several nights after reasonable doses of the bromides and chloral, took a drachm of paraldehyde, and slept seven hours, waking refreshed and hungry. On the next day, this patient, being disturbed after he had taken it, failed to sleep, but succeeded in sleeping on taking a second dose. The other cases were sleeplessness from ordinary causes, and were all more or less fully relieved. It appears speedily to require an increase of the dose. He expressed the view that paraldehyde will prove a useful addition to our sleep-inducing drugs, but will supersede neither chloral, which it resembles in its effects, nor any others among them.

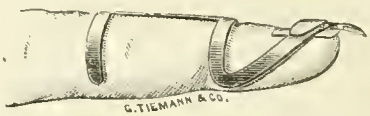
NEW INVENTIONS.

THE "AMNIONTOME."

By GEORGE F. E. WENCK, M.D.,

OF NINETY-SIX, S. C.

Rupturing the membrane during childbirth I believe is considered the most simple operation in medical practice. Still I have found that the finger-nails, as invariably suggested in text-books, are very often of no avail. I have, to accomplish the rupture of the membrane, introduced knives and scissors, which at the best constitutes an awkward procedure. This led me to construct a very simple instrument, which I call the Amniontome, and which was made by Messrs. George Tiemann & Co., New York City. I presented it to the South Carolina State Medical Association in April last. From very satisfactory personal experience with the instrument, I venture to recommend it to the profession. The amniontome, as seen in the accompanying figure, consists of a steel spring frame to which a small blade is attached. It is adjustable to the index finger of the right hand, but will fit any finger, both right and left. Placed in position it will not interfere with the main-joint of the finger, which can be moved at will while it is firmly attached. It has proved in my hands a simple and efficient means to rupture the membrane at any point presenting, during any of the stages of labor, needing very little skill or practice, and I only wish that the instrument may be of some service to the profession.



NEWS ITEMS.

BALTIMORE.

(*From our Special Correspondent.*)

Sanitary Convention in Baltimore.—The Sanitary Convention called by the State Board of Health of Maryland, met in the hall of the Young Men's Christian Association in Baltimore, November 27th and 28th, and listened to a number of interesting papers. The attendance was small, rather discouragingly so, but those who were present were repaid for their trouble.

Dr. Richard McSherry presided, and in calling the convention to order remarked that the political influence of a nation is as much dependent upon its muscular activity as upon its army and navy. Health is wealth. Our design is to combat physical evils by showing the people the best means of obtaining good food and pure air and water. Unthinking persons underrate medicine when they think it is simply the administration of drugs, for, in its higher sense, materia medica covers all that is of value to the physical interests of man. We accept the inevitable, but we must and will contest the ground step by step and inch by inch against all that form of evil which comes under the head of preventable disease. Prevention is better than cure, as primitive innocence is better than sinning and repenting.

Mayor Latrobe, in an *Address of Welcome*, said:

"I am sure the result of your deliberations will be beneficial. No subject is more usefully interesting than that of personal and public hygiene. Upon it depends, in a great degree, the prosperity and happiness of a community. The success resulting from a proper attention to public hygiene is shown by the reduction in the death-rate of so great a metropolis as London, now regarded as one of the healthiest cities in the world. Here in Baltimore, with our surface drainage, abominable system of cesspools, and other nuisances, our health reports show a very small death-rate. I attribute this in a measure to our abundant supply of good water, the rolling character of the ground upon which the city is built, aiding, as it does, the surface drainage, and enabling every heavy rain thoroughly to wash out the streets, the absence of tenement-houses, the naturally healthy location of the most populous sections of the city, and last, but not least, the vigilance of our health department. With a proper system of sewerage for sewage matter (it is a question with me whether surface drainage for storm water is not really more conducive to public health), a more liberal use of our ample water supply, the introduction of public baths, and the entire abolition of the sixty odd thousand sinks now honeycombing the surface ground of our city, I have no doubt our health department would guarantee to make Baltimore the healthiest city in the world.

"I refer to these matters incidentally in my remarks, as I see by the programme that many of them will be matters for discussion in your deliberations. It was with much pleasure that I listened a few days since, at the Johns Hopkins University, to a lecture on the subject of sewerage as applicable to large cities. I believe the time has come when Baltimore must realize that a proper system of sewerage is necessary for the preservation of its public health, and I am sure that a people which has had the courage to invest over nine millions for the introduction of water, will not be alarmed at the contemplation of the cost of a proper system of sewerage, required to protect health, and which, if judiciously controlled, will be as self-sustaining as are our great water works."

The **Hon. H. A. Hallowell**, of Montgomery County, read a paper in which he said: Rural districts are far from being the abodes of health that enthusiasts suppose. Bards have sung the praises of pure water, fresh air and living near nature, yet prosy truth discloses the fact that the rate of mortality of cities is not greater than that of the country. Vitiated air, wretched diet, impure water, never-ceasing toil, exposure, and hardship, claim victims more frequently in the country than statistics show. Country villages are really in need of sanitary information and regulations. In his own county, a certain pond of stagnant water which had been dammed up by the County Commissioners, caused last year several deaths and forty cases of malarial fever. In another part of the county, a neglected fish-pond was the source of an epidemic of fever causing a number of deaths, four of which were in one house.

Dr. W. S. Forwood read a paper on the so-called *Canning-house Fever*, a disease caused by the accumulation of refuse matter from the establishments, for canning vegetables, fruits, etc. There is some difference of opinion among physicians as to the extent to which these canneries are factors of disease, but all agree in declaring them an unmitigated nuisance. So far as stench was concerned, he recommended legislation compelling the proprietors of the canneries to remove all refuse in water-tight tanks within a certain time. He stated that it would make a good fertilizer.

Dr. J. F. McShane, Assistant Commissioner of Health of Baltimore, read a paper on *Vital Statistics*, urging legislation to provide a thorough system of reporting and collecting such data.

Dr. John Morris said that the Secretary of the State Board had been provided with a thousand dollars a year to register births, deaths, and marriages, but that not a single entry had been made. He himself had drawn up a bill to abolish this useless office, but the bill had been stolen.

At the sessions on November 28th, papers on *Sewerage* were read by **Col. George E. Waring** and **Mr. C. H. Latrobe**, C.E. Col. Waring's paper was a criticism upon Dr. Chancellor's recommendation of the Liernur system, pointing out that this system does only a part of what is desired, and that at a very high cost.

Mr. Latrobe said that in regard to the choice of a system of sewerage, we may safely conclude that there are but two fundamental questions, viz., which is the most efficient and economical as applied to each case which arises. In making this choice, the sanitary engineer and the sanitary physician, if I may be allowed the expression, should work in harmony. Each can contribute knowledge gained in his particular branch; the engineer, with his knowledge of physical forces, meteorological phenomena, adaptability of materials. and economy of workmanship, must be aided by the physician's knowledge of the seeds of disease, the dissemination, and insidious modes of attack. Together, they may hope to checkmate the enemy; singly, either may make grave errors. The systems now before the public for the collection and disposal of the sewage of cities and towns are: the system of dry removal, as it is called; the water-carriage system, and the pneumatic system. As to dry removal, this system proposes to deal simply with human excreta, totally disregarding all other household waste, as well as that from manufactories. Such a system must, of necessity, be a failure for large cities, from its want of scope.

After having equipped every house with dry-earth closets, you must, of necessity, provide in addition a complete system of sewers to carry off the waste water of the household and of the factory. Water-carriage is divided into two systems, the combined and the separate. The combined is that system in which a single set of drains or sewers is used to carry off household waste of every description (except ashes and solid garbage), which is pretty accurately gauged by the water supply to each house, the liquid refuse of factories and the storm water which falls upon the roofs, yards, and streets. This system is suited in those places where the conditions require that the storm water should be at once taken underground and carried to a distant outlet, whilst economy and structural difficulties forbid the building of two distinct and equally extensive systems—one for sewerage proper and one for storm waters. The separate system is alike with the combined in the fact that water is the vehicle and gravity the motor, but here the similarity ends. The sewage is conveyed in small pipes. The water, which enters the house clean and pure by the water pipes, after passing through bath-tubs, kitchen sinks, and water closets, leaves it as sewage. Cut off, as these sewers are, absolutely from all storm water flow, their dead ends may be taken care of by artificial means. This need is met by providing automatic flushing tanks, which empty at any interval desired into the dead ends, and being filled with clean water only, send a purifying stream into every small artery of the system. For Baltimore the estimated cost of the separate system, exclusive of outfall main, is $4730 per mile; including outfall main, $9790. This outfall main carries out sewage to the Chesapeake Bay, and is a costly but necessary addition to our city.

At the afternoon session DR. JOHN MORRIS read a paper on the *Etiology of Baltimore Catarrh.* He said there are at least twenty-five thousand unfortunates in Baltimore who are affected with catarrh. Many of those so affected are obnoxious to themselves from the ozœna therefrom. He described the disease and its manner of growth. He said that nasal catarrh was aggravated by certain conditions of the weather. The great prevalence of the disease is due to the character of the house air breathed during the winter and spring months. At the present time more than one-half of the houses of Baltimore are heated by the Latrobe stove, or by modifications of the same. This stove, as originally used, was not injurious to health, but changes were made which entirely changed its effectiveness. The air drawn by the stoves in present use is from the cellars, and the known noxious cellar-gases are not favorable to good health. These gases are caused by the subsoil of the city, which is impregnated with gases. These poisonous germs, which are scattered throughout, are due to the abominable system of wells and cesspools which is in use in Baltimore.

Other papers presented were by Dr. W. S. Wyman, of the Marine-Hospital Service, on *Quarantine;* by Dr. E. J. Henkle, on the last *Smallpox Epidemic in Baltimore;* and by Dr. R. Gundey, on the *Conflict of State Powers and Individual Rights in Sanitary Matters.*

All the papers read will be published by the State Board of Health.

THE JOHNS HOPKINS COURSE ON MUNICIPAL HYGIENE.—Dr. John S. Billings, U.S.A., is now delivering a course of twelve lectures at the Johns Hopkins University on "Municipal Hygiene." These lectures are attracting much attention, not only from the medical profession, but also from civil engineers, architects, plumbers, and others interested in sanitation. Whatever the distinguished lecturer undertakes he does well, and the present course cannot fail to increase his already well-earned reputation as a sanitarian. Most of the questions concerning public health now forcing themselves upon municipal authorities find exhaustive treatment.

THE ENORMOUS MORTALITY OF COLORED INFANTS.—One point of highest importance brought out by Dr. Billings is the small expectation of life of the colored population of our cities, as shown by tables compiled, for the first time, we believe, under his direction. From these it appears that of one million colored infants born in Baltimore, one-half will have perished before attaining the age of two years. A similar mortality prevails in other cities where the colored population is large. When it is remembered that of an equal number of white children born in Baltimore, one-half will live thirty-five years, the disproportion becomes startling, and makes imperative a close investigation into the causes, conditions, and remedies for this lamentable state of affairs. Another interesting feature of these tables is the disproportionately greater number of aged colored females than of males. Of the colored males, there will be left at 65 years 57,252; of females, 93,171; of males at 75 years, 19,440; of females, 56,283; of males at 85 years, 2929; of females, 12,726; of males at 95 years, 315; of females, 1477; while 75 males and 158 females will attain 100 years of age. As will be seen, these figures show rather a remarkably short duration of life of colored men than of longevity of colored women, who appear to be much shorter-lived than their white sisters.

DR. J. SHELTON HILL, a young physician of much promise, died last week of consumption, after a prolonged illness. Dr. Hill, originally from Alabama, had spent all his professional life in our midst, and, until overcome by the malady that destroyed him, bade fair to attain an eminent position in the profession.

WASHINGTON.

(From our Special Correspondent.)

MEASLES has appeared in Washington to a considerable extent, and although the public schools still keep open, several private ones have had to close.

ST. LOUIS.

(From our Special Correspondent.)

THE ST. LOUIS MEDICAL SOCIETY ON THE RECOMMENDATION OF PROPRIETARY MEDICINES.—The excitement which has been brewing in the St. Louis Medical Society within the past few weeks resulted in a slight explosion at the last weekly meeting, Saturday night. Stronger timber had been added to the Committee on Ethics, and a strong report, condemning such advertising as the recommendation of proprietary and other medicines, was presented to the Society. Strange as it may seem, the gentlemen who have fanned the breeze, who first inaugurated the movement, now seem anxious to throw ashes upon the flames, which have spread somewhat beyond their anticipations. The report was attacked, and even high influence was lent to the very mild substitute proposed in its place, the report appearing too harsh, and an endeavor was made to substitute another, to the following effect: "That it is the sense of the St. Louis Medical Society that all endorsements of proprietary medicines are in bad taste." Whatever the opinions of the members be, the Code of Ethics, as such, does not, it is believed, directly cover the ground. In the exciting debate which followed, a motion was even proposed condemning, not only the recommending of preparations and nostrums, but especially the advertising which results from the appending of the titles of college professors, which are often attached to such recommendations, the case of the Cocoa Plug-tobacco being especially cited, in which a number of prominent gentlemen of this city and members present at the meeting are implicated.

Notwithstanding the variety of opinions and motives, the very strict report of the Committee was adopted, to wit: That it is a violation of the Code of Ethics to endorse publicly preparations of any kind, at least, as is the usual fashion, to permit the names of the endorser to accompany the advertisement of remedies, whether they be nostrums or not, of known or unknown ingredients.

This is certainly clear and distinct, and it now remains for other leading societies to follow, that the opinion of the profession throughout the land may find a distinct expression, and that an unquestioned position may be taken. Let the justice of this move be disputed, or let it receive the hearty endorsement of medical societies elsewhere.

CHICAGO.

(From our Special Correspondent.)

THE DISPOSAL OF THE CHICAGO SEWAGE.—Dr. Curtiss, of Joliet, read a paper recently before the Chicago Pathological Society on the subject of the disposal of Chicago sewage. He took strong ground, hardly as rational as strong, against the project of sending our sewage down the canal, through Joliet, and into the Illinois River below, diluted with an abundance of the water of Lake Michigan. He claimed that it would never do, that it would damage nearly the whole State, especially that part bordering on these water-courses, and finally that the sewage should be utilized as it is at the little town of Pullman.

Now, if there is any one thing about which all our local sanitarians, as well as those elsewhere in the State, have been of one mind, it is that the canal ought to be deepened and widened so as to allow the city's sewage all to pass off in the way indicated; that, sufficiently diluted with lake water, it will be rapidly oxidized, and will be devoid of any bad odor.

The town of Pullman has been very successful in utilizing its sewage for fertilizing purposes at a profit. The problem of doing this for so large and rapidly growing a city as Chicago, is one of such proportions that nobody has succeeded in securing even the attention of the public here to this method. Nearly all are agreed that every effort should be put forth to prevent the further discharge of the sewage into the lake; for, even if there is no danger of its reaching the Crib, whence comes our drinking water, the people believe there is, and will act and vote accordingly.

Surgeon-General Murray entered upon the duties of his office on November 28th.

A Romance by Dr. Marion Sims. — It is announced that the late Dr. Marion Sims has left a sparkling sketch which will appear in the February *Harper*. It is entitled, "Lydia McKay and Colonel Tarleton," and describes one of the most romantic episodes of the Revolution, the rescue of her imprisoned husband by the fair and clever Lydia.

The New York Society for the Relief of the Widows and Orphans of Medical Men.—The annual meeting of the New York Society for the Relief of Widows and Orphans of Medical Men was held on November 28th. The reports of the several officers showed that the members of the Society now numbered 140, of whom 92 are for life, and 48 are annual subscribers. The Society has extended aid to thirteen widows and four children of deceased members during the year.

The following officers were elected: President, Dr. Isaac E. Taylor; Vice-presidents, Drs. T. F. Cock, S. S. Purple, and J. L. Vandervoort; Treasurer, Dr. John H. Hinton; Managers, Drs. John G. Adams, William N. Bakeman, William Detmold, S. T. Hubbard, John T. Metcalfe, Robert G. Remsen, and J. Wiener.

The Johns Hopkins University Lectures on Municipal Hygiene.—Dr. John S. Billings has now delivered the fifth, sixth, seventh, and eighth lectures of the course on *Municipal Hygiene*, of which the first four were reported last week. They can be briefly summed up under the following:

Disposal of Refuse.—This important problem can be dealt with in two ways, (1) the savage way of each one attending to it for himself as he pleases, throwing it into cesspools or the street; and (2) the coöperative plan, by which the city takes it in charge. The former existed in Paris until 1870, when the siege put an end to it. The latter plan can be carried out either by the city's employés (the better way), or by contract (the cheaper way). Boston has the most satisfactory system in this country. The whole matter has been for many years under almost complete control of an efficient superintendent, whose employés have been well trained. The cost of this system is $76,000, while the revenue is $27,000 yearly.

Great difficulty is experienced in finding suitable dumping places. Sometimes it is used to fill lowlands (but this is objectionable from both a sanitary and an engineering point of view); or it is carried away by barges, or dumped into the sea at some distance (but here there is at times danger of causing nuisances on adjacent shores); a third method, very good from a sanitary point of view, is cremation, which is employed in Leeds and Manchester. The most important refuse is human excreta or sewage, which is typical filth. The cesspool plan for its disposal is *very* dangerous to the health of the population; all sanitarians agree that it should be abolished. It finally reaches the terrible condition found in Memphis, where the contents of the cistern did not differ materially from those of the neighboring cesspool, and where it contributed greatly to the yellow-fever epidemic. The watertight cesspool is but little better and very expensive.

It has been proposed to remove sewage by water-carriage. Here three things must be considered (1) the conveying away of polluted water; (2) the drainage of subsoil; and (3) surface drainage. Sewers were first intended for surface water only; more recently they are employed to remove other matter.

Systems of Sewerage.—About thirty-five years ago it was suggested in England to carry off sewage by separate sewers. This plan has been applied to Memphis, by Col. Waring, and is a success. Arguments in favor of this system over the combined system, are that: since the amount of rainwater is very large, compared to the amount of sewage, the rainwater sewers are much too large for sewage, and unless made egg-shaped in cross section (with small end down), they accumulate deposits; for the depth and velocity are little. (The egg-shaped sewers are used with success in Mainz, Germany.) Moreover, the sewers for sewage in the separate system contain less noxious gas, are better ventilated than those of the combined system, and cost less than one-half and often only one-third of the latter. Baumeister says that where a town extends along a natural water-course, and has wide cross streets running to the water, the surface water may be run off in gutters. The only underground work then is for sewers for sewage only, to which is eventually added a system of subsoil drainage. There should always be a separate system for carrying off subsoil water—a system of pipes with loose joints is used in Memphis. Even where three separate systems are necessary, one for sewage, one for surface water, and one for subsoil water, the cost is but slightly larger than that of the combined system.

The Liernur pneumatic system is condemned by all leading engineers in Germany, England, France, and America. Dr. Billings is opposed to its introduction into any city on both sanitary and economic grounds. Of all systems with which he is acquainted, he considers that of Philadelphia to be the worst.

House Drainage and Plumbing.—The excreta discharged into house-drains are not dangerous if removed before putrefaction sets in. A good system of house drainage requires the separation of the soil-pipe of a house from the sewer by a trap; the securing of ventilation to the house-side of the trap; and the shutting off of the house-drainage from the sewer by a trap. The fresh-air inlet is very important. Every fixture through which foul water is to pass should have a trap as near the fixture as possible. The best traps are the S and half-S traps. It has been shown that very little gas passes through these, and Carmichael has proved that no germs do. The daily use of so-called disinfectants is not advisable; they are for the most part worthless, destroying only the smell, and not the germs and contagia of disease; and secondly, those that are really good are very expensive. There should be no direct connection between the water-supply pipes of the house and water-closet; for otherwise closet-air is liable to get into water pipes.

Streets.—In regard to their paving with cobblestones and Belgian blocks, there is great objection, on account of the gradual pollution of the subsoil, which in warm weather becomes very dangerous; and on account of the noise and rattle, and injuries to horses and carriages. By placing a layer of cement concrete under the stones, the pollution of the subsoil is prevented, and the pavement becomes more elastic, which quality is desirable for horses and carriages. Wood paving is objectionable from a sanitary point of view. The best pavement where there is little traffic is asphalt laid in concrete. The evils of dirty streets fall most heavily on the children of the poor.

Parks provide means of recreation to the citizens, and are the reservoirs of fresh air to ventilate the city. Their beneficial influence can easily be seen. London owes much to its eleven thousand acres of park for its low rate of mortality. Parks are especially beneficial to the poor.

Cemeteries.—Rural cemeteries have everywhere superseded graveyards in the city. Cases of disease resulting from them are almost entirely unknown. While our cemeteries are generally satisfactory, our methods of burial are bad, often dangerous. Bodies should be buried as soon as possible, in light wood caskets, so as to let the germs of putrefaction destroy it, and any specific germs of disease in it, as quickly as possible. *Cremation*, except in epidemics, is not advisable; it tends to promote crime, and is not cheaper than inhumation.

SUCCESSFUL TREATMENT OF CHOLERA.—The State Department is in receipt of a letter from the United States Consulate at Port Louis, Mauritius, enclosing quite a long account of the successful treatment of cholera by T. Edwards Fyers, Esq., who accidentally discovered the remedy in treating a case of supposed poisoning, but which was in reality a case of cholera.

The treatment is numerously endorsed by medical men of high standing, and the account contains a tabular statement giving date of entering into hospital, name, symptoms, treatment, date of discharge, and result in one hundred fifty cases, only *one* of which resulted fatally. Mr. Fyers is not a medical man, "but being impressed with the idea that the symptoms of the disease were produced by poisonous matter in the stomach and bowels, proceeded on the common-sense principle of giving emetics and purgatives to remove it."

"The emetic employed was thirty grains of ipecacuanha and two grains of tartar emetic, followed by very large quantities of hot water to keep up the action of vomiting, and the purgative was castor oil. In every case but one this remedy appears to have given immediate relief, arresting the progress of the disease. In case either vomiting or purging should continue, the usual doses of dilute sulphuric acid will be sure to stop it. It has been found that sulphuric acid has a more successful effect if the stomach has been thus cleared. The patient should not be allowed to eat anything for several days, till the tone of the stomach has been restored. After the vomiting had ceased a single dose of castor oil was given, but no stimulants administered."

It will be remembered that the dilute sulphuric acid treatment of cholera is mentioned in several places in the *Report on the Cholera Epidemic of 1873*, prepared by order of Congress, by Supervising Surgeon-General John M. Woodworth, and Surgeon Eli McClellan of the Army. It was also highly commended by Dr. Nichols, of New York, who used it in the shape of sulphuric acid lemonade, quite successfully.

CHOLERA IN CHINA.—Consular reports from Shanghai, under date of October 16, state that the cholera has about disappeared in that locality, the last death having occurred on the 21st September. At Calcutta the total deaths from cholera for the week ending September 29, is reported to have been ten.

SMALLPOX IN RIO.—Smallpox is still prevailing as an epidemic in Rio de Janeiro; thirty-nine deaths are reported for the week ending October 20, 1883.

YELLOW FEVER AT SANTIAGO DE CUBA.—There were twenty-nine deaths from yellow fever at Santiago de Cuba during the month ending October 31, 1883.

HEALTH IN MICHIGAN.—Reports to the State Board of Health, for the week ending November 24, 1883, indicate that erysipelas has increased, and that inflammation of the brain, diarrhœa, and remittent fever have decreased in area of prevalence.

Including reports by regular observers and others, diphtheria was reported present during the week ending November 24, and since, at sixteen places; scarlet fever at fifteen places; and measles at six places.

OBITUARY RECORD.—The death is announced on the 19th of November, in London, of MR. C. HILTON FAGGE, Physician to Guy's Hospital, in his forty-sixth year.

NOTES AND QUERIES.

PREVENTIVE INOCULATION OF SCARLATINA.

IN our issue of last week, it should have been stated that the observations on the "Preventive Inoculation of Scarlatina with Scarlatinal Virus derived from a Horse" were made by Dr. J. W. Stickler, of Orange, N. J.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM NOVEMBER 26 TO DECEMBER 3, 1883.

WOLVERTON, WILLIAM D., *Major and Surgeon.*—Assigned to duty as Post Surgeon at Washington Barracks, D. C.—*Par. 7, S. O. 222, Department of the East*, November 27, 1883.

BROWN, PAUL R., *Captain and Assistant Surgeon.*—Assigned to duty in the Department of Arizona.—*Par. 4, S. O. 273, A. G. O.*, November 28, 1883.

CARTER, W. F., *Captain and Assistant Surgeon.*—Relieved from duty at Washington Barracks, D. C., to take effect at the expiration of his present leave of absence, and assigned to duty at Little Rock Barracks, Arkansas.—*Par. 4, S. O. 224, Department of the East*, November 30, 1883.

MERRILL, JAMES C., *Captain and Assistant Surgeon.*—Relieved from duty in the Department of the East, and assigned to duty at Columbus Barracks, Ohio.—*Par. 4, S. O. 270, A. G. O.*, November 24, 1883.

ORIGINAL LECTURES.

FREQUENT AND PAINFUL URINATION.

A Clinical Lecture, delivered at the Long Island College Hospital.

BY ALEXANDER J. C. SKENE, M.D.,

PROFESSOR OF GYNECOLOGY IN THE LONG ISLAND MEDICAL COLLEGE; SURGEON TO THE HOSPITAL.

(Reported by Edward Develin, M.D.)

GENTLEMEN: To-day I desire to call your attention to that condition of frequent and painful urination arising from certain disturbances and anatomical lesions of the sexual organs.

CASE I.—Our first patient is thirty years of age, and has now been married eight months. Her health has always been fairly good until two months ago, when she began to suffer from frequent and painful urination. These annoying symptoms have continued ever since, and have also increased in severity. She states that in the morning and during the forenoon she is comparatively comfortable, and can retain her urine a reasonable length of time; but towards the afternoon the desire to urinate is frequent and urgent, and she has much pain in evacuating the bladder. These symptoms continue until night, and during the early part of the night she is compelled to rise several times and relieve her bladder; but after she has once fallen asleep she remains quiet until awaking in the morning at her usual time for rising.

Now the fact that she is able, while asleep, to retain her urine until the bladder is distended to an average capacity, is an indication that the trouble does not involve the entire bladder, but that it is limited to the urethra, and, perhaps, the neck of the bladder. If she had a general cystitis, the probabilities are that she would not be able to hold even an average quantity of water in the bladder at any time. We cannot, however, be sure as to the extent to which the bladder is involved without an examination of the urine, but it is fair to suppose, judging from her symptoms, that the trouble is limited to the urethra, and probably the neck of the bladder to a slight extent. It is a curious fact in her history that during the latter part of the night and during the forenoon she is comparatively comfortable, but that her symptoms become aggravated in the afternoon and continue during the early part of the night. This may be due to one of two causes.

First: It may be due to the fact that the irritation subsides after lying in bed for a time, and does not return until she has been about for several hours during the early part of the day. The fact of her being upon her feet and maintaining the erect position, naturally brings more pressure to bear upon the neck of the bladder, and would thus aggravate an already existing irritation, and give rise to frequent urination, which continues until she again seeks relief by assuming the recumbent position in bed for a time. This certainly is one of the causes for this frequent urination in the later part of the day.

Secondly: There is a cause which gives rise to the same peculiarity of clinical history, and that is *malarial poisoning*. A patient suffering from malaria quite frequently has irritability of the bladder, indicated by frequent and painful urination, these symptoms being always most marked in the afternoon and evening. In this case, however, there is no indication of malarial trouble; so that the peculiarity of her history is no doubt due to the erect position maintained during the early part of the day.

Regarding the primary cause of her trouble, that is not quite so clear; there is no history of any gonorrheal inflammation which could have affected the urethra or bladder, as it sometimes does; neither has she any uterine or pelvic disease which would directly or indirectly affect her bladder. It is barely possible that it arises from the change in her social relations: having married late in life—some eight months ago—it is just possible that her family relations may have produced an irritation of the urethra and base of the bladder, which, when once established, is very liable to persist if not relieved by treatment. Having an opportunity of examining this patient's urethra and the neck of the bladder, the probability is that we shall find a hyperæmic condition and perhaps some tendency to ulceration of these parts, but of that we cannot speak positively, as the examination has not yet been made, nor shall we trouble her with such examination until we see if we can relieve her by treatment.

In the treatment of this case we will render the urine as bland and non-irritating as possible, by permitting her to drink freely of the alkaline mineral waters—Vichy for instance—and in case she cannot procure that, we will order the acetate of potash. At the same time I will give here a favorite prescription in these cases:

℞.—Fl. Ex. Buchu, ... ℥ij.
Tinct. Conium, ... ℥j.
Sig. ʒj half an hour before meals.

If this fail to give her relief, we will then employ injections of sulphate of zinc, half a grain to the ounce of water, with the addition of a drachm of the fluid extract of hydrastis canadensis. In using this local application we will employ a syringe with rather a large nozzle, which is to be introduced just within the meatus, then slowly and carefully inject the mixture so as to force it along the urethra into the bladder; being careful to have the bladder emptied previously. By adopting this plan we are sure of bringing the remedy in contact with the entire mucous membrane of the urethra. We will also request her to abstain from coition, as that may be the cause of her trouble.

CASE II.—I have here a very interesting case, brought to me by Dr. Stewart. This lady is forty-five years of age, unmarried. She gives us the following history: Up to six weeks ago she menstruated regularly every four weeks; since four weeks ago she has menstruated three times, she is therefore suffering from menorrhagia. She has great pain in the back and suprapubic region, with frequent and painful urination; altogether, suffering extremely, she says. I am now making but very little pressure upon the abdomen, and yet she complains very much. Upon examination I find an extremely interesting pathological condition here. Now bear in mind the prominent symptoms: there are intense backache and pain in the supra-pubic region, with an abnormal condition of the menstruation, and a frequent desire to urinate. Dr. Stewart, in carefully examining the condition of the sexual organs discovered conditions which did not altogether coincide with her history as given by herself. He found the uterus large and well developed, with an os externum which looked as if it had seen service; the same also with the perineum. Upon being questioned very closely, or, as they say in law practice, "cross-examined," she admitted that she had had a child five years ago, and had been also operated on for amenorrhœa.

This gives us a clue as to the cause of the present condition of things which we have here. We find the uterus is large and the fundus is pointing towards the upper part of the symphysis pubis, the os looking towards the hollow of the sacrum; the body of the uterus is therefore pressing upon the bladder and crowding it downward—a condition which is sufficient to account for this frequent urination. The uterus is anteverted, and the prominent symptom is the functional disturbance of the bladder, due, no doubt, to the displacement. I here show you a specimen of her urine. We often have symptoms of cystitis without cystitis being established. In this case we have vesical tenesmus because of the pressure of the fundus uteri. A normal bladder will tolerate pressure for a time, but after a while it will incite this frequent urination; it is therefore a question whether or not we have cystitis here. You will observe in this urine that there is an abundant deposit of the phosphates; if this clear up upon the application of heat, and we find no products of inflammation under the microscope, we will simply say that this is a mechanical derangement of function.

There is, however, another unfortunate condition here, and that is, that while the uterus is anteverted, it remains there in spite of all our efforts to restore it. It is anteverted and fixed in this position because of a former peritonitis. If she has been subjected to an operation for the relief of amenorrhœa, she has been in the way of having pelvic cellulitis or peritonitis, or both, and the evidence is that she has had one or both.

We have here, then, an incurable anteversion; all that we can do is to relieve the symptoms; we cannot remove the cause of her pain, backache, and vesical tenesmus; we can only modify these, while hoping that she will live long enough to pass the menopause and be relieved by the final involution of the uterus. The plan of treatment will be to try and relieve her general condition. This urine shows her nervous system to be below par; when we have this brick-dust deposit, it is said to be a symptom that the waste of the tissues is in excess of the assimilation for their support. It is said of clergymen that the deposit of phosphates in the urine is greater upon Monday than any other day in the week, by reason of the using up of the nerve force on the preceding Sunday. It is possible that we may improve this woman's general health so that her system will be able to tolerate her local difficulty, and thus bear her suffering much better.

It is impossible to use a pessary in this case as the uterus is fixed; part of her vesical irritation may be due to the fact that her old peritonitis involved the peritoneum covering the bladder, so that now it is impossible for that organ fully to distend. This peritonitis has probably extended in front of the broad ligaments, forming adhesions, and thus holds the bladder in a splint so that it cannot extend; this may be another cause of her frequent urination. So that we have here two factors: the displaced uterus, and the thickening of the peritoneum upon the walls of the bladder, which prevent its distention. We can do little but apply the douche and paint the vaginal roof with iodine; we can also introduce a belladonna suppository if advisable. This, however, as I have told you, can only be palliative.

This case is an exceedingly important one, as those who are most prone to this condition are those who abuse the generative functions.

There is one thing more here which however hardly comes under my Chair We find above the umbilicus a marked pulsation which may be an aneurism of the aorta, and which might possibly account for some of the abdominal pains.

CASE III.—This patient is twenty-six years of age, and she informs me that she first commenced to menstruate when she was eleven years of age. She has now been married seven months; her menstrual flow previous to marriage appeared every two weeks, but since that time she has menstruated once a month until within the last three months, when she has menstruated once in two weeks, as previous to her marriage. She now states that she has a frequent desire to urinate, and she is not relieved when she has passed water. She has vesical tenesmus, this is accompanied with some pain; her bowels are also constipated.

Now this is a very interesting history. First, abnormal menstruation, becoming normal after the change in her social relations, and then after a time again becoming abnormal. This is a marked violation of an essential law relating to menstruation, and the one which I dwell most upon in my didactic lectures, viz., that each individual should abide by the rule which she takes upon herself. If she start out in life to menstruate once in three weeks, that is normal for her, and she should continue to do so.

Now on examining this patient, I found the os pointing directly towards the introitus, and the fundus towards the pubes, the uterus being doubled up, both body and cervix being flexed forward, so that the two parts together make pressure upon the bladder, which is in all probability the explanation of her desire to urinate constantly; she informs me that she has to get out of bed several times during the night to urinate. The mechanical pressure in this case is disturbing the functions of the organ.

In this case, if we remove the cause we will in all probability remove the cystic irritation, and possibly correct the menstrual derangement. Sufficient to say just now that we will employ the usual treatment for anteflexion of the uterus, and, if we can overcome that, all the symptoms will subside.

CASE IV.—This patient, a married lady, menstruated regularly until four years ago. She comes to us to-day complaining of some disturbance of the bladder. I think I shall be able to illustrate to you a prolapsus of the bladder, which gives rise to much annoyance in this case. Now, here, as you observe, we have both walls of the vagina coming down; here, also, we find from one-half to three-quarters of an inch of laceration of the perineum. The posterior vaginal wall, as you will observe, is not prolapsed as much as the anterior wall and the bladder.

Now, as I introduce the sound into the urethra, it should, of course, pass in an upward direction, but, as you can see by the arc the handle of the instrument describes, it passes backward, giving us the diagnostic sign of prolapsus of the bladder and upper portion of the urethra. These parts have been torn away from their original support and carried downward, the bladder and the urethra have parted company with the structures of the pelvis which support them; this, therefore, would result in partial incontinence of urine, owing to the undue pressure brought to bear upon the sphincter of the bladder.

Incontinence, however, is most marked when the prolapsus of the bladder is in the first degree; in complete prolapsus incontinence disappears, and gives place to difficulty in urinating. I have seen some cases where the bladder had to be restored to its position before it could be emptied; in such cases I have instructed the patient to urinate while lying down upon the face. I remember being called in a case of this kind, in which the uterus was atrophied and the bladder rested upon the floor of the pelvis. She was unable to empty the bladder while in the erect position, but the moment the patient turned upon her face in the reclining position she could urinate with great comfort, and for the rest of her life I believe this patient will have to urinate in the knee-chest position. It is well to bear this point in mind.

In the case before us we must endeavor to do something to relieve her, as during the ensuing warm weather this prolapsus and partial incontinence of urine will be a source of great irritation and annoyance. I would, therefore, advise that she have perfect rest; tampon the vagina until this organ regains some tonicity, restore the perineum, and then introduce an anteversion pessary. Sometimes the restoration of the perineum and rest will suffice, but in other cases we fail with all the means which we have named, because the pessary does not come down far enough to keep the bladder in place. There is, however, a little instrument recently invented by Dr. Malcolm MacLane, of Harlem, which answers when the anteversion pessary fails. This consists of a little grooved instrument, which is passed under the arch of the pubes lying up against it, which is secured by a cord attached to it and passed around the abdomen, the only difficulty being that the two bars running up on each side of the meatus cause some irritation, but it really answers the best purpose in these cases when rest, restoration of the perineum, and all other pessaries fail.

A question here arises, viz.: If you support the bladder and urethra, and retain them in position, will the attachments ever become restored? To this I must answer that I do not know. I have seen a large number of these cases, and watched them with great interest, but I have not yet seen any case in which such an event took place. My experience would lead me to say that they are never entirely cured, although made quite comfortable by proper treatment.

Case V.—This patient now before you is fifty-three years of age, has been married twenty-six years, and has three children. She is now suffering from prolapsus uteri, and also prolapsus of the bladder, as you all observe. This tumor projecting from the vulva is the uterus, bladder and vaginal walls. When I pass a sound up to the fundus, I find that the uterus is four and a quarter inches in length, showing it to be very much larger than it ought to be in a patient of this age. This which I now hold between my thumb and finger is a portion of the bladder. I need hardly add that we have here a well-defined prolapsus uteri in the third degree. We are sometimes in doubt as to the degree of prolapsus in some cases, but here we are fortunate enough in having it so clearly defined as to be unmistakable. Now, to prove to you that this is the bladder which I hold in my hand, I pass the sound into it, and in place of the instrument taking an upward direction it curves downwards, and those who are near by can see that I can put my finger upon the point of the sound within this sac in my hand, you can see it move my fingers. We have then complete prolapsus of the bladder as well as of the uterus. I will now carry the uterus up to its place in the pelvis, and in doing so you see that I press the cervix backward. If I did not do that, I should transform the prolapsus into a retroversion of the third degree. On making pressure I am very careful to carry the fundus upward. Sometimes it is impossible, as the uterus will double upon itself, the fundus falling backward; we then transform it into a retroflexion. In such cases it is then necessary to pass the sound into the uterus and guide it into position by this means.

In this case we have also an anatomical lesion of the perineum, and in addition to this we have also a functional lesion, a relaxation of the muscles. When I make pressure backwards there is not much muscular resistance.

Now the point which I wish you to carry in your mind is the changes which occur in the other organs of the pelvis owing to this uterine displacement. In addition to the uterus becoming displaced, the bladder also comes down with the uterus; and in all these cases of displacement, if they have existed for any length of time, the vaginal walls become relaxed, which leads to or follows the abnormal position of the uterus.

Sometimes we have only one vaginal wall prolapsed; usually, however, both. In this case both of these are entirely out of the pelvis, as you see, but the posterior vaginal wall does not come down so far as the anterior. In managing a case of this kind, just do as you see me now, push the uterus up in position, keep the patient in the recumbent position, and use the vaginal tampon to retain it there. I have just such a case at the present time in my private practice. Before the uterus was restored to place, she spent most of her time in urinating. Now I have her lying in bed under the treatment I have just described, and she can retain her urine as long as anyone. When the relaxation has been overcome to some extent, and the parts have regained their tonicity, we will restore the perineum in this case so as to get as much normal support as possible, making a restoration of which at first appears to be more than is necessary to compensate for the tendency to prolapsus.

So we bring the vivifying process a little higher up into the vagina and bring together as much tissue as possible, making the perineal body run up into the vagina, so as to make a support for the bladder. But even then, in some cases, you will find that in time the bladder will gradually slip down, so that, perhaps, this lady will come back at the end of a year and say that our operation did not do her any good. We will have, however, gained much, having secured a good perineum upon which to rest a globe pessary. We will follow out precisely this treatment here, keeping the parts in position for a time, then by and by restore the perineum, and afterwards introduce the globe pessary, if need be.

Case VI.—Our next case is also one of incontinence of urine; the cause, however, of this condition in this patient is entirely different from that of the preceding ones, and therefore must not be arranged under the same head. The patient, however, comes to us suffering from this incontinence, and I now present her to you as illustrating another cause of this difficulty. This little girl is twelve years of age. When she was three years old she had an attack of scarlet fever, and has never been well since; she has not accomplished much in the way of growth or development; she looks somewhat anæmic. During the night she has to get up six or seven times to pass her water, and, unless exceedingly tired, the desire always awakens her. During the day the passing of water is equally, or more, frequent; for this reason she has been unable to attend school. This is very interesting, as it illustrates a class of cases which you will meet quite frequently. When urinating there is always pain, and she informs me that, if she attempts to restrain herself, it increases the pain; but immediately upon evacuating the bladder there is complete relief for a time. For the last nine years this has been going on. It is, however, a rare thing as a rule in this difficulty for the patient to awaken at night, the urine being generally passed in bed. This is a most miserable condition for a child to be in, being obliged to get up to urinate many times every night, or else to sleep in a bed saturated with urine.

Acute cystitis often follows the eruptive fevers, and sometimes in these cases it becomes chronic, as in this case, so that we should always be on our guard in the eruptive fevers and see to it if there is any cystitis following, otherwise the result will be the same as in this case. Now, whether the child has general cystitis or an inflammation of the neck of the bladder with urethritis remains to be seen. The way to make the diagnosis is repeatedly to examine the urine, selecting the last drachm or two which is passed, and if it contains pus and epithelium we may be tolerably sure that there is general cystitis. The order of the development of the pathological conditions in this case is as follows: first, scarlet fever, which gave rise to acute cystitis, or urethritis, which in place of ending in recovery, ran into the chronic or continuing variety.

ORIGINAL ARTICLES.

GLANDULAR HYPERPLASIA AT THE VAULT OF THE PHARYNX.

BY J. SOLIS-COHEN, M.D.,
HONORARY PROFESSOR OF LARYNGOLOGY, JEFFERSON MEDICAL COLLEGE; PROFESSOR IN THE DEPARTMENT FOR DISEASES OF THE THROAT AND CHEST, PHILADELPHIA POLYCLINIC AND COLLEGE FOR GRADUATES IN MEDICINE.

IN many individuals, chiefly adolescents, and according to my own experience most frequently females, imperfect nasal respiration with impaired enunciation will be found to be due to hyperplasia or exuberant overgrowth of the conglobate mass of glandular tissue normally situated at the vault of the pharynx directly behind the upper portion of the septum of the nose. The hypertrophied tissue blocks up to some extent the posterior outlets of the nares. It thus mechanically interferes with normal nasal respiration, and produces the peculiar intonation acquired when resonance is lost in the nasal passages. The intensity of these symptoms is proportionate to the amount of occlusion of the nares. Additional symptoms are usually present, similar to those attending a protracted cold in the head, but unaccompanied by discharges of mucus from the nostrils, unless catarrh of the nasal passages coexists with the condition under consideration.

Although this affection did not prominently attract professional notice until after rhinoscopy was introduced into medical practice, it had long before been recognized post-mortem, and been accounted for pathologically. Some exquisite preparations of this glandular tissue, in both normal and morbid conditions, prepared more than a hundred years ago by the celebrated William Hunter, are preserved in the anatomical section of the Hunterian Museum at Glasgow.

For recognition of this affection during life, the profession is chiefly indebted to Prof. Voltolini, of Breslau; for anatomical descriptions of the tissue and its relations to other structures, to Prof. Luschka, of Tübingen; and for its careful histological and clinical study to Dr. William Meyer, of Copenhagen.

Except in individuals with defect in the palate, the glandular tissue at the vault of the pharynx cannot be observed during life without the rhinoscopic mirror. Hence the comparatively late date of its recognition.

It consists of adenoid tissue, identical in structure with the tonsils, and the agminated glands of the intestine. Its similarity to the tonsil has caused it to be termed the *pharyngeal tonsil*. It is most usually described as the adenoid tissue of the vault of the pharynx, and its hyperplasia as adenoid vegetation.

The hyperplasia presents two different forms, between which and beyond which there is a variety of gradations. These two forms are, macroscopically, a uniform hypertrophy similar to ordinary hypertrophy of the tonsil, and a series of dendritic outgrowths in pendant clusters. The clusters of outgrowths are isolated in some instances, and in close apposition in others. They are quite pink at the base, and become much lighter in color at the apex. They are occasionally so abundant as quite to cover the vault of the pharynx, and occlude much of the calibre of the cavity. In occasional instances, too, they extend along the lateral walls of the pharynx. Their free surface is usually smooth, though sometimes villous. They are often so soft in consistence that they bleed on palpation, or when rubbed with a sponge or cotton-wad, or even when impinged upon by a stream from the syringe. Microscopically, the mucous membrane is seen to have participated in the hyperplasia, so that, in consequence, isolated fields, or small sections, often resemble papillomata. The main portion of the mass, however, consists of lymphoid, or immature connective-tissue cells. Bloodvessels are few, but blood-channels are seen at the periphery.

The tissues immediately surrounding the diseased structure, be it hypertrophic or fimbriated in variety, are usually in a state of chronic catarrhal inflammation. A condition of hypersecretion usually exists. In the purely hypertrophic variety the mucus often undergoes desiccation in *sitû* with a series of scabs, which become detached at intervals of a few days; provoking a little bleeding at times, when the tissue is soft and succulent. From a similar cause some patients are troubled by blood in the mouth almost daily on awakening.

In the dendritic or fimbriated variety of the disease, the mucus is liable to drop from time to time, and thus provoke cough, often referred to disease of the larynx. Sometimes it descends the posterior wall from time to time in viscid, discolored strands or masses. When the hyperplasia extends as far as the pharyngeal extremity of the Eustachian tube, disorders of hearing, catarrhal or mechanical, are frequent. Peculiar headaches ensue in some instances, usually referred to the top of the cranium, but really proceeding from its base at the point where the tissue in question is located.

The affection is often easily diagnosed by the symptoms incidentally alluded to, and the diagnosis is placed beyond doubt by inspection rhinoscopically, and by palpation.

The affection requires surgical intervention when the masses obstruct nasal respiration, or are in a condition of hypersecretion. The plan pursued by me during a long series of years, consists mainly in excision in fragments by means of curved forceps with cutting cup-shaped blades, passed behind the palate: instruments practically the same as those devised much more recently by a number of specialists abroad and at home. A properly guarded electrocautery is useful when the growths cannot be grasped by the forceps. Such cases have been very infrequent in my own experience. For this purpose I have used either an electrode guarded in front by soft or hard rubber, so as to avoid burning the palate; or, in more recent work, an electrode made to be pushed forward and retracted at will through an insulating canula.

Injections of a solution of bicarbonate of sodium will relieve the pain produced by the incandescent cautery, when that is severe.

A number of operations are required to get rid of these growths, in the manner recommended; but I consider the method far preferable to prolonged efforts to rid the pharynx at once. Serious reaction has followed attempts to do too much at a time. The manipulations should be performed under guidance of the rhinoscopic mirror when practicable; when immediate rhinoscopic supervision is impracticable, the manœuvres should be practised under guidance of a finger of the disengaged hand. Under all circumstances the parts should be examined rhinoscopically after each operation. Bleeding is slight after excision with forceps, much slighter than after the use of ring-knives or sharp spoons. I have no practical acquaintance with the removal of the growths with snares, cold or incandescent.

In children, it is often practicable to tear these growths away with the finger-nail; a practice preferable to the use of cutting or burning instruments, though more bloody than the use of forceps. It is unnecessary to cauterize the parts or inject astringents upon them after the use of the cutting instrument. It is far better to leave them covered by the blood-magma which coagulates upon them.

After a large portion of the mass has been removed, sufficient, say, to reëstablish free nasal respiration, there is no absolute necessity to continue the ablations; for the remaining shreds, injured in their nutriment, usually shrivel into harmless insignificance.

No recurrences of hyperplasia after treatment have occurred to my knowledge, in my own practice, although inquiries have been made concerning patients where growths were removed by forceps more than fourteen years ago.

There is a natural tendency to spontaneous absorption of the tissue under consideration, after the patient has reached, say the twenty-fifth year. In this respect the analogy is maintained with the behavior of the adenoid tissue in the tonsil and in the solitary follicles of the intestine. Instances of hyperplasia are rare after development to full maturity, unless in subjects affected for several or many years. It becomes a question, then, whether it is proper at all to operate in children and adolescents, seeing that the condition may subside spontaneously in early adult life. This question receives an affirmative response in view of the injury to general health, and the impairment of hearing and of enunciation, apt to result from years of continuance of the infirmity.

Although impracticable in many instances to trace a connection between the affection discussed and scrofulosis, or any other diathesis, it has been my custom for years to employ antiscrofulous constitutional treatment with advantage. Two remedies, mainly, have been selected—the one for its specific influence upon glandular hyperplasia generally, and the other for its specific influence upon secreting mucous membranes. The one is the hydrated chloride of calcium in simple syrup, thirty or more grains daily in divided doses; and the other, the oleoresin of cubeb, ten to twenty-five drops, on sugar, immediately after meals.

SUDDEN DEATH DURING OR SOON AFTER CONVALESCENCE FROM DIPHTHERIA.

By J. FERGUSON, M.A., M.D., L.R.C.P.,
ASSISTANT DEMONSTRATOR OF ANATOMY, TORONTO SCHOOL OF MEDICINE, TORONTO, CANADA.

What the experience of other physicians may be regarding sudden deaths during the progress of diphtheria I cannot venture to say, as I have not been able to collect many cases which bear directly upon the question. I shall briefly mention three fatal cases that occurred under my own observation, more for the purpose of eliciting from others a record of such experience as will throw some light upon this feature of the disease.

Case I.—Frank W., a young man of twenty-one, was taken ill with an attack of diphtheria in August, 1882. He made a good recovery, with the exception of slight paralysis of the right arm. While sitting on a log of wood, near the front of the house, he quickly picked up a stone and threw it at a small bird, which was hopping along on the ground near him. He had scarcely projected the stone from his left hand when he fell over from his seat, and expired before he could be carried into the house.

At the post-mortem examination, the left side of the heart was found empty, while the right was distended with blood. This condition had no doubt been produced by a sudden paralysis of the organ. When Frank threw the stone, the heart had contracted with sufficient force to empty itself; but, ceasing to act, the right passively filled with blood which it could not expel. In such a condition as this, the effort at breathing—indeed, the deep-drawn sigh—would bring the blood to the chest from the jugulars, the subclavians, and the inferior vena cava, for the purpose of filling the right side of the heart. The pulmonary veins, lying in the cavity of the thorax, would not be similarly acted upon during inspiration. Should the death take place very suddenly, the left ventricle might be almost devoid of blood.

Case II.—Charlie H., aged five, was taken down with diphtheria in April, 1883. To all appearance this case was doing well. His bowels moved, and his mother placed him upon the chamber. At this juncture, I visited the house. On entering the room, the little patient said, "I am weak, put me in bed." This was quietly and quickly performed;

but after some few minutes of restlessness he expired.

The post-mortem revealed the heart to be full of blood, the right side more so than the left.

CASE III.—Annie W., aged thirteen, an active young girl, was attended by another physician during her attack. She recovered sufficiently to be sitting in the parlor. While there, her little sister, who was also ill of the same disease, died. She became at once so much affected that she had to be carried up-stairs to bed. I was sent for, and on arrival found her in an extreme state of collapse. Fearing to try stimulants by the mouth, I gave them hypodermically; but she died in about one hour from my arrival. No post-mortem.

Now, what is the cause of these sudden deaths? In the first place, it cannot be due to the mere presence of some poison circulating in the blood, and thereby injuring the nerve-centres; for two of the above cases might be fairly regarded as having recovered from the disease. In the case of Charlie H., there might be some ground for supposing that the cause of the heart's failure was due to a poisoned state of the blood, as the child was then under the influence of the disease. In the next place, the theory of Edward Woakes, of London, could hardly explain the first and third cases I have just recorded. This theory was enunciated at the International Medical Congress, in London. It claims that sudden death is due to a vaso-motor paralysis of the nutrient vessels of the vagi, so that these nerves are gorged with blood, and the fibrillæ jugulated to such an extent that they are unable to conduct inhibitory impulses, and the heart speedily wears itself out, being exhausted by a succession of rapid beats. It seems very difficult to explain how this gorged and jugulated condition of the vagi could exist and cause death so suddenly as in the case of Frank W., who had convalesced so far as to be out of doors.

We know that strong emotions produce marked effects on the heart, and especially if the person is of an excitable turn. After a prostrating disease, such as diphtheria, where the tendency to produce nerve complications is so great, the sympathetic or motor cordis, the vagi, or inhibitorius cordis, and the ganglia in the substance of the heart are very much weakened. In such a condition, a slight impulse or emotion acts so powerfully through the mind on the heart, as to produce an amount of derangement in its action sufficient to cause sudden death. That there is much in the theory of Woakes which is deserving of attention, I do not deny; but I feel that it cannot explain such cases as the first and third, and that we are forced back to the opinion, that there is still something wrong in the nervous system during and after this disease which cannot be explained by any known change in them; call it functional, if you will.

I have already said that, in cases where sudden death occurs when the patient has recovered from the disease, I do not think this sad termination is due to the actual presence of poison circulating in the blood, and coming into contact with the nerve-centres; yet the sudden death could follow as a direct result of the depressing influence this poison had upon them during the continuance of the disease. Though this poison no longer exists, yet the weakened state of the nerve-centres exists; and a strong emotion or a sudden effort proves too much. The effort or emotion is the extra straw that breaks the camel's back. The weakened nervous system, which can just carry on the great involuntary functions of circulation and respiration, while everything is quiet, suddenly fails when an extra task is imposed upon it, of either a physical or an emotional character. From two of my cases, I firmly believe that the condition is central, and not peripheral; but what that central condition really is remains for the future to reveal. I regard it as a depraved and weakened one. If I am asked why it should occur with dipththeria, I can no more answer the query than tell why the poison of typhoid fever causes the very circumscribed congestions which produce the rose-colored spots.

In the case of Charlie H., I made a careful microscopic examination of parts of the vagi; but with negative results. No evidence could be found of the existence of a hyperæmia, nor of plastic effusion, within the nerve-sheaths, as one would expect were the theory of Edward Woakes true, as this case died during the progress of the disease.

FIVE OVARIOTOMIES.

BY THEOPHILUS PARVIN, M.D.,

PROFESSOR OF OBSTETRICS AND GYNECOLOGY IN THE JEFFERSON MEDICAL COLLEGE, PHILADELPHIA.

THE following are the only ovariotomies I have performed during the present year. It will be observed that they all occurred within a period of less than six months.

CASE I.—The first case was that of Mrs. W., twenty-two years of age, who had been married between one and two years. She resided at Loogootee, Ind., and was under the care of Dr. S. H. Brittain, to whom I am indebted for the following[1] history of the patient, and of the operation and after-treatment.

"Mrs. W. came under my care the last of January, 1883. She first noticed a lump in her left side about one year ago, it steadily grew since that time; absence of menstrual flow since October; she was emaciated, feeble, pulse 120, temperature 101°, abdomen so greatly distended that she could not lie down. My diagnosis was ascites and an ovarian tumor. For the purpose of making her more comfortable, though I believed she could live but a short time, I performed paracentesis abdominis, removing nearly two gallons of ascitic fluid. After this she could lie down, but otherwise there was no improvement in her condition until the fifth day; then her appetite and strength were increased, and she did very well for two weeks, when the peritoneal cavity began to fill again. On the first of March, assisted by Dr. Trueblood, I tapped again, but first directly passed the trocar into the ovarian tumor;

---

[1] In justice to Dr. B., I ought to state that in rewriting I have condensed somewhat this history.

only a few flakes of cheesy matter escaped, and this not until the cyst contents had been partially broken down by a probe passed through the canula. The canula was now withdrawn from the cyst, and one and a half gallons of fluid taken from the peritoneal cavity. Her improvement after this was so rapid, that I was encouraged to believe ovariotomy was advisable, and wrote to Dr. Parvin, requesting him to visit the patient for this purpose. He replied, directed the preparatory treatment, and in company with Dr. L. S. McMurtry, then of Louisville, now of Danville, Kentucky, came to see Mrs. W. on March 15th. After we had all carefully examined the patient, who was now very feeble, pulse 125, temperature 100°, and after the matter had been fairly presented to her and her friends, an immediate operation was decided upon.

"The patient was etherized by Dr. Trueblood, and an incision made from just below the umbilicus to two or three inches above the pubis; when the abdominal cavity was opened, about two gallons of fluid escaped. The tumor, adherent at few points, and these adhesions not extensive, was punctured with an ovariotomy trocar; but the contents of the first cyst opened as well as of others, for the growth was multilocular, were so thick that they could not pass through the canula; the instrument was therefore withdrawn, and the hand used to scoop out the half-solid material. After thus reducing the size of the tumor, it was readily withdrawn through the abdominal opening; the pedicle, the left broad ligament, was quite long, and a clamp was applied to it; it was then divided by Paquelin's thermocautery between the clamp and the tumor; a blunt needle threaded with a double ligature of fishing-silk was carried through the pedicle below the clamp, the silk firmly tied on each side, then the two halves united in a single ligature encircling the pedicle and also firmly tied, the ends being cut off short. After thoroughly sponging the abdominal cavity, removing some blood-clots and some of the cyst contents that had escaped into it, the clamp was removed and the stump of the pedicle dropped into the abdomen. Deep silk stitches, with intervening superficial horse-hair stitches, were used to close completely the abdominal incision, except at its inferior angle, where a drainage-tube was passed. Carbolized cotton and oiled silk were placed over the incision, absorbent cotton put over the abdomen, all secured by a firm flannel bandage. She was then put in bed, bottles of hot water placed about her limbs and body, the temperature of the room increased, and a hypodermatic injection of morphia given.

"*March 16.*—Pulse 133; temp. 101°; urine drawn by a catheter three times in twenty-four hours, about four ounces each time. Patient resting well. Diet, hot water, and occasionally a tablespoonful of rice water.

"*17th.*—Pulse 135; temp. 101½°; somewhat annoyed by flatus, but relieved by the introduction of a tube in the rectum.

"*18th.*—Pulse 139; temp. 102°; urine scanty; gave small doses of infusion of digitalis and acetate of potash. Milk added to the rice water diet.

"*20th.*—Pulse 110; temp. 100½°; secretion of urine is free, and it is passed voluntarily.

"*21st.*—Pulse 108; temp. 99¾°; no important change.

"*22d.*—Pulse 102; temp. 97°; brandy given, and an improved diet. A purulent discharge through the drainage-tube, and the evening temperature increased.

"*23d.*—Pulse 96; temp. 98¾°; removed the silk stitches, replacing them by strips of adhesive plaster.

"*24th.*—Pulse 94; temp. 98¾°; disposition to a movement of the bowels, which was assisted by a warm-water enema.

"Until the 29th but little change; pulse and temperature becoming normal; some diarrhœa, for which occasional doses of camphorated tincture of opium were given.

"*29th.*—Removed horse-hair stitches. Pus still discharging from the drainage-tube, and wound shows a disposition to reopen.

"*May 15.*—Patient has steadily improved; the drainage-tube was removed soon after previous date, the gap closing by granulation. She is now in good health, save occasional attacks of intermittent fever; before she came under my care she had been living in a very malarious part of Illinois."

I will merely add to Dr. Brittain's faithful narrative, that Mrs. W. menstruated first after the operation in June (the right ovary, examined after the removal of the tumor, was found healthy), and that she has been regular since. She is now, as Dr. Brittain informs me in a letter received last month, in good health.

Case II.—The second case was that of Mrs. J. L., formerly of Brookville, and who was directed to me by my friend, Dr. George Berry, of that place. Mrs. L. was forty-two years old; married, had three children, the oldest thirteen, the youngest eight years old; since the birth of the last had one miscarriage; menstruation regular; five years ago first noticed a tumor in the right side, it has gradually increased until the abdominal circumference is thirty-nine inches. For some months past she has been losing flesh and strength; becomes fatigued with even moderate exertion; pulse generally from 90 to 100.

She entered St. Vincent's Hospital, Indianapolis, July 10th, taking a private room, and was operated on the next day, July 11th. I was assisted in the operation by Dr. Joseph Eastman, who has been a tried and ever-trusted assistant in sixteen of the ovariotomies I have done, by Drs. Maxwell, Button, Long, and my student Mr. H. S. Rooker, all of Indianapolis, and by Dr. Newcomer, of Tipton, Indiana.

The patient was etherized; an abdominal incision three inches long was made, and then increased one inch. The tumor, which was a monocyst, had no adhesion and, after its contents were evacuated, readily collapsed and was withdrawn; the pedicle was four inches in length, broad and thin, and a double ligature was passed through it, and tied as in the previous case, when the tumor was separated by the thermo-cautery, and the stump dropped in the abdominal cavity. Weight of cyst and contents thirty pounds; the color of the fluid was that of pea-soup, and the consistence that of cream. The abdominal wound was closed by silk sutures, and iodoform freely sprinkled over it; a very thick layer of absorbent cotton was placed upon the abdomen, and a flannel bandage firmly applied. Very little shock was observed; considerable ether-nausea troubled the patient, for the relief of which occasional teaspoonfuls of hot water were given, as first advised by Dr. Keith. The third day the temperature was 102°, and the pulse 120; a somewhat troublesome diarrhœa came on the fifth day, and continued eleven days before yielding to dietetic and medicinal means. The stitches were removed on the tenth day, and on the eighteenth she left the hospital, being quite well, and has so remained.

CASE III.—On the 11th of July I performed a second ovariotomy. Miss H., thirty-six years of age, first consulted me the middle of May. Two years before this date she noticed an enlargement of the abdomen, but no defined tumor. The enlargement increased so that she seemed like a woman far advanced in pregnancy, and yet for some time after this she continued her work, that of a clerk in a dry-goods store. Finally her health became so impaired that she had to give up her place, indeed was confined to her bed much of the time. Upon examination I found a large tumor, apparently divided by a transverse constriction about the level of the umbilicus into two unequal parts; in the lower part fluctuation was plain, but the upper part was fixed, firm, resisting, and fluctuation was indistinct.

Several reasons led me to advise tapping before performing ovariotomy. In the first place, to confirm the diagnosis; next, I hoped by temporarily lessening the mass to give the patient comfort, improve her health and strength, so that she could better bear the final operation, for her condition was very bad; beside, believing that the upper part of the tumor was adherent, I had a hope that when the lower portion was emptied, gravity might put those adhesions somewhat upon the stretch, and thus one of the difficulties and dangers in operating would be lessened. Tapping was twice done by Dr. Eastman, once in my temporary absence from the city, and the other time when I was present; each time a bucketful of glue-like fluid was obtained from the lower mass, but the upper was unchanged in size, position, and solidity. The second time an effort was made to aspirate the upper portion of the tumor, but only a small quantity of ovarian fluid was obtained, and the operation was followed by some bleeding.

Under the use of a liberal milk-diet, quinine and iron, there seemed, sometimes, a slight improvement in the patient's health, but irregular attacks of chills, followed by high temperature, nausea, and vomiting, and subsequent loss of appetite destroyed the little gain. More than once when a day had been fixed for the operation a postponement was rendered necessary by these attacks.

Finally, however, as before stated, the operation was done on the 11th of July. Ether was given; an abdominal incision of three, subsequently increased to ten, inches was made; the lower portion of the tumor was emptied by an ovariotomy trocar and canula, and a similar effort was made as to the upper part, which had remained almost solid and immovable; but it proved to be a very thick-walled cyst, from the inner wall of which sprang a large number of cysts, varying in size from that of a walnut to that of the largest orange; these were broken up, and their contents scooped out with the hand. Adhesions to the omentum, to the abdominal wall, and to the liver made the removal of the tumor tedious and difficult; nevertheless, this was finally accomplished, thanks especially to my friends Drs. Eastman and Taylor, who applied for me a dozen ligatures to bleeding parts. The pedicle was tied and secured in the same way as in the previous cases; so, too, as to the sutures of the abdominal incision: the iodoform and cotton dressing was used, and a drainage-tube. The shock was very great, and death occurred on the third day, reaction never having been complete. The tumor weighed seventy pounds.

This is the third ovariotomy which I have done when there were adhesions to the liver, and each patient died—indeed, this experience leads me to dread hepatic almost as much as pelvic adhesions. However, this was one of the delayed operations, which are so dangerous. If the patient had been operated on a year sooner than she was, the probability is that she would have recovered.

CASE IV.—This case is given so well by my friend Dr. Kemper that not a word further need be prefixed, not a word need be added:

Mrs. S. L. L., age thirty-two years, native of Ohio, married eight years, nullipara. In the early part of the year 1879, she first noticed abdominal enlargement. The growth was slow, but gradual, and, as months elapsed, the first supposition of pregnancy was, of course, abandoned. Finally, an impairment of the general health becoming perceptible, Dr. Kemper was consulted on the 19th of July, 1883. The tumor was well marked; lines from the umbilicus to the anterior superior spinous processes of ilia showed the left one inch longer. The tumor was readily perceptible by touch through the vaginal walls. No pain had been present, but a peculiar throbbing in the abdomen had annoyed the patient for some weeks past. The menses had been regular. A diagnosis of ovarian tumor was made, and the patient advised to consult Prof. Parvin, of Indianapolis, which she did on the 10th of August. The diagnosis was confirmed, and an operation advised.

On August 16th, at two o'clock P. M., in the city of Muncie, Ind., the operation was performed by Prof. Parvin, assisted by Dr. Eastman, of Indianapolis. The following gentlemen were present: Drs. Vinnedge, of La Fayette; Kemper, Winton, and Boyden, of Muncie; and Mr. Rooker, medical student, of Indianapolis. Ether was administered by Dr. Vinnedge.

An incision, three inches in length, was made at the usual site in the median line. No adhesions were present, and, after withdrawing the fluid, a unilocular sac was readily removed. The pedicle, a moderate sized one, springing from the left ovary, was divided by the thermo-cautery, thoroughly ligatured, and returned into the abdominal cavity. After a thorough cleansing, the wound was closed with the aid of deep and superficial silk sutures, and covered with iodoform. All instruments used were immersed in carbolized water. The entire operation and dressing consumed but twenty-five minutes. Reaction was rapid. No nausea was developed.

No untoward symptoms were subsequently shown in the case. The incision healed by first intention. Menstruation appeared on the 21st, and continued three days. She made a rapid and satisfactory recovery.

Case V.—Mrs. M. S., thirty-five years of age, married sixteen years; has had two children—the first thirteen months after marriage, the second six years after the first; consulted me in July last, at the suggestion of Dr. George Duzan, for a tumor of the left side, believed by him to be ovarian. The tumor was first noticed sixteen months before; it now distends the abdominal cavity, the circumference at the umbilicus being thirty-nine inches. The patient for the last two months has been losing flesh, and her strength is decidedly impaired. I advised an early operation. She delayed, however, until September, and probably would not have been willing to have it done then had it not been that I was about removing from Indianapolis to Philadelphia. The operation was done on September 4th, Drs. Duzan and Brown, of Zionsville, and Dr. Eastman and my student, Mr. Rooker, of Indianapolis, assisting me.

After the usual anæsthesia and the abdominal incision, a non-adherent tumor, consisting almost exclusively of a single cyst containing a bucketful of chocolate-colored fluid, was found, and which, after evacuating its contents, was, of course, readily removed. The pedicle, which was long, was ligated and divided as in the previous cases; the abdominal incision was closed by silk sutures, and the dressing of iodoform and absorbent cotton used.

Dr. Duzan had charge of the patient after the operation, and from his notes I make the following statements:

Sept. 5.—Pulse 80; temperature 98½°.

6th.—Pulse 100; temperature 100°.

7th.—Pulse 120; temperature 103°. Menstruation came on; there was some diarrhœa; gave quinine, opium, and tincture of veratrum viride.

8th.—Pulse 106; temperature 100½°. The diarrhœa continuing, injections of laudanum and tannin were successfully used. From and after the fifth day, the pulse and temperature were normal. On the twelfth day, the stitches were removed, and the wound was found perfectly united. About the 5th of October, there was some swelling of the left leg resembling *phlegmasia alba dolens*, but it soon yielded to rest, an anodyne, and sedative lotion, and bandaging. The patient is now quite well.

Dr. Duzan adds to his letter, which was received on the 27th of October: "I neglected stating that I gave Mrs. S. quinine from the day after the operation until convalescence was fairly established. I never fail to give this medicine after surgical operations, continuing it until wounds are healed." Dr. Duzan's large experience and great sagacity as a practitioner entitle his opinion to respect.

Philadelphia, November 2, 1883.

A RARE CASE OF LARGE CYSTIC TUMOR OF THE POSTERIOR NARES; REMOVAL; CURE.

By GEORGE M. LEFFERTS, M.D.,
PROFESSOR OF LARYNGOLOGY IN THE COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

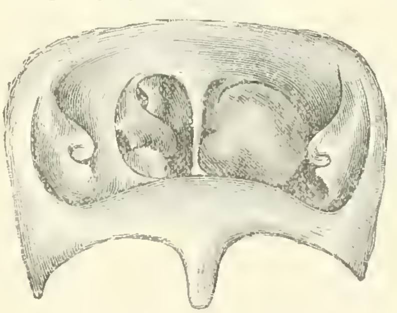
The following case is, it appears to me, of sufficient interest, on account of its rarity, to warrant its being placed upon record:

I was recently consulted by a young lady who desired relief from the ordinary symptoms of a hypertrophic nasal catarrh, which she was supposed to have, and for which she had undergone various plans of treatment, both local and general, for a lengthened period of time.

The main symptom, and the one of which she mostly complained, was complete obstruction of the left nasal passage to the respiratory current. This condition had become progressively worse during the last year.

An examination of the anterior nares by means of the nasal speculum and reflected light, showed nothing but the common appearances—hyperæmia and slight thickening of the mucous membrane—incident to an ordinary chronic catarrhal process (simple chronic rhinitis). The rhinoscopic mirror, used in the examination of the posterior nares, a procedure not before attempted in her case, determined at once the cause, and, as I supposed, the nature of the obstruction to nasal respiration.

A large tumor, smooth, more or less rounded, and of a grayish color, resembling precisely an ordinary gelatinous polypus, for which I at once mistook it, fully occupied and completely closed the left posterior naris, projected outwards into the free space of the upper pharynx, and lay in close apposition to the pharyngeal orifice of the left Eustachian tube. Its removal by means of the nasal polypus forceps was at once determined upon; this instrument in my judgment, affording the quickest and surest method of extirpation.



The first introduction of the forceps, their correct application to the growth being guided, by means of a direct inspection, through the posterior nares before their closure, succeeded in bringing away a large portion of the tumor.

My mistake now in the treatment of this particular patient, and I believe that it is a common one, and therefore mention it here, not hesitating to criticise it, even in my own case, as a bad practice, was in reapplying the forceps to the location of the supposed polypus before syringing away the blood and reinspecting the parts before reintroduction of the instrument. Had I done so, and I have made it a rule since, where it was the exception before, I should have recognized the true character of the growth earlier and spared the patient some unnecessary, even though slight, laceration of the parts in the neighborhood of the posterior extremity of the middle turbinated bone, at which point the tumor was subsequently found to have been attached. Failure to obtain any further portions of the tumor, led me to inspect more closely the portion that I had removed; to my surprise, it proved to be the entire sac of a large cystic growth, broken at only two points; one that of its small point of attachment, the other a small rent, where it had burst in the grasp of the forceps and discharged its contents. This discharge of a large amount of glairy mucus had not been noticed by me; had it been, it might have furnished a valuable clue to diagnosis.

The removal of the tumor at once relieved the patient of the most annoying of the symptoms. Others readily yielded to the treatment of the slight catarrhal condition.

Remarks.—Instances of true cystic tumor, originating in the mucous membrane of the nasal passages proper, are very rare, the invasion of the latter by mucous cysts having their point of primary development in the antrum of Highmore is the rule; but even these cases are infrequent.

I am familiar with but one case in literature similar to that which I here report; it concerned a patient of Dr. George Johnson. The growth was located in the right posterior naris, and, curiously enough, was attached to the posterior extremity of the middle turbinated bone, as in my case. The details will be found in the *British Medical Journal*, May, 1874. One or two writers upon diseases of the nose mention the possibility of the occurrence of such tumors, but fail to report specific examples. Watson (*Diseases of the Nose*, 1875), while giving many interesting instances of cystic tumor of the antrum, says that he can find but one recorded of cyst of the nasal passage (the case of Johnson, before alluded to), and believes that they are very seldom met with.

The interesting question of differential diagnosis suggests itself here. I cannot conceive that there would be any great difficulty in differentiating the primary location of a growth of this character—viz., whether, in the antrum, thence extending to the nasal passage, or in the latter itself. The points upon which a diagnosis must rest will suggest themselves. Between ordinary gelatinous polypus of the nasal passage and cystic tumor of the same locality the question will always be a difficult one to decide. I am aware of no distinctive differences as far as external appearances go. Fortunately, it is not of great importance. The treatment is similar—viz., extirpation. Prognosis as regards recurrence is, however, decidedly in favor of the latter form of growth.

HOSPITAL NOTES.

WILLS' EYE HOSPITAL, PHILADELPHIA.

THE USE OF JEQUIRITY IN EYE DISEASE.

Reported by CHARLES W. KOLLOCK, M.D., Resident Surgeon.

JEQUIRITY has been used for some time past at the Wills' Eye Hospital, in the treatment of obstinate cases of trachoma and corneal pannus, which all other known remedies have failed to improve. The number of cases in which it was used is not great, but is sufficient to demonstrate beyond a doubt its efficacy in those that have continually grown worse under other treatment, or were at a provoking stand-still.

A report of a few cases may prove interesting.

CASE I.—S. G. (service of Dr. Keyser), both eyes had been sore for eight years, but the left had finally been almost entirely cured by other means. The right eye, however, defied all treatment; the lids were thick, hypertrophied, slightly rough, and beefy in appearance. The cornea was entirely covered by a thick fleshy pannus, and at no point was the iris visible. She had light-perception only, and photophobia was intense. An infusion of jequirity was applied, the strength of which was eighteen grains to the ounce. In a few hours the lids began to swell, became stiff and very painful; lachrymation, not marked at first, soon increased, and became, after two or three applications, purulent. Along with the above conditions appeared a whitish-gray and filmy membrane which covered the mucous surfaces of both lids. This became more consistent and adherent as the inflammation increased. Adhesions formed between the pannus, grown puffy and swollen, and the palpebral conjunctiva which necessitated their being broken up daily by the probe. The cornea had in fact every appearance of sloughing, though it was not in the least injured. Six applications were made to the everted lids, when it was deemed advisable to discontinue its use on account of the intense inflammation. The patient was now in anything but a comfortable condition, on account of the constant pain and lachrymation, and could scarcely bear to have the lids touched for the purpose of cleansing. This state, however, was of short duration, for, left to itself, the inflammation quickly subsided, and the swelling, lachrymation, and pain disappeared. A boric acid collyrium (gr. x to ℥j water) was now used several times a day. A small clear spot appeared in the centre of the ulcerating pannus, which increased in size daily, spreading rapidly towards the margins of the cornea. Through the clear space the patient saw distinctly, and each day the vision improved as the pannus disappeared. A month later the pannus was entirely absorbed, the lids were smooth and soft, the cornea was hazy from cicatrices and facets, the iris was visible at all points, and vision was improved from light-perception to counting fingers at three feet. In this condition the patient was discharged.

CASE II.—C. W. (service of Dr. Schell), right eye has been sore off and on for several years; lids in state of dry trachoma and cornea partially covered by pannus. On September 20th, at 8 A. M., first application of a nine grain solution of jequirity was made. At 1 P. M., a distinct film covered both lids, which was easily detached; there were slight pain, lachrymation, and swelling. A second and third application were made that day, and the fourth the next morning. The lids were now very chemotic, discharge muco-purulent, and membrane thicker and more adherent. Four applications were made in this case, the patient having, in the mean time, been compelled to take his bed on account of pain and general uneasiness. The inflammation was left to work its own cure. 22d: Lids considerably swollen, discharge continuous, pannus ulcerating, and cornea intact. By the 27th the discharge had ceased, the lids were smooth, and the cornea was daily becoming clearer. The patient was discharged on October 18th, wonderfully improved, though the vision was not as clear as might be expected. This is accounted for by the number of facets on the cornea caused by the pannus, which, though entirely absorbed, had left its marks firmly imprinted.

Case III.—J. W. (service of Dr. Goodman), an old and obstinate case of granular lids with pannus, which resisted all remedies, and continually grew worse. The lids of both eyes were rough and flabby, the corneæ were covered by pannus, and photophobia was most distressing. Four applications were made to both eyes, with similar results to those above described. A boric acid collyrium was then used, and the inflammation quickly subsided, leaving the lids perceptibly smoother and corneæ clear. Both corneæ were found to be covered by excavations, which caused a great deal of irregular astigmatism. The left cornea became entirely free from pannus, but the right, not progressing so fast, the jequirity was again applied, with like results and improvements. A third time the infusion was used, and the result encouraging. Photophobia, so distressing before the use of the jequirity, is much relieved, and, though the patient is not yet cured, his present condition is so marked an improvement upon the former that there is reason for great encouragement.

Case IV.—C. A. (service of Dr. Hall), chronic case of granular lids and pannus in both eyes. The granulations were prominent and hard. Jequirity was used but twice, on account of the intensity of the inflammation excited. The granulations underwent marked absorption and flattening, and pannus has disappeared.

Case V.—E. C. (service of Dr. Keyser), heavy, flat granulations with fleshy pannus and hypertrophy of mucous membrane. Jequirity applied, with usual results. Ten days later: pannus absorbed, cornea a little hazy from cicatrices, and lids very much smoother. Patient discharged.

Case VI.—C. G. (service of Dr. Schell), lids thick, stiff, and very rough; corneæ hazy from old cicatrices, but no pannus. Jequirity applied three times. Roughness almost disappeared, no discharge, but vision not much improved on account of the cicatrices of old ulcers which were not acted upon by jequirity. Patient discharged.

Case VII.—R. I. (service of Dr. Goodman), lids of both eyes studded with large, prominent granulations, and corneæ streaked by numerous vessels. The granulations were first flattened by the use of the mitigated stick of nitrate of silver (thirty-three per cent.), and jequirity then applied in the usual manner, and with like results. Thirteen days after, the patient was discharged, to all appearances cured, excepting the cloudy condition of the corneæ, which can only be improved by time.

Case VIII.—M. G. (service of Dr. Schell), trachomatous lids very rough, with corneal pannus in both eyes. Two applications of an eighteen grain infusion were made here, causing great pain, swelling, and lachrymation. After subsidence of inflammation, lids were found smooth, pannus entirely disappeared, but cornea covered by facets, which prevent distinct vision.

Remarks.—The preparation of jequirity used, is a cold infusion prepared by Mr. L. E. Sayre, at Eighteenth and Market Streets. The strength of the infusions was, in all cases but two, nine grains to the ounce; in the two it was eighteen. The latter was found too severe in its action, and for that reason its use was discontinued. These preparations are very prone to decomposition, and when in that condition give out a most offensive odor; but the power of causing inflammation is as active as when freshly prepared. To prevent this decomposition, which rendered its use very disagreeable both to patient and physician, it was decided to try the effect of boric acid in the preparations. Accordingly, Mr. Sayre added to each ounce of the infusion, four grains of the acid. The results surpassed our most sanguine hopes, for not only were all preparations kept pure and sweet, but the action was not in the least diminished.

The infusion is applied to the everted lids by means of a camel's-hair brush, or a swab of absorbent cotton—the latter is preferable on account of cleanliness.

It has been observed that pain is first noticed about four hours after the application, and simultaneously the lids begin to swell, and the filmy deposit appears on their mucous surfaces. Its action should be watched most carefully, for though no case of sloughing cornea has followed its use here, it might easily be a sequel through carelessness and inattention. Its use should be discontinued when the lids become chemotic, mucous surfaces well covered by the membrane and the discharge muco-purulent. Pain is in the majority of cases quite severe, but soon ceases after the applications are stopped. The discharge is very tenacious and rarely escapes beyond the lids.

Corneal opacities, *i. e.*, cicatrices of old ulcers, are not removed by jequirity. Its use upon acute granulations, etc., is not warranted; for, though it seemingly makes them no worse after its discontinuance, still they are not in the least improved. A marked improvement in vision has not been seen to follow its use unless the pannus was complete. This is accounted for by the condition of the cornea, which closely reminds one of a hammered button, with the light glistening from its numerous surfaces. This causes for the time being an irregular astigmatism, which of course prevents accurate vision for such objects as test-letters, and is the reason why the vision has not been recorded in the report of these cases.

It will be readily seen from the above report that only chronic diseases, such as trachoma, granular conditions, and pannus seem proper cases for the employment of jequirity. Its use in acute troubles has been thoroughly tested here, and found to be contra indicated.

MEDICAL PROGRESS.

Helenol.—Helenol is one of the active principles contained in the root of *Enula campana* or *Inula helenium*, the more common name of which is elecampane.

The decoction of elecampane has been recommended as an antidartrous remedy by Knakstedt, and as antipsoric by Hufeland and Guibout. M. Paul Blocq has recently made some experiments as to the antifermentative properties of helenol. [The active principles of elecampane are alantol and helenin. Helenol is probably written here for helenin.] His experiments were based upon those of Korab, which showed that this substance possessed valuable antiseptic properties. Though the experiments of M. Blocq are too few upon which to base general conclusions, yet his results have been very satisfactory in simple and recent traumatisms, in wounds of inflammatory origin, in callous and indolent ulcers, in dressing amputations, and in other cases requiring antiseptic dressings. This substance is a colorless liquid, of slightly aromatic odor. It is not irritating when used as a dressing, and its agreeable odor is a decided advantage in its favor.—*Progrès Méd.*, Nov. 17, 1883.

SYPHILITIC NEURALGIA.—PROF. SEELIGMUELLER read a paper on this subject at the Fifty-sixth Versammlung Deutscher Naturforscher which recently met in Freiberg.

Neuralgiæ, he said, which are certainly related, etiologically, to constitutional syphilis, are nothing like so uncommon as would be supposed on reference to the literature of the subject. He does not refer, of course, to the cases of neuralgia following syphilitic periostitis, or to the osseous pains, but only to such cases in which the pains occur along the tracks of nerves. Such cases have been observed by Fournier in the course of the supraorbital and sciatic nerves. Seeligmüller has also observed them in the course of other nerves, as the intercostals, the brachial plexus, and the great occipital.

Lately he has observed, it seems, a very typical localization of syphilitic neuralgia in the head, and certainly along nerve tracts, which were formerly supposed to be cases of isolated neuralgic affections in unusual places. In these cases the pains were spontaneous, as though pressure had been made along a track two or three fingers wide, and which extended on both sides from the ear upward to the top of the head. He has further seen cases in which the pains were confined to a limited zone and to the course of sensitive nerves, as the auriculo-temporal and small occipital. There was no middle-ear disease in any of the cases.

The time at which the neuralgic affection comes on after syphilitic infection varies from two to fifteen years. The treatment is, of course, antisyphilitic.—*Deutsche med. Wochenschr.*, October 24, 1883.

CICATRICIAL STENOSIS OF THE PYLORUS WITH DILATATION AND TETANUS.—M. DUJARDIN-BEAUMETZ reported this case at the meeting of the Société des Hôpitaux, on October 26th. The patient presented on his entrance into the hospital, the symptoms and physical signs of enormous dilatation of the stomach, with pyloric stenosis. The enormous size of the stomach was easily appreciated by the ordinary methods of physical diagnosis. Uncontrollable vomiting gave evidence of the state of the pyloric orifice. Washing out the stomach gave such relief that the patient was able to leave the hospital, but returned in a short time with an obstinate diarrhœa, produced by taking proprietary pills.

After entering the hospital the second time, he had tetanic seizures, such as have already been described by Kussmaul, as occurring in cases in which washing out the stomach is resorted to, and of which there have been many cases of late years. The tetanus, instead of being limited to the limbs, as is usually the case, became generalized, and the patient succumbed to asphyxia produced by spasmodic contraction of the diaphragm.

During life there had been diagnosticated a cicatricial contraction of the pylorus, due to a round ulcer of the duodenum or pylorus. At the autopsy the stomach was found distended with water and invading the whole abdominal cavity. In the duodenum, just beyond the pyloric orifice, there was a stricture, beside the one involving the pylorus. The orifice was so small that a quill could scarcely be passed. M. Dujardin-Beaumetz thought that under these circumstances extirpation of the pylorus offered the best chance for the patient's life. This opinion was concurred in by MM. DÉBOVE and MILLARD.—*Gaz. Méd. de Paris*, November 3, 1883.

THE USE OF CORROSIVE SUBLIMATE AS A DISINFECTANT IN OBSTETRICS.—At the Fifty-sixth Deutschen Naturforscher Versammlung, in September, 1883, DR. KEHRER, of Heidelberg, read a paper on this subject.

Since April, 1882, he has used corrosive sublimate in two hundred and twenty-one labors. In four only was there an urticarious eruption, beginning on the thigh and extending over the whole body. This disappeared in three or four days. Attacks of stomatitis occurred in one lying-in woman and in three gynecological cases; the first having previously undergone a process of inunction, and two of the last had been taking mercury. Kehrer first used corrosive sublimate solutions of 1 to 2000; lately, of 1 to 1400. During labor he makes a vaginal irrigation before making the vaginal examination. As to the results of corrosive sublimate disinfection in the lying-in state, he states that two-thirds of the women remain entirely free of fever. Before the use of the sublimate two-thirds of them had febrile actions.

KUESTNER, in discussing this paper, was strongly in favor of the sublimate disinfection as a means of thorough disinfection. He has found that, after carbolic irrigation of the uterus, the cocci did not disappear, but their disappearance was very prompt after the sublimate irrigation.—*Centralbl. f. Gynäkol.*, Nov. 3, 1883.

HYSTERECTOMY IN PREGNANCY.—PROF. KARL BRAUN VON FERNWALD read a paper on this subject at the meeting of the k. k. Gesellsch. der Aerzte in Wien, on October 19th. He reported five cases in which he had performed Cæsarean section by Porro's method, on account of the absolute indications of very narrow rachitic and osteomalacic pelves. At present the women were all doing well. One, a case of severe osteomalacia was so much improved as to be able to assist in the ward-work. His statistics of the Cæsarean section with hysterectomy and castration during six years, are twelve cases: Recovered, seven; partially favorable consequence in one case; and bad results in four cases. Of the twelve children, eleven are living. The general mortality as regards the women, is 33.3 per cent.

The extra-peritoneal method of treating the stump was employed in eleven cases, with bad results in three cases; mortality, 27.27 per cent. The three deaths were due to peritonitis within from two to four days. The stump was dropped in one case, with a fatal result.

Prof. Braun recommended the Porro operation with the extra-peritoneal treatment of the stump, and altogether rejects dropping the stump in these cases, as well as the return to the old operation with the new uterus suture of Sänger and Leopold. He finally recommended the following modifications for Cæsarean section with amputation of the uterus, castration, extra-peritoneal treatment of the stump.

1. Early operation at the end of pregnancy, before the beginning of labor, as the most proper time.
2. Antiseptic prophylaxis with 5 per cent. carbolic acid water before, and thymol water (1 to 1000) during the operation; anæsthesia with the alcohol-chloroform-ether mixture.
3. After the abdominal incision has been made the uterus should be drawn out, and an elastic loop thrown around the cervix, before the incision into the uterus is made.
4. A high elastic permanent ligature just above the cervix, and over that a strong Billroth's écraseur chain before the amputation of the uterus. Cauterization of the stump.
5. Closure of the abdominal wound with a metallic-plate and silver-wire suture, and with carbolized catgut. Fixing of the stump by means of a diagonally placed lance needle, and bringing together the peritoneal walls.
6. Cleaning and dusting of the wound with iodoform and the use of the Lister iodoform-gauze and wadding dressing.—*Wien. Med.-Presse*, October 28, 1883.

THE MEDICAL NEWS.
A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

Communications are invited from all parts of the world. Original articles contributed exclusively to The Medical News will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

Subscription Price, including Postage,
Per Annum, in Advance, ... $5.00.
Single Copies, ... 10 cents.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

Address, HENRY C. LEA'S SON & CO.,
Nos. 706 & 708 Sansom Street,
Philadelphia, Pa.

SATURDAY, DECEMBER 15, 1883.

THE VAGINAL EXTIRPATION OF THE CANCEROUS UTERUS.

Extirpation of the cancerous uterus is an operation which belonged almost exclusively to the first third of the century until within the last few years. Langenbeck, in 1818, seems to have been the first, or among the first, to remove successfully a prolapsed cancerous uterus; but he was less fortunate in his removal of the uterus by the abdominal method, laparo-hysterectomy, an operation proposed by Gutberlat in 1813, and performed in 1825. The vaginal method seems to have been much oftener preferred. The undisplaced uterus affected with cancer, was successfully removed by Sauter, of Constance, in February, 1822. Blundell, who operated in four cases, had his first and only successful case, in February, 1828. Récamier was the first to do the operation in France, in 1829. Among other operators were Roux, Siebold, Delpech, Lizars, and Dubled.

The operation was abandoned, and its great mortality very well explains the abandonment. Duparcque, writing in 1839, *Maladies de la Matrice*, observes that of forty cases in which this operation has been done, there was one partial success, and there were two complete successes; Marjolin stated in 1846, *Dictionnaire de Médecine*, that nine-tenths of the patients died within a few days, and the rest were only apparently cured, surviving but a year.

There are some striking contrasts between the operation as first and as now done. One of these is that to day anæsthesia saves the patient from suffering, and greatly facilitates the operation; it required great heroism on the part of the operator, and still greater on the part of the patient, in the day when anæsthetics were unknown. Again, most of the first operators were indifferent as to the loss of blood, no hæmostatic means being used: hence we read in the history of the old operations that one patient lost a pound and a half, another nearly two pounds of blood, collapse following the operation, which often proved fatal in twenty-four hours. Récamier indeed tied the lower third of each broad ligament, thus securing the uterine arteries, but this does not seem to have been the general practice. Another contrast is in the rapidity with which the operation was done; in many of the cases only thirty minutes or so were required, though Blundell was an hour doing his first operation, but now twice or thrice thirty minutes may be necessary.

Schroeder, at the last meeting of the British Medical Association, gave an account of his method of operating, that which is generally followed. Two volsella are applied to the uterine lips, and the uterus drawn down as far as possible; next a circular incision is made in the healthy tissue about the cervix, and the vaginal mucous membrane pushed back and upwards as far as possible; then the retro-uterine pouch is opened, and the uterus retroverted so as to bring its fundus into this opening; after this the uterus is separated from its anterior attachments, and then the broad ligaments are ligated, sometimes a single ligature answers for each, at others several ligatures are used, the ligaments being tied in several parts; the ligaments are then divided close to the uterus, and the organ removed. The stumps of the ligaments are drawn into the peritoneal wound, one on each side, and a T-shaped drainage-tube inserted. He observes that the chief danger is from the slipping of the ligatures. He also states that the technical part of the operation is not easy, and the operator ought to be accustomed to using a knife and to applying ligatures in the depth of the vagina. The sutures, for he closes the peritoneal wound, are removed on the fourteenth day.

Schroeder states that the operation is very difficult if the vagina is narrow, not easy in nulliparæ, often impossible in old women. These difficulties did not deter the earlier operators; they did not hesitate to enlarge by incisions the vaginal entrance. Lizars, for example, split the perineum so that the vagina and the rectum were converted into a common canal.

Olshausen guards against slipping of the ligature which is applied to the broad ligament, by using an elastic thread carried by means of a bent aneurism needle. Is it not possible that a Bellocq's canula might be used for placing the ligature?

Rydygier ties the uterine artery before dividing it.

Mueller, in the *Centralblatt für Gynäkologie*, 1882, suggested that the uterus should be first split vertically, dividing it into symmetrical halves, when the ligation of each broad ligament could be readily done, while the hemorrhage from the incision might be perfectly controlled by compression and torsion. So far as we know, this suggestion has not been tried.

Fritsch, in a recent paper in the same journal, very fully presents his method of operating: the salient points in this method we give our readers.

The first cutting is done at the side of the uterus; vessels that bleed are immediately tied, and the author states that he has sometimes applied twenty ligatures to one side of the uterus; the tissues are always to be cut, never torn; as soon as one side is separated and all hemorrhage stopped, the other side is to be similarly treated, only after incising the vagina let the incision be carried anteriorly and posteriorly so that the cervix is completely circumscribed, and into the sulcus thus formed place an elastic ligature which prevents all bleeding from the cancer; next the operator separates the uterus from the bladder; the uterus is now drawn downward, but not retroverted, and ligatures applied to the oviducts and round ligaments, sometimes three or four ligatures being used on each side, and so applied that the under ligature always includes a portion of the tissue embraced by the upper one; if the ovaries and oviducts are prolapsed they are removed, otherwise they are not disturbed. The uterus is now removed, and the opening immediately filled with a sponge the size of the fist; upon its removal the ligatures are drawn down to expose to view the cut surfaces, new ligatures are applied to bleeding points, the entire part covered with iodoform, the lower peritoneal cavity cleansed with iodoform gauze, and the vagina also thus cleansed; when there is hemorrhage from the connective tissue between the peritoneum and vagina, the two latter are stitched together; an iodoform tampon is placed in the vagina. The novelty of the method consists, according to Fritsch, in the lateral incisions, the elastic ligature of the cervix, and in drawing the uterus forward instead of retroverting it in its removal. So far as not turning the uterus backward, but drawing it forward is concerned, Fritsch states that Kraussold did it first, and therefore priority is due him.

We merely add that in the account of one of Récamier's cases of extirpation of the uterus, in January, 1830, anteversion, not retroversion, of the uterus was done in the operation, and that Gendrin, in the *Journal Générale de Médecine*, October, 1829, expressly advises that the operation be begun at the sides of the uterus so as to reach the broad ligaments, and thus be able to control the hemorrhage.

JEQUIRITY.

We have already called the attention of our readers to the remarkable properties of jequirity. The observations of MM. Cornil and Berlioz, which we have quoted, have been resumed, and new facts have been developed. Before speaking of the new points, it may be well to give an account of the knowledge already existing of the peculiar powers of this agent.

It has been proved that the active constituent of jequirity is a microbe—a minute organism—and that if freed by proper filtration from these bodies, the infusion no longer possesses the power to excite inflammation. This disease-producing microbe is derived from the atmosphere, as Sattler has demonstrated. The infusion is prepared by macerating one part of the finely pulverized seeds, in seven hundred and sixty parts of cold distilled water, which, after digesting twenty-four hours, is then filtered and placed in flasks, so closed as to prevent the admission of the germs of putrefaction. Thus prepared, the infusion will retain its activity for several weeks. The germs derived from the air find in the albuminous matter of the seeds the material suited to their pullulation—in other words, the infusion of jequirity is a "culture fluid." A few drops placed in contact with the conjunctiva excite an active inflammation which may supplant an existing morbid process. It has been shown to cure pannus, trachoma, and other affections by this "substitutive inflammation" produced by the action of the microbe. An aerial disease-producing microbe has thus been proved to exist. The agency of aerial minute organisms in the causation of fermentative and other morbid changes, as maintained by Pasteur, is therefore confirmed.

The recent observations of MM. Cornil and Berlioz add new facts equally convincing of the substantial accuracy of Pasteur's doctrines, and of the important generalizations based on them. By subcutaneous injection of the infusion of jequirity, in frogs, rabbits, and guinea pigs, they have produced phlegmons of the skin which were followed by suppuration and gangrene. They find that if the animal survive these lesions, a second and greatly stronger injection produces no result, and, hence, they conclude that the first operation has the effect of a vaccination. They further ascertained that by injecting into the pleural or peritoneal cavity of a rabbit, even the fourth of a drop of the infusion, peritonitis or pleuritis followed, and the microbes were diffused throughout the circulation. The injection of this small quantity into any part of a frog, was followed by general septic infection, millions of the microbes being produced, and they were found in all organs and tissues, except the cornea. A drop of the blood of such an infected frog caused in another frog the same septic infection and the same generalization of the microbe. If, instead of injecting the infusion, the grains of jequirity are mixed in and taken with the food, systemic infection does not occur. The elimination of the microbe from the system takes place by the kidneys and the intestinal mucous membrane.

THE PRESENCE OF BACILLI IN SURGICAL AFFECTIONS OF TUBERCULAR OR SCROFULOUS ORIGIN.

During the current year, as we learn from the *Fortschritte der Medicin*, Nos. 9 and 17, the *Journal de l'Anatomie*, No. 4, and the *Revue de Chirurgie*, No. 11, Schuchardt and Krause, Schlegtendal, Cornil and Babes, and Bouilly have made numerous researches which demonstrate the presence of the bacillus tuberculosis in certain affections that were manifestly tubercular, or were suspected to be of that nature. Of the lesions, the most frequent were cold abscesses, strumous synovitis, and tubercle of the bones, lymphatic glands, and the skin. The cases examined included also at least two of fungous synovitis of the sheaths of the tendons, and one each of tubercle of a muscle, of the tongue, of the epididymis, of the testicle, and of the female genital organs.

In all of the minute examinations, with the exception of those of Schlegtendal, bacilli were discovered; but in the majority they were so few and so difficult of detection that as many as three in the interior or vicinity of a giant cell were quite uncommon. In the case, indeed, of a cold abscess of the thigh, at least twenty sections of the limiting membrane were required to discover two of the organisms, and in only one example out of the forty recorded by Schuchardt and Krause were ten met with on the first section.

From their rarity and the difficulty of their detection, erroneous conclusions may be drawn as to the true nature of the lesions. More than this, their number does not correspond with the gravity of the affection. This point is well illustrated by one of the cases of Bouilly, in which, despite the fact of extensive tubercular deposits in various organs and tissues, only two bacilli were found in a presternal cold abscess. It should, however, be remarked that these organisms may be detected in the pyogenic membrane when their presence cannot be shown in the pus of a tubercular abscess. Their association with fungous synovitis proves, moreover, the tubercular nature of that affection, a fact which had been surmised by Trélat, Terrier, and other observers.

The investigations of Schlegtendal were confined entirely to opened and closed collections of pus in the bones, joints, glands, and soft tissues. Of the 100 cases, which included 520 preparations, 26 were attended with positive and 74 with negative results. Of 40 examples of unopened abscess, bacilli were found in 17, while of 60 examples of fistules and ulcers, they were present in only 9. In these statistics are included, however, some cases which certainly have nothing in common with tubercle, as, for example, 1 of abscess from caries of a tooth, and 3 of chronic ulcer of the leg. The examinations, moreover, appear to have been hastily conducted, since in at least one-half of the negative results only two preparations were inspected.

The latter objection becomes the more serious when it is remembered that a negative result is only declared after at least four examinations of the sputum of phthisis pulmonalis, in which bacilli are far more abundant than in pus. Had more frequent examinations been made, particularly in the cases in which there were also tubercular lesions of the lungs and other organs, it is highly probable that the positive results would have been materially increased in number.

The absence of bacilli from pus appears to support the view that tubercle alone does not cause suppuration, but that the pus found in the immediate vicinity of tubercular deposits is due to some other factor. Hence their presence is merely accidental, and denotes possibly the breaking down of tubercular tissue and its diffusion in the purulent collection.

SCHEDE'S OR LORETA'S OPERATION?

In The Medical News, of April 21, 1883, Dr. R. P. Harris gives an account of four cases of digital divulsion of the pylorus for cicatricial or carcinomatous stenosis, by Professor Loreta. The first case was one of cicatricial obstruction, following ulceration, in which, on September 14, 1882, the stomach was opened, after having been liberated from its attachments, and the stricture divulsed with the fingers. The gastric and abdominal wounds were then closed; the man made a rapid recovery, and experienced no trouble five months subsequently.

In looking over vol. vi., 1877, of the *Verhandlungen der deutschen Gesellschaft für Chirurgie*, we accidentally discovered that Schede, of Berlin, had anticipated Loreta by seven years. At p. 107, he describes a case of attempted suicide by swallowing sulphuric acid, which resulted in strictures of the cardiac extremity of the œsophagus and of the pylorus. He established a gastric fistule, with a view to gradually rendering both orifices permeable by bougies, and actually passed an instrument through the pylorus. The patient, however, expired in fifty-eight hours, and his object was defeated.

The only difference between the two operations consists in the fact that Schede intended to dilate the stricture gradually, while Loreta practised rapid dilatation or divulsion. The credit of the feasibility of rendering a strictured pylorus permeable by opening the stomach, therefore, must be awarded to the German surgeon.

THE TREATMENT OF CICATRICIAL STRICTURE OF THE ŒSOPHAGUS THROUGH A FISTULE OF THE STOMACH.

IN the preceding article it has been shown that Schede conceived the idea of dilating cicatricial strictures of the pylorus and of the cardiac extremity of the gullet through an artificial opening in the stomach; and we find that at a subsequent meeting of German surgeons, Trendelenburg, in reporting the case of a boy, eight years of age, in which he had done gastrotomy for cicatricial stricture, stated that he had failed in his attempts to overcome the œsophageal obstruction through the new route.

In the *Deutsche medicinische Wochenschrift* of October 24, 1883, Von Bergmann records the case of a man who suffered from fibrous stricture of the cardiac extremity of the œsophagus, the result of drinking lye, in which the operation was successfully performed. The stomach was opened on the 29th of January, and a large fistule established. At the expiration of one month, attempts were made to reach the cardia with the fingers, at the same time that a probang was passed by the mouth, and, after several failures, a thick band of tissue could be distinctly felt between the probang and the finger. With the aid of an instrument constructed especially for the purpose, through the branches of which firm pressure was made from the œsophagus and from the stomach upon the band, the latter finally sloughed, and the opening thus made was plugged with a bit of compressed sponge, armed with a strong thread for the purpose of withdrawal. After its removal, a bougie, thirty millimetres, or one inch and one-fifth, in circumference, was passed into the stomach through the mouth. The bougie was used several times a day, and the sponge every other day until April 25, when the normal size of the gullet was reëstablished. The dilatation was, however, continued until the middle of May, when a sound, twenty-five millimetres, or one inch, in diameter, could be passed with ease. The introduction of the instrument was now entrusted to the patient himself, and Von Bergmann closed the fistule on the 21st of May. The man continued the use of the large bougie daily, and when he was exhibited at the meeting, on the 10th of October, his condition was all that could be desired, a cure having practically resulted.

In a clinical note contained in the *Gazetta degli Ospitali*, for November 14th, may be found a brief account of two cases of successful instrumental divulsion of cicatricial stricture of the lower third of the œsophagus, by Loreta. The stomach having been opened, the divulsor was passed through the cardia into the stricture, the latter was expanded to what was considered to be a sufficient extent to admit of the passage of food, and the incisions in the stomach and abdominal wall were closed with sutures. The subsequent condition of the subjects was most satisfactory.

The first of these operations was performed on the 24th of October, or nine months after that of Von Bergmann, and several years after the proposition of Schede and the actual attempt of Trendelenburg. Despite these facts, however, the credit of attacking a stricture of the œsophagus through the stomach is awarded to Loreta, and no notice whatever is taken of the operations of his German *confrères.*

NERVOUS ACCIDENTS CAUSED BY THE MATERIALS OF PHOTOGRAPHY.

DR. NAPIAS (*Gazette Médicale de Paris*, No. 40, 1883) has already given an account of an amblyopia and a form of professional cramp similar to writer's cramp, which happen to those engaged in the preparation of photographic plates. These observations have been confirmed by MM. Duchesne and Meichel, who have also furnished new facts. It may be of interest to the large number of those engaged in the business of photography, as well as to amateurs, many of whom are physicians, to learn the nature of the dangers to which they are exposed in the pursuit of this mode of bread-winning, or of pleasure-getting.

There may occur poisoning by the vapor of hydrocyanic acid, which is formed by the decomposition of cyanide of potassium by bichromate of potassium. Nervous phenomena may result from the breathing of an atmosphere in a dark room without oxygen, this necessary element being taken up by pyrogallic acid when in contact with the alkali, ammonia. If to this loss of oxygen be added the vapor of ammonia, it is not surprising that such an atmosphere must, if long breathed, damage the blood, and cause a more or less profound anæmia with its attendant symptoms.

In the preparation of the plates by the gelatine bromide of silver process, every ray of light must be excluded, and the operator pursue his work by the aid of a feeble illumination afforded by the red-ray lantern. Besides the foul air thus caused, the narrow and gloomy apartment is filled with the vapor of ether. Unless great care in the ventilation is practised, the necessary detention in the dark-room proves very hurtful.

REVIEWS.

La Longévité et les Moyens de l'acquérir. Par Joseph G. Richardson, Professeur d'Hygiène a l'Université de Pensylvanie, associé etranger de la Société d'hygiène Française, traduit de l'Anglais, avec l'autorisation de l'auteur, par P. Barrué. 8vo., pp. 180. Paris: Asselin et Cie, 1884.

Long Life, and How to Reach It. By Dr. J. G. Richardson, etc.

Some time ago our British cousins showed their appreciation of what is known as the "Health Primer Series" by republishing it in England, with the names of the authors carefully omitted from each book, and every evidence that it was not the product of British intelligence suppressed. To this compliment has now been added the more acceptable one of a French translation and publication of Dr. Richardson's member of this series, entitled, "Long Life, and How to Reach It," with due credit to the author.

The views expressed in this book do not need to be dwelt upon here, for they were reviewed when they appeared in their original form. One point may, however, be referred to. This relates to a subject which just now is seasonable, namely, the question of protection against catching cold, as influenced by the clothing.

This is sensibly discussed by our author; but one thing which has struck the reviewer is not mentioned. This is that the custom of wearing thick undershirts in winter, while it keeps the body warm enough out of doors, keeps it much too warm when in the house. The consequence is that indoors, with the thermometer at a summer height, one is unable to suit the clothing to the conditions, without so extensive an act of undressing as no one can go through. The most proper plan would, in our opinion, be—and it accords with successful personal practice—to wear only moderately thick undershirts, and make the necessary addition in the shape of coats and overcoats on going out. In this way the body need not be overheated in the house, and it can be made warm enough in a moment for going out of doors. The great thing in this plan is to see that the forearm is not exposed by having the sleeves of the undergarment so short that chilling may take place at this place.

A System of Human Anatomy, including its Medical and Surgical Relations. By Harrison Allen, M.D. Section V., Nervous System. 4to. pp. iv., 459 to 583. Philadelphia: Henry C. Lea's Son & Co., 1883.

With one more part Dr. Allen's fine work will be completed. The present one deals with the entire nervous system, and is very satisfactory. He records briefly but clearly the usual anatomical arrangements of the particular parts, next their variations, and then follows that which distinguishes this from all other anatomical text books—practical remarks on the medical and surgical relations, the diseases and accidents peculiar to each part. Generally these remarks are very useful from the clinical point of view. They add greatly to the interest of the book, and aid the practitioner in his every-day work. Copious references to the original sources are given, thus doubling their value. We are somewhat surprised, however, to see no reference to the operations of nerve-stretching, especially in connection with the great sciatic nerve.

In the description of the brain, we are glad to see the numerous drawings of sections at various levels. These aid one greatly in getting an exact idea of the internal and varying relations of any given part of the brain, and, in fact, are indispensable in the modern more exact descriptions of the brain both anatomically and pathologically.

The local student in Philadelphia can well supplement these plates of sections by a study of the splendid series of mounted sections by Schmidt, in the Mütter Museum of the Philadelphia College of Physicians.

The text is in general clear, brief, and sufficiently minute, and usually very accurate. In Fig. 92, p. 469, it is correctly stated that no central canal exists in the *filum terminale*, so that we were surprised to learn, on p. 465, that in this part of the cord it was T-shaped, or cordiform. In fact, it is a misfortune that this canal is called the canal of Stilling, or the central canal. Its best name, by far, is the "ventricle of the cord," for it is precisely analogous to the ventricles of the brain in its development.

Another slip we observe on p. 510, where the falx cerebelli is misprinted cerebral falx; and on p. 527 Vanzetti's name has the z omitted.

The plates in general are very good, though we observe some inaccuracies, chiefly in spelling. Thus, in Pl. 83, Fig. 5, "cervical" is misdrawn as "cercival." In Pl. 85, Fig. 1, the facial nerve is called the "fascial." In Pl. 86, Fig. 2, the flexors of the forearm are styled "flexors of foramen;" and in the description of Fig. 113, "i. c.," the internal capsule, is designated "i. e," which is very apt to mislead. In Pl 86, Fig. 1, at the bottom the median nerve is labelled as the ulnar artery by error. In the same figure, on a curiously shaded deltoid muscle, runs an unlabelled, and surely an impossible, nerve.

We have pointed out these few errors for future correction; but while they mar the complete accuracy of the work, they are but trifling blemishes, which but act as foils to the many and marked virtues and excellences of the entire book. None of us escape errors, but many do, unhappily, escape the merits of the present author. The work is a monument of careful, patient, long-continuing toil, well rewarded in its valuable results.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Thursday, December 6, 1883.

The President, Fordyce Barker, M.D., LL.D., in the Chair.

NOMINATION OF OFFICERS.

After the reading of the minutes, the nomination of officers was made, as follows:

For *Vice-President*, Drs. Weir and H. D. Noyes.

Trustee, Drs. Purple and C. R. Agnew.

Treasurer, Drs. Cushman and E. R. Peaslee.

Treasurer of the Board of Trustees, Drs. J. H. Hinton, D. B. St. John Roosa, and F. A. Castle.

Committee on Admissions, Drs. James and Daniel Lewis.

Committee on Education, Drs. W. G. Wylie and John Shrady.

Committee on Ethics, Drs. C. D. Varley and F. V. White.

Committee on Library, Drs. A. Jacobi and H. D. Nicoll.

REPORTS.

After a report from the Committee on Admissions, a number of new Fellows, elected at the last meeting of the Academy, were presented with diplomas and copies of the Constitution and By-laws by the President.

Dr. Alexander Hunter, Secretary of the Section on Obstetrics, announced that at the last meeting of the Section Dr. W. M. Chamberlain had presented a paper entitled, "Notes on Displacements of the Uterus."

A COMMUNICATION FROM THE COUNCIL

was then read, recommending the appropriation of $2000 for the use of the Library Committee during the ensuing year, and that a tax of three dollars, in addition to the regular dues, should be levied upon each Fellow for one year, in order to place the Academy on a sound financial basis. On motion of Dr. E. D. Hudson, the recommendations of the Council were adopted.

PROF. T. GAILLARD THOMAS then read a paper on

THE PREVENTION AND TREATMENT OF PUERPERAL SEPTICÆMIA.

At the present day, he said, when medical literature had assumed such enormous proportions, every scientific paper ought to be challenged for its *raison d'être*, and he did not hesitate to accept the challenge in regard to the essay which he was about to present to the Academy. He would freely confess, at the outset, that it contained nothing original, and that it was devoted to a subject which had received for a considerable time the careful attention of the progressive obstetricians of the world. Nevertheless, he ventured to hope that the lessons which he desired to inculcate might be productive of some good, and be of practical benefit to the profession. In support of the fact that the subject was not yet as well understood as it ought to be, he would mention two points: When at the meeting of the American Gynecological Association at Baltimore, in 1878, he advocated the use of intra-uterine injections in puerperal septicæmia, there was but one gentleman present who agreed with him: again, about one year ago he read the history of a case of this disease, treated in the manner presently to be described, at a meeting of the New York Obstetrical Society. This was published in some of the medical journals, and very soon afterwards he received at least half a dozen letters from practitioners in various parts of the country inquiring more particularly into the details of the method of treatment adopted. Finally, he said, he was, if not the first, among the very first to adopt the use of intra-uterine injections and external refrigeration in the treatment of puerperal septicæmia, and as a teacher and a consultant, who had had a very large experience in the matter, he felt entitled to speak.

In the last quarter of a century, he continued, more advance had been made in the study of the febrile conditions incident to the puerperal period than in all the preceding ages. It was true that long before this the communicability of puerperal disease was recognized, but it was reserved for the development of the germ theory to throw new light upon the subject. Ever since the time of Hippocrates, more than two thousand years ago, the profession had been striving to master the problem presented by such affections, and it was only now that it was beginning to find its way out of the darkness in which it had hitherto labored. We were now beginning to understand something of the nature of puerperal disease. Having given Hervieux's classification, he went on to describe the condition of the blood, with its marked excess of fibrin, and the exalted excitability of the nervous system in the parturient woman, the consequences which were likely to result from these factors; after which he spoke of the rapid physiological hypertrophy undergone by the uterus and other organs during gestation. He then described the appearances which would be presented by the genital organs of a woman dying forty-eight hours after delivery. Among the conditions noted would be found two or three small rents in the cervix uteri, which would be swollen and œdematous; while in the vagina would probably be found several superficial ruptures of the mucous membrane. About the vulva, also, would be found lesions of continuity. The fourchette would be torn through and at least one or two small rents in the mucous membrane covering the ostium vaginæ would be seen. From the fact that the ichorous and irritating fluid coming from the interior of the uterus was constantly flowing over these various lesions, we would naturally expect to find that infection and its dangerous consequences in the form of lymphangitis, phlebitis, peritonitis, or other inflammatory affection, would result. Yet these conditions existed in the case of every puerperal woman, and the ordinary result was complete and satisfactory recovery, unless some unusual event occurred to interrupt the physiological process going on. There were a number of recent wounds constantly bathed with a fluid made up of decaying animal tissue, and a bad result would naturally be anticipated; yet, according to the latest statistics of Tarnier, only one woman out of a hundred died in the lying-in hospitals. In fact, death was the very rare exception.

Occasionally, however, the ordinary course of progress towards recovery was interrupted, and striking, alarming, and often fatal phenomena suddenly presented themselves. On the morning of the third day after delivery, it might be that the physician would leave his patient in a perfectly natural condition, and on returning in the evening would find that she had had a chill of greater or less severity, that the lochia had ceased, that she was suffering from great general distress, and more or less pain in the head, back, and pelvic region; while the pulse had gone up to 130 or 140, and the temperature to 104°. All this would indicate that a dangerous poison had reached the genital tract, though the physician might flatter himself it was only an attack of malaria or milk-fever. Within a week we should find that parenchymatous metritis, lymphangitis, phlebitis, peritonitis, endocarditis, pneumonitis, pleuritis, or other form of septic inflammation had become fully developed, and the patient would probably die from continued high temperature and exhaustion.

In regard to the pathology of the disease, he believed that puerperal fever, in whatever form it might show itself, was puerperal septicæmia: the cause of the affection being the absorption of a poison by a solution of continuity in the genital tract. In 1871 Hervieux had said: "Here I stand. . . . . I believe in the multiplicity of puerperal diseases. I believe in their origin from puerperal poison." This aphorism he accepted as expressing his own views. The special committee of the Berlin Obstetrical Society, composed of the most distinguished names, with Schröder at its head, which was appointed to investigate and report upon the subject of puerperal fever, had expressed the same tenets, and Dr. Thomas here quoted at length from the report of the committee. As to nomenclature, he thought the word "metria," recently proposed by the Dublin School of Obstetrics, was even more objectionable than the old term puerperal fever; while, on the other hand, puerperal septicæmia conveyed a clear and definite idea of the origin and nature of that affection. He thought that in spite of the fact that complications were of such frequent occurrence, the septic element was so paramount that the term should be adopted. Barnes had recommended the same, although he had adopted it with the proviso that it did not indicate a distinct and specific poison. He himself, however, believed that there was a specific poison.

What, then, was the nature of this poison? How did it originate? What encouraged its life, and what crippled its activity? Unfortunately, in the present state of our knowledge, these questions could not be definitely answered; but the same was true in regard to the germ of scarlatina, variola, and many other zymotic diseases. Many German authorities had insisted on the agency of micrococci in the production of the disease; but the opinions regarding them are as yet too unsettled to permit of a decision in the matter. Many investigations, however, were at present being pursued in the laboratories of Germany and France, and there was a fair prospect of success in the solution of the problem. But, although we did not know the exact nature of the poison, there could be no doubt that such a poison did exist, and that there were only two methods by which it could be introduced into the system. These were, first, through the atmosphere, and, secondly, by the contact of the hands of the physician or nurse, or of clothing or bed-covering with the genital tract.

While in lying-in hospitals positive rules were always adopted for the management of all cases, in private obstetric practice there was, as a rule, a laxity of caution which bordered closely on criminality. Prophylaxis was, however. the plain duty of every practitioner, and the following rules ought to be carried out in every case of confinement:

First. The room should be cleared of all upholstery, as far as possible, and the floor, walls, ceiling, and every article of furniture sprinkled with a ten per cent. solution of carbolic acid, or a solution of bichloride of mercury of the strength one part to a thousand of water.

Second. The nurse and accoucheur should be scrupulously clean about their persons, and use upon their hands and clothing some antiseptic wash, especially if within the past fortnight they have been exposed to the contagion of scarlatina or other septic influence. The disinfectant preferred was a saturated solution of boracic acid,

Third. As soon as labor begins, the nurse, having cleansed her hands thoroughly with a stiff nail-brush, should make a warm antiseptic vaginal injection, and repeat it every four hours, in the mean while keeping a cloth over the vagina.

Fourth. Both the physician and nurse should use upon their hands and upon every instrument or utensil employed during the labor a solution of bichloride of mercury (1 to 1000).

Fifth. The third stage of labor should be efficiently produced, and ergot should be immediately administered, and afterwards kept up in moderate doses three times a day for at least a week.

Sixth. The physician should take nothing for granted on the nurse's assertion, but, at the end of labor, should make an examination of the genitals. If rupture of the perineum is found, it should be united at once by suture. If a slight abrasion is discovered, the parts should be cleansed with a linen cloth, and persulphate of iron and carbolic acid applied, after which the parts should again be dried with a cloth, and painted with gutta-percha collodion.

Seventh. In six or eight hours, a suppository of cocoa butter, containing from three to five grains of iodoform, should be placed under the os uteri. This should be repeated every two or three hours for at least ten days.

Eighth. In ordinary cases, vaginal injections of a solution of bichloride of mercury or other disinfectant should be made every eight hours with a syringe throwing an intermittent stream.

Ninth. When catheterization is necessary, use a new gum-elastic instrument, first dipping it in an antiseptic solution. Nurses should never be allowed to use the old silver catheters which they are sometimes in the habit of keeping about them.

Tenth. Last, but not least, let the physician convince himself practically of the nurse's ability to use the syringe and catheter, and to insert suppositories properly.

Even if all the above suggestions were carefully carried out, the trouble of the plan would not be great, and the accoucheur would be amply repaid by the satisfaction of having performed his duty. In the case of a fatal result, this would be a source of unspeakable comfort to him. It was clear that the observance of such rules as these would do much to increase the importance of parturition in the eyes of the profession; so that a woman about to bring forth would come to be regarded in the light of a patient who was to undergo a capital operation. Having again quoted the report of the Berlin Obstetrical Society in support of his views, he went on to say that he wished to record in the strongest language his protest against the use of intra-uterine injections as a prophylactic, except after very severe operations within the uterus which rendered the occurrence of septicæmia almost certain. It was a dangerous method, which was only justifiable as a means of treatment in the presence of a still greater danger.

In spite of every measure taken to prevent it, septic disease sometimes occurred. The poison might not be a necessarily specific one. It was probably the same as that giving rise to septicæmia after gunshot wounds. It was, he believed, however, entirely different from the kind of infection arising from an adherent placenta or a retained mass of blood. It was capable of causing the true, specific lymphangitis, and in many country neighborhoods it was entirely unknown. Out of three thousand cases, Hervieux had had but one case of puerperal septicæmia. As soon as the patient is stricken with the poison, marked phenomena present themselves; after a chill, high temperature and quickened pulse follow. The fever was accompanied by headache and pain in the back, and sometimes by nausea and vomiting. At the beginning, the physician could form no idea of what course the disease might pursue; but if the precious moments at the outset were passed in inactivity, an advantage would be lost which could never be regained. Whatever form the disease might ultimately take, whether cellulitis, phlebitis, peritonitis, or other variety of trouble, he could strike at the root by taking prompt action. In the case to be supposed, it was assumed that the attack was a violent one, and that the patient's friends were possessed of ample means. The method of treatment recommended was as follows:

First. As soon as it becomes probable that puerperal septicæmia is setting in, a hypodermic injection of Magendie's solution of morphia should be given (unless there is some special and strong contraindication), to allay pain and nervous irritability. Afterwards, this should be repeated every six or eight hours, as a rule. In Dr. Thomas's experience, no method of administering opium compared with this in efficiency. If a new hypodermic needle, first washed with soap and water, and then dipped in a solution of bichloride of mercury, was employed, there would be no danger of causing abscesses. It was the old, rusty needle which did this.

Second. An India-rubber cloth should be spread over the edges of the bed, and the patient's feet having been placed on chairs, and the knees carefully covered with blankets, an intra-uterine injection of solution of bichloride of mercury (one to one thousand) should be made. The tube recommended was the glass one of Dr. Chamberlain, modified by reducing the number of waste holes, so that the injection could be carried more effectually to the fundus. Another instrument recommended was the ingenious metallic tube devised by Dr. George H. Lyman, of Boston, which had the advantage of affording a perfect means of escape for the fluid injected into the uterus. In either case, the instrument was to be fitted to a Davidson or Higginson syringe, the intermittent action of which was considered much preferable to the continuous but feeble stream of the fountain syringe. In any case where it was supposed that a portion of the placenta was retained, chloroform was to be given, and the adherent parts, if found, removed by means of the nails acting as a curette. In other cases, it was desirable to carry a sponge dipped in antiseptic fluid up into the uterus.

The method of intra-uterine injection was attended with the following dangers:

First. The entrance of air into the uterine sinuses.

Second. Hemorrhage.

Third. The carrying of poison by the extremity of the syringe directly into the circulation through the open sinuses.

Fourth. Pain, shock, or convulsions, from the effect upon the nervous system.

Fifth. Entrance of fluid into the peritoneum through the Fallopian tubes, and consequent peritonitis. Great care should, therefore, be practised in making the injections, and the tube should never be allowed to fill completely either the *os internum* or *os externum*. In order to prevent this, it is sometimes necessary first to dilate the os with the fingers, by means of Barnes's dilators, or in some other way.

It is desirable to have persulphate of iron always on hand, in case of hemorrhage from dislodgment of a thrombus. If this occurred, ergot should also be used freely. Several deaths have been reported from the use of intra-uterine injections. In a considerable experience with them, Dr. Thomas, however, has met with but one fatal case. The frequency of the injections should vary according to the severity of the disease. In mild cases one in every five hours was sufficient. In others the injections should be repeated every three hours, and in bad cases every hour. They should always be made by the physician, and administered with strict attention to details; special care being taken that the fluid always reached the fundus. Dr. Thomas had himself believed for several years in the efficacy of the steady stream of the fountain syringe; but he had afterwards become convinced that the intermittent stream was much preferable. Some had adopted the plan of continuous irrigation; but this he believed to be a delusion and a snare. The objection to it was the difficulty of getting the germicide fluid in contact with the whole endometrium by this means. For use in the vagina it was very desirable, and in very severe cases it might be useful to keep up constant irrigation of the uterus, and then, in addition, use the intermittent stream every three hours. That plan was the best which accomplished most thoroughly the cleansing of the parts.

The third point in the treatment was to control the high temperature, which was one of the immediate factors of a fatal issue. Even if the fever did not prove fatal, its effects are always more or less serious. For the reduction of this he had formerly employed Kibbee's cot, but was now in the habit of resorting to the use of Townsend's rubber coil in preference. This was simply a mat made up of a long rubber tube coiled in circles upon itself and which, when in position, covered the entire abdomen; extending from the symphysis pubis to the ensiform cartilage. Through this a constant stream of iced water flowed: the extremity into which the water entered being provided with a little strainer to prevent the tube from becoming clogged by any impurities contained in the ice employed. The tub of iced water was placed about two or three feet above the level of the patient's body, and the end of the tube containing the strainer was anchored in it by a weight. The other end, by which the water escaped, emptied into a tub on the floor. By means of this refrigerating coil a temperature of 104° could be reduced to 100°, and kept at this point for weeks together. To this excellent method, however, the nurse, the patient, and the friends of the latter are apt to make the strongest objections, and even some physicians denounce it as liable to give rise to pneumonia, pleurisy or other serious attack. But such fears are entirely groundless. In the Woman's Hospital after laparotomy it was as freely in use as poultices, and every one of the successive house-staffs leaving the institution went away thoroughly impressed with its superior advantages. In some cases its effect was not apparent for a considerable time; so that the temperature was not reduced for twenty-four hours, and even longer. In every case its prolonged use was essential, and removing the coil from the body for even an hour at a time might be productive of much injury. Dr. Thomas had never seen any bad results from it if hot water bottles were kept applied to the soles of the feet. He had never known pleurisy or pneumonia to be caused by it.

In the fourth place, febrifuges given by the mouth were advised, especially for the purpose of keeping off chills. Fifteen grains of quinine might be employed night and morning, or, in place of this, two capsules of Warburg's tincture, as recommended by Dr. John T. Metcalfe. Salicylate of soda was also of service in some cases.

Fifth. The patient should be sustained principally by a milk diet, but the animal broths are also to be freely used.

Sixth. Efficient and abundant assistance is absolutely essential for the proper carrying out of the treatment. With only one nurse and one physician, this is simply impossible. A day nurse and a night nurse are required, and it is highly desirable that a physician should be in the house the entire time. As to the various antiseptic agents to which attention had been called during the last few years, only two seem to be of really practical service, carbolic acid and bichloride of mercury. For the use of the latter in this connection, the profession is mainly indebted to the investigations of Koch, and for a intra-uterine injection it is to be used in the strength of one part to a thousand. If carbolic acid be used, a two per cent., or two and one half per cent. solution is the best for this purpose.

Dr. Wm. M. Polk said that the Academy was deeply indebted to Dr. Thomas for his able and even eloquent presentment of this most important subject. He had left but little to be said, as regards the treatment of puerperal septicæmia. In the matter of pathology, he thought it would perhaps have been better if he had planted himself squarely in the position that puerperal fever was identical with pyæmia and septicæmia. For himself, he considered it absolutely identical with surgical septicæmia and pyæmia. The lesions were those which belonged to these affections; and it was only in the domain of etiology that those who were opposed to this view found their ground of support. They claimed that there was some peculiar and specific germ which gave rise to the trouble. In regard to the treatment, the principles of Listerism, as laid down by Lister and his followers, and as ably set forth to-night by Dr. Thomas, entirely covered the ground. He would merely add that in this city, where there was so much bad drainage, the question of the purity of the air breathed by the patient assumed great importance. So far as the means of actual treatment were concerned, he had one suggestion to make. In his experience, he had found, sometimes, that he had been using intra-uterine irrigation when the lesion which was killing the patient was really in the cervix, and the stream employed was not of sufficient strength to separate the surfaces. His plan now, therefore, was to place the patient in the ordinary position for the purpose, and make a thorough examination by means of Sims's speculum. The entire canal as far as the os uteri could thus be observed, and if any lesion were observed, a strong solution of carbolic acid or other antiseptic was applied directly to the spot. If no source of trouble could thus be detected, he swabbed out the interior of the uterus with borated cotton dipped in a two per cent. solution of carbolic acid, and perhaps used in addition Skene's broad curette, the edge of which was blunt. In conclusion, he would only say that if we were to adopt the preventive measures so forcibly insisted upon in the paper, we must go further and plant ourselves firmly on the ground that puerperal fever was identical with surgical pyæmia and septicæmia.

Dr. James B. Hunter said that he wished to speak of only two or three purely practical points. There was great difficulty in carrying out the energetic plan of treatment recommended by Dr. Thomas. Thus there are many people who are neither poor nor rich, and while they could not avail themselves of the facilities offered by the hospitals, they could not possibly afford the expense which such a plan entailed in their own homes. It was very important, he thought, that the patient should be disturbed as little as possible, and on this account he considered it objectionable to have to move the patient to the edge of the bed every time that an injection was made. His own plan was simply to slip a bed-pan under her, and administer the injection while she was lying upon the back. As to the instrument employed, he had found that with the ordinary Chamberlain tube the fluid could not be carried to the fundus, and he had therefore had a tube made which was about half the size of this, and which had orifices only at the end. The reason that he employed so small a tube was that he had found that the os uteri contracted considerably after two or three hours, and it was sometimes necessary to dilate it. Nott's double catheter answered very well for making intra-uterine injections. In carrying out the plan of injections, opposition was likely to be met with on the part not only of nurses and patients, but of physicians. In one or two cases, he had seen slight chills caused by them, but he believed them to be due to the fact that the water was not warm enough. In regard to the cooling apparatus, he did not believe that the coil was called for in simple puerperal septicæmia. In peritonitis, however, and after laparotomy, he had the strongest faith in it, and constantly employed it in his practice. In septicæmia, even if the fever were kept down to a low point, the disease might be of the most serious nature. When the coil was used, he preferred the metallic tubing, as being lighter and more readily kept clean than the other.

Dr. Partridge advocated the injection of iodoform suspended in glycerine after the ordinary douche, as suggested by the late Dr. Brinsly Livingston.

The President then said that twenty-five years ago the Academy had had a long discussion on puerperal fever, and eight years ago a similar one had been held in the London Obstetrical Society, during which he had had the honor of having a special evening set apart for the exposition of his own views on the subject. He believed that there were many others present who would like to have an opportunity of expressing their opinions, but who could not do so this evening on account of the lateness of the hour; and he would, therefore, make the proposition that the first meeting in February should be devoted to a discussion of this subject. At the second meeting in January, a well-known surgeon was to read a paper on antiseptic treatment in general surgery, and it would, therefore, come in very appropriately. On motion, Dr. Barker's suggestion was adopted, and the Academy then adjourned.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

Stated Meeting, Thursday Evening, Nov. 22, 1883.

The President, James Tyson, M.D., in the Chair.

Dr. J. H. Musser exhibited the

LARGE INTESTINES FROM TWO CASES OF CHRONIC DYSENTERY; ONE OF THEM SHOWING PSEUDO-POLYPI.

Case I.—The patient had chronic dysentery; further clinical information cannot be given. No record of autopsy preserved. The specimen is from the museum of the Presbyterian Hospital, and is presented on account of its rarity. It is a part of the large intestine, fourteen inches long. To the naked eye it shows thickening of the mucous and submucous layers, and hypertrophy of the muscular layer. On the surface of the mucous coat, innumerable polypoid growths are observed, some pedunculated, some sessile The sessile growths are from the size of a millet-seed to that of a chestnut, round or ovoid. The others also vary in size from a pea to a large bean; their pedicle is generally from one-sixteenth to one-eighth of an inch long. The reporter remembered seeing the specimen when recently removed, and knows there were more pseudo-polypi than are here visible, many having fallen off from handling, etc.; that there was scarcely any healthy mucous membrane; that in this part of the intestine, there was almost complete ulceration of the mucous coat. At one point, a large stellate cicatrix, depressed in the centre, is noticeable, while all over the surface cicatricial lines are observed, most distinct about the bases of the growths.

In connection with this specimen, Dr. Musser called attention to a minute description of a similar specimen by Dr. J. J. Woodward, U. S. A., whose article appeared in the American Journal of the Medical Sciences for January, 1881, and is entitled "Pseudo-polypi of the Colon; an Anomalous Result of Follicular Ulceration." According to the writer, the origin and development of these polypi are as follows: 1. A granulating ulcerated surface of the intestine. 2. Numerous islets of mucous membrane on this surface. 3. "The formation of cicatricial contractions commenced in the infiltrated submucosa, constricting the margins of the islets of mucous membrane which were further transformed by hyperplastic inflammatory processes until ultimately they acquired the form of pedunculated excrescences, and projected into the lumen of the intestine, like so many little polypi"—being pushed out by the contraction of the connective tissue. Although the surface of the mucous membrane appeared to the naked eye healthy, the microscope showed that it was submucous connective tissue infiltrated with lymphoid elements. The pseudo-polypi were composed of a central portion of connective tissue and a peripheral portion of diseased mucous membrane, the former continuous with the submucous layer, the latter limited to the surface of the growth. The histological changes in the mucous and submucous layers resembled those of chronic inflammation. The remainder of the bowel showed follicular ulceration. I am unable to say what was the condition of other parts of the bowel in the specimen exhibited.

Case II.—The specimens were removed from a patient who had been a sufferer from chronic dysentery for some time. The bowel affection was especially severe during the past summer. He had been ill of an acute exacerbation for about one week when medical advice was sought. The symptoms were those of an acute dysentery, but were not alarming. The effects of the habit of using chloroform, chloral, and alcoholics to excess, which habit he continued during his illness, complicated the clinical features. About the tenth day of his illness the typhoid state suddenly developed, and he died in coma two days thereafter. His temperature never was higher than 102°, tormina and tenesmus were marked, bloody and mucous discharges were excessive.

Autopsy, eighteen hours after death: Rigor mortis marked; body well nourished. On section, the abdominal walls were loaded with fat, and large deposits of this tissue were found in the great and lesser omentum, the mesocolon, and the epiploicæ. The mesenteric and lumbar lymphatic glands were not enlarged. The cæcum was surrounded by old lymph; the appendix was bound down by adhesions and thickened. The cæcum was dilated, the transverse and descending colon contracted; the walls of the entire colon were thickened. On opening the large intestine, it was found to be extensively ulcerated. The mucous membrane and the ulcers were strikingly anæmic, and of a pale cream color; there were no points of hemorrhage. The walls were thickened, the mucous membrane swollen, the ulcers were more numerous and larger in size at the cæcum. The smaller ulcers were the size of a dime; some of the larger extended around the gut, and were from one-half inch to an inch wide. The edges of the ulcers were regular, bevelled, and thickened, the floor rather clean; the deepest did not extend beyond the muscular coat, the more superficial only included the mucous membrane. The larger ulcers were on the tops of the folds of the intestines. A tenacious, thick mucus covered alike the ulcers and the adjacent structures.

Condition of other organs: Liver enlarged and fatty; kidneys markedly cirrhotic; spleen normal; heart slightly hypertrophied. Microscopical examination revealed the changes in the intestine of chronic inflammation, and that the ulceration was of a simple nature and not due to tubercle.

DR. W. G. MACCONNELL presented the specimen from

A CASE OF CARCINOMATOUS SARCOMA OF THE LEFT TESTICLE

which was removed from a young man, by Prof. Brinton, at the surgical clinic of the Jefferson Medical College Hospital, on Wednesday, November 7, 1883. History: Jacob A., æt. 26 years, a clerk; about eighteen months ago he struck his testicle in mounting his horse on the pommel of the saddle, from the pain of which he fainted; no inflammatory enlargement however of the organ ensued. Last May he noticed that the left testicle had begun to enlarge, and continuously increased in size until it had attained its present volume. There was a sense of heaviness in the tumor, but no pain was experienced until about two weeks prior to its removal, when he noticed a periodical pain of a burning nature, which, with the increasing size of the organ, caused him to apply for relief. It weighed about eight ounces and measured in its long diameter four and a half, transversely three and a quarter inches, and about two and a quarter inches in thickness. No lymphatic involvement was present, nor was the cord involved; the veins of the scrotum were enlarged and prominent. The tunica vaginalis testis is slightly thickened, and very opaque; the tunica albuginea is also thickened; a slight remnant of the epididymis exists, in the form of a small fibrous lump. Its shape is somewhat that of a kidney, and upon section showed a moderately firm buffy colored tissue; it did not cry under the knife. In color and consistence it resembled the soft fibromata; distinct remains of the fibrous septa are to be seen; there are no cystic changes or any chondroid tissue present. Its macroscopical appearance and consistence suggested a spindle-celled sarcoma, and as such upon section I diagnosed it. Microscopically at a first examination, from the great ecstasy of the epithelium present, I was inclined to regard it as a pure medullary carcinoma; but after a careful study of several sections, I am inclined, by reason of the juvenescence of the connective tissue, both round and spindle-cells being present, to call it a carcinomatous sarcoma. There was no history of syphilis, scrofula, or tubercle, nor had any member of his family ever labored under any form of tumor.

DR. NANCREDE called attention to the fact that modern microscopic study has shown that carcinoma of the testicle is a rare disease, most malignant tumors of that organ being really sarcomata. In this connection it is of much practical interest to note that the system becomes infected at a relatively late period of the disease, so that when a sarcomatous testicle is removed at an early stage of the disease, prolonged immunity, if not actual cure, resulted. The inguinal and retro-peritoneal glands were those affected, their enlargement, by pressure, pain, etc., being the ultimate cause of death. Even more distant lymphatic glands are in rare cases involved.

DR. FORMAD agreed with Dr. Nancrede. Some years back he had paid special attention to the study of malignant growths of the testicle and ovary. Of the former he had examined thirty cases, all of which were sarcomata. He did not believe in the existence of such a growth as true carcinoma of either the testicle, ovary, or kidney. The so-called carcinoma of those organs exhibits cells of a *connective-tissue type*, rather than of an epithelial. Dr. Formad considered, with many other observers, that the so-called epithelial cells of kidney, testicle, and ovary are really *endothelial*, and gave reasons in support of this view. He further said that there is a variety of endothelial carcinoma occurring in the breast, which is that usually described as alveolar sarcoma. Here the endothelial cells of the lymph-spaces proliferate, but the glandular elements of the mammæ do not participate. It is doubtless from the examination of such tumors that Virchow and Cornil and Ranvier have gained the erroneous idea that true carcinoma takes its origin from connective tissue. He suggested the term "*endothelial* carcinoma" for such tumors, instead of "alveolar sarcoma."

NEW YORK SURGICAL SOCIETY.

Stated Meeting, November 13, 1883.

THE PRESIDENT, THOMAS M. MARKOE, M.D., IN THE CHAIR.

TUBAL GESTATION; RUPTURE OF THE TUBE AT THE END OF THE SECOND MONTH; INTERNAL HEMORRHAGE; ABDOMINAL SECTION: LIGATION OF TUBE; DEATH IN FORTY-SEVEN HOURS, FROM SHOCK.

DR. CHARLES K. BRIDDON presented a specimen, accompanied by the following history: Mrs. K. I. K., æt. 28, a short, stout brunette, measuring five feet and less than one inch, and weighing one hundred and fifty-five pounds, is the mother of two children, one three years, the other thirteen months old. She has always enjoyed good health. Her last normal menstruation occurred on the tenth day of August, 1883. Two months subsequently, on the tenth day of October, she had a flow of clotted blood, accompanied by pain of an intermittent character. On the sixteenth day of the same month, while out walking, she was taken with sudden severe pain, and was obliged to sit down for some minutes. The pain continued with diminished severity until after she reached home. When I saw her she was suffering considerably. The pain was pelvic, and did not appear to be more acute on one side than on the other. It was continuous, but aggravated at uncertain intervals by paroxysms of increased severity. She says that when the pain attacked her in the street she felt something flow from her vagina, but on examining her linen found it only soiled with a little mucus. She complained of being unable to urinate. There was no increase of temperature; no acceleration of pulse, or of respiration. On making an examination, I found the os low, and slightly displaced forward. It was soft, and dilated sufficiently to admit the first phalanx of the index finger. The body of the uterus was exquisitely sensitive and enlarged. Though the physical conditions of retroversion were not present, I thought the inability to urinate might be occasioned by some mechanical impediment. I emptied her bladder, and placing her in the knee-elbow position, found that on opening the vulva the uterus receded, and there was nothing at all to be felt in the cul-de-sac. Rest, and a few doses of chlorodyne for treatment, and in a few days she was well.

On the afternoon of the 29th she was again attacked with pain, and although there was no flow I suspected that abortion was imminent, and prescribed an anodyne and rest. I received a second urgent message to see her at 7 P. M., and found her suffering from symptoms of internal hemorrhage. She exclaimed that she was dying. Her extremities were cool, her face was pallid, and I could detect no radial pulse. I had no hesitation in expressing the opinion that the case was one of tubal pregnancy, and that rupture had taken place. I explained the dangerous character of the condition to her husband, the probability that prompt action would have to be taken, and I requested counsel. Dr. H. F. Walker saw the case with me before nine o'clock, and suggested that we should call in Prof. T. G. Thomas, who saw the patient at half-past nine. There was no division of opinion, all were agreed that an abdominal section and the institution of such means as would secure against the further escape of blood, were the only ones calculated to afford even the slightest chance of recovery. The consent of the patient and her friends being obtained, the only delay was occasioned by the insistance on their part that she should receive the sacrament before the operation.

I was ably assisted by my friends, Drs. Gerster, Walker, and Scharlaw, and it affords me great pleasure to testify to the kindness and promptness with which they responded to my call for assistance under very trying circumstances. Ether was administered by Dr. Scharlaw, and very little indeed was used. The corpulence of the patient made it necessary to make a long incision, reaching from the umbilicus to the pubis. Her collapsed condition rendered this almost a bloodless proceeding. When the peritoneum was exposed a small incision was first made, which gave exit to a large amount of fluid blood. The incision was then enlarged sufficiently to admit the hand, and at least a pint of blood-clot was scraped out as rapidly as possible. The uterus was then drawn up as far as its connections would permit, and the cause of trouble was at once apparent. Part of an ovum, one inch and a quarter in diameter, was found protruding from a rent in the left Fallopian tube close to its uterine extremity. The broad ligament was lifted as much as possible, and a probe armed with a double, stout, plaited silk ligature was passed through it as low down as could be done, and the ends were firmly secured above the free border. In these manipulations the ovum was forced from its bed in the oviduct, and was removed entire. The hemorrhage appeared to be entirely controlled. The ligatures were cut short, and the toilet was completed by thorough cleansing of the cavity. The wound was then closed by silver-wire sutures. No time was lost in completing the dressing, but the patient was removed at once to bed, and surrounded with blankets and hot bottles. Her head was enveloped in a warm woollen shawl. A small hypodermic of morphine was administered, and brandy used subcutaneously. It was not, however, until after midnight that an occasional flicker could be felt in the pulse at the wrist. Vomiting, which occurred, was treated by frequent sips of hot water, nutrient and stimulant enemata were used all through the night. On the morning of the 30th, her appearance was much improved. She was inclined to talk, was even cheerful, and expressed herself as entirely free from pain. She only complained of vomiting, but notwithstanding these favorable signs her pulse could scarcely be felt, much less counted. At times it could not be distinguished at all. Temperature was 101°, respiration 36. At 10 A. M., her pulse could be counted, 126, and after this it improved for twenty-four hours, averaging 130; temperature for the same period, 101° to 102°. In spite of the most assiduous stimulation, the circulation could not be maintained. She began to sink on the afternoon of the 31st, and died at 9.30, forty-seven hours after the operation.

Sectio Cadaveris.—October 31st, 11 P. M. Abdomen only moderately distended. Abdominal wound agglutinated, but easily separated. Omentum adherent to peritoneal surface in the neighborhood of the line of incision; no general diffuse peritonitis. About two ounces of odorless bloody fluid in the cavity of the pelvis; the left broad ligament adherent to anterior wall of rectum; uterus enlarged to nearly twice its normal dimensions. At the junction of the left oviduct with, and encroaching upon the cornua itself, was an ovoid swelling about one inch in diameter, darker than the surrounding structures, of a mottled violaceous maroon color. Near the junction of the posterior wall of the duct with this swelling was a ragged opening, half an inch in length, and leading into a cavity formed mainly out of that portion of the duct which traverses the uterine wall, so that the specimen might be said to represent the variety known as interstitial, or, more correctly, sub-interstitial. On incising that portion of the cavity which was developed at the expense of uterine textures, it was found filled with adherent coagulum. The cavity of the uterus was not lined with decidua, and the uterine opening of the oviduct was impervious. Outside the rent were found the ligatures applied during life, and which had effectually controlled the hemorrhage.

Remarks.—About twenty years ago, a surgeon of this city, the late Dr. Stephen Rogers, was a vigorous advocate for the performance of laparotomy in cases of internal hemorrhage due to rupture of the oviduct, but the profession at that time was not prepared to accept the proposition. The great advances that have been made in abdominal surgery since then have paved the way, and although I am not aware that the operation has been performed, I can state advisedly that the matter has been much debated, and that the views of Dr. Rogers are now generally approved. Grailey Hewitt says, in the last edition of his work on the pathology, diagnosis, and treatment of the diseases of women:

"In cases of Fallopian pregnancy, if it were possible to make an exact diagnosis of these cases of rupture and hemorrhage during life, it would undoubtedly be better to open the abdomen, and endeavor to secure the bleeding vessels than to allow the patient to die of hemorrhage. No operation of the kind has ever been attempted, but the subject has formed matter of discussion on more than one occasion at the meetings of the Obstetrical Society of London."

Lawson Tait, in his recent book *On the Diseases of the Ovaries*, says:

"I have very little doubt, however, that many of these cases would be saved by prompt action. The difficulty is, of course, in the diagnosis, some certainty of which is requisite before an abdominal section can be performed. I have twice been on the point of performing abdominal section on account of suspected rupture of a Fallopian tube, and have been prevented by scruples as to the correctness of the diagnosis. In both cases, post-mortem abdominal section showed that the suspicion was correct, and I believe both of these patients might have been saved."

Other authorities might be quoted, endorsing the opinions thus expressed, but I think these will suffice to show the general conclusions of those most familiar with the subject. In the case which forms the basis of this communication, the subject of transfusion was entertained, and rejected. Previous to the operation, I could only conceive that it would have been harmful where we have to deal with concealed hemorrhage, and there are such doubts as to its precise location and character as may render it questionable whether we are warranted in adding the shock of an operation to that already existing. The issue of the case will dedend upon the success with which we can keep the circulation at a minimum consistent with life. If we resort to means which raise arterial tension, we shall interfere with the conservative progress which we initiate with more or less success in the application of hemostatics, and certainly cause further leakage from partially occluded vessels. In this case, after the blood-supply was cut off by the application of ligatures, I had faith in the natural robustness of the patient, and though she hovered between life and death for twenty-four hours, the condition of the pulse after that time and up to within a few hours of death justified the confidence I had placed in those resources. The heart failure, which occurred more than forty hours after the bleeding was arrested, I attributed to shock, which I did not think could be beneficially influenced by transfusion, and, consequently, did not feel warranted in resorting to a means that I certainly do not regard as free from danger.

ANCHYLOSIS OF KNEE IN FLEXED POSITION; RESECTION; WIRING BONES TOGETHER IN A STRAIGHT POSITION; GANGRENE OF LEG AND FOOT; AMPUTATION OF THIGH; DEATH.

DR. A. C. POST presented a specimen, accompanied by the following history: A. P., mulatto, ætatis 38, left knee anchylosed in a flexed position at an angle of 60°. At the age of eleven years, he cut his knee with an axe, and the anchylosis was the result of the inflammation which followed the injury.

July 5, 1883, I operated on him by making a transverse incision over the greatest convexity of the knee, the incision dividing the integument over the anterior and lateral parts to the extent of three-quarters of the circumference of the limb. Several small arteries were cut and tied. I then with a saw removed a large wedge-shaped segment of the bone, and afterwards several smaller fragments. I also divided the tendon of the biceps, semitendinosus, semimembranosus, gracilis, and sartorius, after which I was able to bring the bony surfaces in contact, in an extended position of the limb. Considerable resistance was offered by the popliteal nerve, which finally yielded without rupture. I then drilled four holes obliquely through each segment of the bone, through which I inserted flexible iron wires, which I twisted so as to keep the bones in position. After this, I applied an iron splint along the posterior surface of the limb, and one on each lateral surface. The lateral splints were each bent at four right angles, so as to leave an open surface on each side of the knee. Plaster-of-Paris bandages were then applied over the thigh and leg, holding the splints in position, but leaving a space of more than six inches over the knee uncovered, so as to give free access to the wound. The wound was washed with carbolic acid, 1 to 40, and the integuments were brought together with sutures, except at the posterior part, where a large, open space was left for drainage. The parts about the wound were then covered with lint, wet with carbolic acid, 1 to 40. The operation was completed at about seven P.M. At about eleven P.M., I was summoned to the patient, on account of hemorrhage. I found that there had been considerable oozing of venous blood. I had the limb elevated; applied compresses over the wound, secured by a roller bandage, and suspended the limb to the ceiling, with the foot elevated about fifteen inches above the bed.

July 6.—There has been no return of bleeding. The patient has been much more comfortable since the suspension of the limb. As his circulation was very languid, and he had been accustomed to the free use of alcoholic drinks, I directed an ounce of whiskey once in three hours, in the form of eggnog or of milk-punch.

7th.—He has had frequent vomiting, and has scarcely retained anything on his stomach. A sinapism was directed to be applied over the epigastrium, and a scruple of calomel was administered, after which porter and lime-water were directed to be given, a half ounce of each every hour. Rectal alimentation was ordered, with stimulants.

8th.—Vomiting has nearly ceased. His pulse has a little more force, but is still feeble. The integument about the heel has a livid appearance, but has not lost its sensibility. The lower flap of integument in front of the knee is quite hard, but the upper flap is of a good color.

9th.—The leg and foot are decidedly gangrenous. I amputated the thigh about eleven centimetres above where the bone had been divided in the resection, leaving a large anterior flap.

10th.—The patient has not rallied well since the amputation. The pulse is feeble and the surface cold. He continued to sink, and died in the afternoon. He had taken stimulants freely, but very little food.

The fatal result in this case was largely to be attributed to the previous habits of the patient.

TUBERCULAR ORCHITIS.

DR. A. G. GERSTER presented a specimen with the following history. It was a testicle removed from a man forty-one years of age, and was the seat of tubercular orchitis. A diagnosis was made before any fistula formed, from the fact that an acute orchitis, which resulted from injury, had never completely subsided. The patient, two or three weeks before Dr. Gerster saw him, had chills and night sweats, and the spermatic cord became infiltrated and indurated close up to the internal ring. Castration was performed and the patient did well. When the tunica vaginalis was opened the tissues presented an appearance similar to that seen in fungous condition of the joints, but the centre of the testicle contained a large tubercular focus.

The Society then proceeded to the transaction of miscellaneous business.

NEWS ITEMS.

BOSTON.

(From our Special Correspondent.)

The Children's Hospital.—A description of the new building for the Children's Hospital of this city, completed one year ago, was given at that time in The Medical News. It will be remembered that the building, as it then stood, was composed of the central main structure and the western wing. The plans of the architect include an eastern wing, which has not yet been added, but will be so soon as needed and the means allow. The large dwelling-house formerly occupied by this charity had accommodations for thirty patients. The new hospital, as now arranged, can accommodate sixty patients. The number treated during the past year has been much larger than ever before, and it is for this reason that the hospital management has just issued an appeal for more funds. If the public fails to respond, the alternative pronounced is either that the use of the hospital must be limited to a few patients or be closed.

This rather startling statement undoubtedly will arouse the friends of the institution to the necessary effort, for the charity is one which cannot be spared. The appeal calls for funds, not only for this year, but for several years to come. The invested funds of the hospital pay an income of $5000. The income necessary for the proper conduct of the hospital is $16,000. The need, therefore, is about $12,000 additional yearly. The names attached to the appeal are so influential that it is thought a generous response will be made.

HARTFORD.

(From our Special Correspondent.)

Typhoid Fever in Connecticut.—There has been during the last few years a very marked increase in the prevalence of typhoid fever in this State. From 1872, when malarial diseases had become prevalent over a wide area, until 1880, there was a very decided decrease, in fact, a total disappearance of the disease in many places, so that the percentage of deaths, from all reported causes, fell from an average of about 4.54 to 1.77 in 1879. Since then, there has been a rapid increase in the number of cases of typhoid fever. This has been very noticeable from the fact that for a long period so few cases were seen. Even where malarial diseases did not exist, there was a decrease in the prevalence of typhoid fever. This is clearly shown in the table on pages 77–82 of the fifth report of the State Board of Health of Connecticut, also in the one on page 110 concerning typhoid fever since there has been a registration law in the State. Since 1882, the disease has about reached its former rank as one of the ten principal causes of death, and not the lowest place among them either.

In many places outside of Connecticut, there have been during the last two years epidemics of typhoid fever in Paris, London, New York, Providence, and elsewhere, so that it would appear that there were some general conditions favorable to the development of typhoid fever, in addition to the local unsanitary conditions that might determine the place where the epidemic should appear, or else a general movement in obedience to some law of periodicity not yet generally understood.

Whatever may be the causes, there has been a very decided increase in the number of cases of typhoid fever. There have been no extensive epidemics—that in *Waterbury* has been the most marked. There the upheaval of the streets in laying a system of sewer pipes for the city, and the long-continued dry weather, favoring all unhealthy telluric influences, as well as lowering the reservoirs and wells, furnished the only general local conditions favorable to the disease.

Last autumn there was quite a large number of cases in *Hartford*, with ten deaths in September.

This year there is more typhoid fever than there has been for some years in *New Haven*, but no epidemic.

Had there been the usual amount of typhoid fever from year to year, the number of cases would not attract so much attention. There have been many exaggerated reports, and other diseases have been confounded with typhoid fever. This is the case in regard to *Forestville*, where the closing of the schools to prevent the spread of diphtheria, has been stated to be due to an epidemic of typhoid fever, of which there have been but three cases, as far as I can learn. So in *New Haven*, there have been several cases of typhoid fever among the students, but one or two of which were contracted at the college, or were among persons occupying rooms at the college. The fact that typhoid fever is unusually prevalent in the city, has, no doubt, led to the mistaken idea that there has been a large number of cases at the college.

From reports from other places, it would appear that there have been some general conditions during the last few months favorable to the development of typhoid fever, and that there has not only been an unusual prevalence in localities where local unsanitary conditions favored its development, but also here and there epidemics of greater or less severity.

In this State where there had heretofore been supposed to be such an antagonism between the diseases that when one appeared the other must of necessity disappear, we have of late seen side by side typhoid fever and tertian ague, and, in fact, typhoid fever in one house, and typho-malarial fever in the next, or some other variety of malarial disease. While we hope that this return of typhoid fever is an indication that malarial diseases are about to leave us, and, in fact, a noticeable decrease in their frequency and in the general tendency towards periodicity in all diseases strengthens this hope. There is no such antagonism between malaria and typhoid that excludes the one if the other be present.

CHICAGO.

(From our Special Correspondent.)

St. Luke's Hospital.—The new building of St. Luke's Hospital, which, it was expected, would be ready for occupancy this winter, it is now announced cannot be completed before next June. There have been expended already $70,000, and nearly as much more is asked for. In the old building the institution, during the past year, cared for upwards of eighteen hundred patients both in and out of the wards. This hospital is the work of the Protestant Episcopal Church, and draws most of its support from that order. Six beds have been endowed at $4000 each, and eighteen are supported by annual payments of $300 each. This is certainly a fairer basis for endowment of beds in hospitals than that adopted by our "Relief and Aid Society" after the great fire. The Society endowed nearly or quite one hundred beds in the various hospitals of the city, from funds donated at the time of the fire, at $1000 each. Of course the Society does not keep these beds full, even in times of epidemics. If they did, it would ruin any one of the hospitals.

ST. LOUIS.

(From our Special Correspondent.)

A New-Code Society to be Formed.—A new medical society is being formed consisting of a few dissatisfied members of the St. Louis Medical Society, headed by the gentleman who resigned because he was unwilling to accede to the rules of the Association. As announced under his signature in the various daily papers, this new growth, to be called the Pathological Society, is to consist only of men who had already attained a high degree of culture before they began their medical studies. "In the matter of advertising, both in the daily and medical journals, the most liberal principles will govern 'this new society,' and," this modest annunciator continues, "it will league with the New York Academy of Medicine, the Pathological Society of Philadelphia, and other similar associations, for purposes of united action." *Nous voila !*

WASHINGTON.

(*From our Special Correspondent.*)

The National Board of Health, which met in Washington, D. C., on the 5th inst., decided to present its claims to Congress in a request for the reënactment of the Quarantine Bill of June 2, 1879, without the penalty clauses in said bill, it having been found to be impracticable to enforce the penalties.

No other business of importance was transacted. Dr. H. A Johnson, of Chicago, a member of the Board, signified his intention to resign before the next meeting.

CANADA.

(*From our Special Correspondent.*)

Actinomycosis in Canadian Cattle.—In the morbid anatomy demonstrations on November 24 and December 1, at McGill College, Dr. Osler showed five specimens of this disease, which he stated appeared to be very common in Canadian herds. During the past summer he had with Mr. Clement, V. S. Assistant Government Inspector of Stock, seen many cases among the animals inspected prior to shipping. As the Department of Agriculture had no orders regarding the disease, the animals were not condemned. The specimens shown were two jaws in an advanced, and one in an early stage of the disease, and two of throat and contiguous lymph glands. In only one of the animals had the growth produced much constitutional disturbance, as shown by the rough coat and emaciated condition. The characteristic fungus actinomyces was present in each instance. In cattle the affection is local, rarely attacking the internal organs, and does not seem to disturb the general health until the jaw tumor interferes seriously with mastication. It is inoculable, but probably not directly contagious. The origin and life history of the fungus still remain dark. Additional interest pertains to the disease from the fact that it occurs in man, in whom some twenty cases have been described; all in Germany. The human affection is more severe, metastasis is common, and it is possible that the *actinomyces hominis* may be a separate variety. It is a significant fact that Johne inoculated without success two hogs and a calf with fresh material from man. A question of sanitary importance arises in connection with the flesh of animals so affected. Is it fit for consumption? Certainly not when the general health of the animal appears to have suffered in consequence; but when the disease is local and not advanced, the animal may be in excellent condition, as was the case with many of the large-jawed oxen sent from this port to England during the past summer. Cattle-dealers, however, seem to know that the disease damages the animal. Principal McLachran, of the Montreal Veterinary College, informs me that in the purchase of cattle in the western ranches, the stipulation "no big-jawed animals" is not infrequently made.

Leprosy in New Brunswick.—During the past summer Dr. Graham, of Toronto, spent ten days at Tracadie, and made a thorough investigation into the history of leprosy in this settlement. His results have appeared in the October and November numbers of the *Canada Medical and Surgical Journal.* In the latter genealogical charts are given of the chief families affected.

The Medical Schools.—The business depression throughout the country has had the usual effect of forcing a larger number of young men into the professions. The attendance of students at the medical schools is considerably above the average. The total number last session at all the schools, was not quite seven hundred; this year it is estimated, from the returns available, that the number reaches eight hundred. McGill and Trinity have each over two hundred; and the Toronto School numbers over seventy new entries.

A new school has been opened at Winnipeg, Man.

The papal delegate Monseignor Smeulders has been busy taking evidence in the Laval-Victoria case. He has, it is understood, full power to settle the differences between these rival schools.

The British Association for the Advancement of Science.—Notice has just been received of the appointment of the local Vice-Presidents and Secretaries of sections for the meeting which takes place in Montreal on the 27th of August next. Over five hundred members have signified their intention to come, and among them will be many of the leading scientific men in the profession.

La Société d'Hygiene du Province de Quebec.—An association with this title has been organized by the French Canadian Physicians. Dr. Tafard, of Montreal, is the President.

LONDON.

(*From our Special Correspondent.*)

Myxœdema.—On Friday evening, November 23d, the subject which occupied nearly the whole of the time of the meeting of the Clinical Society of London was "Myxœdema." The discussion was excited by the narration and exhibition of a well-marked case of the disease in a middle-aged woman (fifty years) by Dr. Drewitt. After a short pause, during which it was evident that the members awaited the introduction of the debate by Sir William Gull, the work began. This distinguished physician had nothing new to impart, and merely gave a brief sketch of the main features of the disease, as well as a short excursus into the possible pathology of the affection. The course of the malady was described as progressively, but slowly, onward to a fatal termination. In the way of treatment Sir William said that he knew of nothing which could stay its progress.

Extirpation of the Thyroid.—Dr. Felix Sémon read a brief communication comprising some account of certain results, which Prof. Kocher had noticed as ensuing on extirpation of the thyroid gland, and which fairly took the majority, if not the whole, of the audience by surprise—for no one present seemed to have heard of these remarkable statistics. It appears that Prof. Kocher, of Berne, has done something like one hundred extirpations (partial and complete) of the thyroid body. In a large number of the cases in which total extirpation had been practised a train of symptoms had come on insidiously, after considerable periods of time had elapsed since the operation. The patients, previously bright and active, tardily became dull and incapable of exertion; swellings of different parts of the body, but notably of the eyelids, came and went before making a permanent appearance—in fact a concourse of symptoms presented themselves, which tally very closely with the signs and phenomena observed in myxœdema. Many of the principal clinical physicians present at the meeting took part in the debate, but there were only three features which could be singled out as representative of the evening's work. Sir Andrew Clarke, the President, and others had had cases under their care in which the clinical course of the disease was by no means progressively worse. Indeed, one or two of the patients expressed themselves as perfectly well, but the eye of the physician was still able to see the remnants of the malady in their faces and actions. So that in the progress of the disease a new or, at all events, not hitherto well-known observation was brought to light, *i. e.*, the fluctuating course of the affection, and possible termination in nearly natural health.

Sir Andrew Clark also said that the amount of urea discharged per diem was sometimes in excess and sometimes below the average daily discharge. On this point Dr. Burney Yeo remarked that he had observed similar fluctuations in the amount of urea daily discharged in altogether different kinds of disease.

Dr. Radcliffe Crocker went further, and said that even in apparent health there was nothing which could with certainty be called an average daily amount of urea excretion. This statement was made from the results of experiments on dogs subjected to precise conditions. The last incident on which stress was thrown was the apparently great improvement in the state of the patients which could be effected by the internal use of jaborandi and the subcutaneous injection of its alkaloid (pilocarpin). Half drachm doses of infusion of jaborandi or one-twelfth of a grain to one-quarter of a grain doses of the nitrate of pilocarpin, given by the mouth or hypodermically, respectively, were stated to produce profuse diaphoresis and remarkable improvement of the powers and faculties of the patient.

The New Jersey Sanitary Association held its Ninth Annual Meeting at the State House, Trenton, on Thursday and Friday, December 6th and 7th. The address of the President, J. C. Bayles, C. E., of Orange, N. J., showed the methods by which sanitary information can be popularized. He objected to much of the floating and misleading sanitary items of newspapers as being from sources not reliable, although often good in intent. Sanitary lectures and tracts, and local sanitary associations were earnestly urged. The address well enforced the radical necessity of accurate sanitary knowledge for physicians and in the interests of the public and of the State. A paper by Dr. T. W. Harvey, of Orange, sustained the paludal view of *Marsh Miasm*, and also gave some personal experiences as to the power of well water from marshy lands to convey the malarial poison. Apropos to malaria, Dr. H. P. Godfrey, of Camden, read an elaborate essay on germs, and the value of our present knowledge as to them.

A paper by Prof. A. R. Leeds, on *The Agencies, Natural and Artificial, Affecting the Purity of the Passaic River below Paterson*, gave rise to an animated discussion, which at length was transferred to the Delaware and Philadelphia. Dr. Leeds maintains the power of some rivers, with due space between the reception of fresh sewage and the place of securing potable water, to dispose of all sewage.

Domestic Wells and Cisterns, and Their Best Method of Construction, was well presented by Dr. I. N. Pinkham, of Montclair. The contention was that most open wells are unsafe and must go, and be substituted by the driven well, or the common well closely cemented and arched about six feet below ground. Well constructed cisterns and the use of cistern water were also commended.

Appliances for Raising and Distributing Water were illustrated by Prof. C. L. Brackett, of Princeton, in a most interesting manner. He showed how electrical power, transferred from one dynamo machine to others, could overcome gravity, and how water be brought for use or removed for drainage from inland cities surrounded by hills, like Mexico. He also showed how sewage in the course of its distribution, as to a river, could, on the way, be greatly purified by small air-pipes all along the course, just touching the sewer stream, so as to secure the effect of the adhesion of air to the flowing liquid and consequent mixture and aeration.

Engineer J. J. R. Lewes discussed *Methods of Sewage Disposal without Discharge into Streams.* He agreed with J. Bailey Denton as to the power of soils to deal with sewage chiefly because of the access of air in the soil. He spoke of the various chemicals which will precipitate organic matter, and thought that a new plan of mixing this material with saw-dust and then using it for the fires under the boilers of the works promised success.

Prof. George H. Cook, of New Brunswick, discussed the various methods of *Filtration.* While recognizing most filters as removing only matter in suspension, he showed the importance of this. Beside, some filters, such as those of gravel, sand, and charcoal, give access to air and help oxidation. The value of alum as a precipitant was shown, and doubts expressed whether in moderate quantities there was any objection to its use.

School Hygiene was ably presented by Prof. H. B. Pierce, of New Brunswick; James Green, of Long Branch; and J. Madison Watson, of Elizabeth. Instead of generalizing, these papers proposed a model school-room, and model methods of applying physical exercises. A lively discussion was had over the present recess system, Prof. Pierce claiming that, with calisthenics, and with permission to children to go out as occasion might require, there was no need for the fifteen-minute recess. Others advocated a five-minute recess each hour or hour and a half.

The meeting brought together about fifty representative men from various parts of the State, besides a small local attendance. All felt well repaid by the excellent character of the papers and most of the discussions.

Yellow Fever in Mexico still exists in several towns, Manzanillo and Acapulco being the principal sufferers. Assistant Surgeon Main, U.S.M.H.S., stationed at Brownsville, Texas, states that the Mexicans are more alarmed at the appearance of scarlet fever, which is now prevailing as an epidemic in Puebla, than of yellow fever, as its mortality or sequelæ have proved more disastrous. He reports that quarantine restrictions were raised at Brownsville and Matamoras on the 15th of November, having been merely a quarantine of observation of late. He also states that a large lagoon which nearly surrounded the city of Matamoras has recently been drained, temporarily adding much to the unhealthfulness of the inhabitants, though of great importance for the future sanitary condition of the city.

The Sanitary Convention at London, Ontario.—The Province of Ontario, Canada, has just had a Sanitary Convention, at London, which was well attended. Typhoid fever has prevailed to an unusual extent in the province. Malaria has excited much attention the last two or three years. A paper on the typhoid plant quite took it for granted that its botany was complete. Prof. Arnott, of London, seemed quite in favor of a mill-dam war. Sixteen papers on various subjects occupied two days, and gave rise to much discussion.

The Provincial Asylum of Ontario, near London, has eight hundred and ninety nine inmates. In addition to a very large building, it has three cottages, and so combines the two systems. For the last two years the non-restraint method has been practised, with most excellent results. The resident physicians, once opposed to it, are now warm in its advocacy.

International Health Exhibition in 1884.—At the close of the International Fisheries Exhibition, His Royal Highness the Prince of Wales announced his intention of arranging to hold in the same buildings an International Exhibition of Food, Dress, Habitations, and Educational Appliances. This exhibition will be held on a great scale, and will, it is understood, be organized so as to embrace and bring into prominence illustrations of all that most affect the welfare of the people, not forgetting the poorer classes.

The New England Medical Register.—A new edition of the Register, revised by Dr. Francis Brown, will be published shortly.

Dr. William B. Platt on Saturday, November 24, obtained by examination the degree of Fellow of the Royal College of Surgeons of England. He is said to be the first native-born citizen of the United States who has obtained this degree. There were seventeen candidates, and nine succeeded in passing the examination.

Busts of von Langenbeck, Gräfe, and Dieffenbach, have been recently placed in the surgical amphitheatre of the University of Berlin.

Professor Johann Schnitzler.—The Emperor of Germany has recently appointed Dr. Schnitzler as Professor Extraordinary in the University of Vienna.

Dr. Markbreiter's Jubilee.—On November 4, Dr. Philip Markbreiter celebrated his fiftieth doctorate jubilee. He was the founder of the *Wiener Medizinal-Halle*, which subsequently became the *Wiener Medizinische Presse*, now current. He was presented with congratulatory addresses by his Vienna colleagues.

Schultze's Jubilee.—On November 1st the Twenty-fifth Jubilee of Prof. B. Schultze, as Professor and Director of the Gynecological Clinic, was celebrated in Jena. His colleagues and pupils presented him with a memorial album, and in the evening a reception was given to him.

Biographical Lexicon of Physicians of all Times and Peoples.—The first two fasciculi of this work, edited by Prof. A. Hirsch, with the assistance of an able corps of coeditors, have just appeared in Germany.

Real-Encyklopädie der Gesammten Heilkunde.—This valuable work, under the editorship of Professor Eulenburg, has just been completed.

The City of Vienna, Austria, is not a very healthy place for consumptives, judging from the weekly reports: For week ending October 27th, there were eighty-two deaths from consumption and thirty-six deaths from acute lung diseases in that city, and the week previous a still greater mortality.

Concerted Action by State Boards of Health.—There has been a growing conviction among leading sanitarians intrusted with the official execution of practical health measures, that while the work of the American Public Health Association is of inestimable value in promoting the interests of sanitary science and sanitary reform, there is a constantly increasing need for an annual conference of State and other health officials in regard to practical affairs of their everyday work, some part of which work cannot profitably be discussed in a public meeting consisting largely of persons not familiar with its details.

After due consideration, a meeting of representatives of State boards was held at Detroit, during the recent meeting of the American Public Health Association, at which, after discussion, it was decided to call a meeting of the secretaries or other representatives of all State Boards of Health, in Washington, during May, 1884, for the purposes mentioned, and with the view of organizing a section devoted to State Board work in the present Association, or the formation of a permanent separate organization especially adapted to the needs of State Boards of Health. Drs. Henry B. Baker, of Michigan, and J. N. McCormack, of Kentucky, were appointed a committee to confer with and secure the coöperation of all the State Boards in fulfilling the object of the meeting, and Drs. C. W. Chamberlain, of Connecticut, J. E. Reeves, of West Virginia, and Stephen Smith, of New York, were appointed a Committee on Organization, to report at the meeting in May. The American Medical Association meets in Washington in May; and another reason for holding the meeting in Washington is that the representatives of the State Boards may also have an opportunity for conferring with the Senators and Representatives in Congress from their respective States, in regard to national sanitary legislation. It would seem that whenever the health authorities of all the States shall meet, discuss, and agree upon the course they will pursue with respect to yellow fever, cholera, smallpox, or any disease which endangers public health, without regard to State lines or borders, and whenever all State Boards shall act in concert, considerable progress will have been made in solving the problem of what are the best methods for national action in regard to inter-State and maritime quarantine or inspection and disinfection, as well as in the practical control of epidemic diseases within the several States of this country.

Health in Michigan.—Reports to the State Board of Health, for the week ending December 1, 1883, indicate that bronchitis, remittent fever, inflammation of kidney, and puerperal fever have increased, and that typhoid fever, intermittent fever, and dysentery have decreased in area of prevalence.

Compared with the average for the month of November in the preceding six years, remittent fever, consumption, typho-malarial fever, intermittent fever, diphtheria, bronchitis, and typhoid fever were less prevalent in November, 1883.

Including reports by regular observers and others, diphtheria was reported present during the week ending December 1, and since, at seventeen places; scarlet fever at eighteen places; and measles at eight places.

The Medical News *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the News *should be addressed to No. 1004 Walnut Street, Philadelphia.*

ORIGINAL LECTURES.

INJURIES OF THE HEAD.

A Clinical Lecture,
Delivered at the Hospital of the University of Pennsylvania.

By JOHN ASHHURST, Jr., M.D.,
PROFESSOR OF CLINICAL SURGERY.

Gentlemen: There are in the Hospital at present three cases of injury of the head to which I will call your attention to-day. The subject of head injuries is one of great interest and also of a great deal of importance. With the present cases I will endeavor to illustrate several more or less obscure conditions, and will try to give you a clearer view of their pathology and treatment than you would be able to obtain from your text-books.

Our first case is that of a man who yesterday morning fell from the steps of the Chestnut Street bridge. Immediately after the accident he was brought to the hospital, where, on examination, we found that he had a very severe wound of the scalp. The wound was crescentic or horseshoe-shaped, and the tissues being entirely separated, the flap thus formed was turned over the left side of the head, leaving a considerable portion of bone denuded. We could, however, detect no fracture, though whether there was present or not a fracture of the base we could not positively tell, though as no fissure could be detected passing up into the vault, we thought not, since these fissures almost invariably accompany fracture of the base. In addition to this wound, our patient presented a very interesting constitutional condition, namely, that of shock, from which he was suffering on entering the hospital. Dr. Martin took his temperature when he was admitted and found it considerably below the normal, being but 96° F. In addition to this, there was present another constitutional condition depending on a local trouble, the result of violence done to the brain; the condition known as cerebral concussion.

These conditions of shock and concussion are very often confounded together. Sometimes we see the statement that shock is particularly met with in cases of head-injury; it may, however, not only be found in connection with head injuries, but may be met with in injuries of any part of the body. It is a general condition of the whole system depending on any very severe lesion—of the arm, the leg, the head of course, or abdomen, and many of the worst cases are those of abdominal injury. The symptoms are no doubt manifested through the nervous system, but this is no reason for saying that it is a condition depending entirely on nerve structures. The condition involves all the structures of the body, the digestive organs, the lungs, and the heart as well as the nerves. Concussion of the brain, on the other hand, is exclusively an affection of the brain. We may have other varieties of concussion; for instance, we may have concussion of the nervous centres in the abdominal cavity, more particularly of the solar plexus, which is sometimes occasioned by abdominal injuries. Besides this there is also a condition of the lungs sometimes spoken of as concussion. It is a curious condition, met with where the chest has been violently squeezed, and where, as a result of this, the respiratory functions are almost abolished, the lung not expanding and contracting with the efforts at respiration. It generally passes off in two or three hours. For want of a better name, it has been termed concussion of the lung. It is a condition somewhat analogous to concussion of the brain, but the fact that this term has been used to designate several different conditions has been the source of considerable confusion to the student as well as to the medical practitioner.

The meaning of the term concussion is a shaking. In fact, however, concussion is usually more than a shaking, as we find in every case when there is an opportunity for examination, some lesion; there are no doubt cases where the lesion might not be perceptible, but this does not disprove the presence of a lesion. Almost every one has, at some time, experienced the symptoms of concussion, at least in a mild degree, as the result of some fall or blow which has stunned him; the resulting loss of consciousness, however, passing off in a few seconds. In these conditions there is probably a stasis of the capillary circulation with temporary interruption of cerebral function. Where concussion has a fatal termination it is always attended with definite lesions. In these cases we have a characteristic lesion known as punctiform hemorrhage; a peculiar form of hemorrhage which is different from that met with where the sinuses are ruptured, as also from the hemorrhage found in apoplexy; it is a hemorrhage which has taken place from the minute arteries or capillaries in the form of minute spots or dots; it is distinguished from simple congestion by the fact that we can pick out the points, when we find that they are absolutely clots.

The dividing line between compression and concussion, in books, is frequently very sharply drawn, but it is a difference in degree rather than in kind. We meet with the same lesions in compression as we have in concussion, but the lesions are more severe. In concussion we may also have more profuse hemorrhage, as well as slight laceration of the brain, but these lesions are in most cases repaired in a very short time, and therefore leave no marks perceptible after death. Where, however, death occurs from concussion, there is nearly always some laceration, together with contusion of the brain. Where the injury is carried to a still further extent, we may have compression of the brain. Cases of compression and concussion run into each other, so that some are on the border-line, and no distinction can be made either in the symptoms or as concerns the lesion. The symptoms of the first stage of concussion are relaxation of all the tissues of the body, without, however, necessarily any depression of temperature; there is not an entire obscuration of the mental faculties, but the patient presents rather a slowness or weakness in performing mental actions. The pupils are variable; sometimes dilated, sometimes contracted, sometimes dilatation of one and contraction of the other, or they may respond differently to light; both may be movable, but irregularly movable. There is no very valuable information to be derived from the state of the pupils, though the older writers laid great stress upon their condition, saying that they were dilated in concussion and contracted in compression. When compression is present from any cause, we have complete cessation of the mental functions. The compression may come from hemorrhagic clots as in apoplexy, from bleeding from a ruptured sinus, from a depressed fracture, or from a foreign body in the brain, as in gunshot wounds, or it may be occasioned by a secondary condition—the effusion of serum into the brain, which is known as serous apoplexy, or the formation of an abscess.

The condition of the brain itself in compression is not what probably you imagine it to be. The brain itself is really in a condition of anæmia, contrary to the popular idea, which holds that the brain is very full of blood. There may, of course, be a congestion of the brain, which may ultimately lead to compression; but whenever compression is present, though the vessels may be gorged with blood, the brain-substance itself is in a state of anæmia.

In this case, there are no symptoms of compression; nor is the concussion of such serious aspect as to indicate definite, gross lesion of the brain. When the patient came into the hospital, he was to some degree sensible; he was able to answer questions; he was able to tell how he was hurt, and he made some resisting movements when his head was dressed. Besides this, his position was characteristic of the second stage of concussion—that stage which has been described by Mr. Erichsen as cerebral irritation. He was curled up in bed, lying on his side, not relaxed: this posture is characteristic of the condition in question. The term cerebral irritation seems to me an unnecessary one, as the condition is really but the second stage of concussion. Our patient, then, was lying on his side, curled up, with his members flexed. His mental condition also was characteristic: he was irritable, drawing himself away when touched. This second stage of concussion may last from a few hours to several days, and then gives way to the third stage, when there may be gradual improvement, the third stage terminating in convalescence, or, when the injury has been more serious, we may have a condition of weak-mindedness, with increasing fatuity, and ultimately cerebral softening and death.

When our patient came into the second stage of concussion, he was not in the second stage of shock. As the second stage of shock, we have reaction, often running into a condition of fever, with a form of delirium known as traumatic delirium. This patient passed into the second stage of shock at a later period than that at which he passed into the second stage of concussion. His temperature was not above normal for four or five hours after he had passed from the first to the second stage of concussion. This morning his temperature is nearly normal, while last night it was slightly above normal. He is not going to have a very severe attack of traumatic fever.

He is not entirely rational; there is still some mental obfuscation present; this may, however, be due to the use of alcohol, under the influence of which he appears to have been when the accident occurred. This fact is in these cases always an unknown quantity.

He is doing very well. There was a little hemorrhage from the scalp wound, but this was not very great. It was dressed with the gauze and collodion dressing. We used narrow gauze strips, which have the advantage over strips of adhesive plaster, that they allow the dressing to remain more permanently; they stick better; and have the additional advantage that, by not putting the collodion over the line of the wound, the effused fluids can find their way out without disturbing the dressing. The wound, as you see, began at the median line of the occiput and swept around irregularly to the left temple, being five or six inches long. The hemorrhage occasioned by the scalp wound was controlled by pressure, applied by means of a compress and bandage. Pressure will always control hemorrhage from the scalp. The use of ligatures is not desirable in these cases, not as being dangerous, but simply as being unnecessary; they are also difficult to apply and apt to become detached. The use of sutures, again, cannot be considered dangerous, but it is unnecessary. The older writers considered that, in using ligatures and sutures in the scalp, there was great risk of erysipelas occurring. This I do not consider to be the case; but as we should always avoid doing too much as well as too little, and as the gauze dressing and the simple compress and bandage are sufficient, I think it useless to apply either ligature or suture. Scalp wounds usually unite by adhesion, and we seldom have sloughing. In any scalp wound, no matter how much torn or bruised the tissues may be, we should be careful to keep all the parts and put them into position, and thus we will seldom have any marked loss of substance.

This case has, I hope, served to show you the difference between shock and concussion of the brain, as you see that both or either may be present and run its course without regard to the other; it may also serve to illustrate what I have said in regard to the identity in some respects, and the difference in others, of cerebral concussion and compression.

I have yet two other cases of head injury to show you. This man has been in the hospital since the 13th of September; nearly a month. He was injured while riding on the top of a railroad car, striking his head in passing under the bridge at Paoli. He had a small scalp wound; and, when admitted, there was noticed a peculiarity about his vision—he had diplopia or double vision. After a time it became evident that the patient was suffering from a severe injury of the head, and soon there was noticed ptosis of the left eye, which has now passed off to a great extent, so that it is now rather the right eye which appears prominent, than the left which appears closed. In addition to this, there was slight facial paralysis of the left side, the mouth being drawn to the right. The tongue did not appear to be affected; had it been so, it would have been protruded to the paralyzed side, as the muscles of the tongue are pushing, not pulling, muscles. The paralysis, being all on the left side of the head, pointed to injury of the right side of the brain. We have no positive evidence here of fracture of the skull; but in some of the worst cases of cerebral injury, such as those which have been called "traumatic apoplexy," we have no fracture. This fact of the occurrence of the most severe brain injuries without fracture may be illustrated by a familiar fact, often noticed before the days of the hunting-case watch, that, when the watch sustained a fall, if the crystal broke the mainspring escaped, whereas if the crystal was not broken then the mainspring broke. With the hunting-case, the cover will fly open, and both crystal and spring may be unhurt. The force must be expended somewhere, if not on the outside, then on the inside. Fracture of the base usually results from force applied to the vault—fracture by counter-stroke. The skull is oval, and when force is applied to one surface, having a certain amount of elasticity, the oval changes its shape; the short axis lengthens and the long axis is shortened, and then the skull is thrown into a state of oscillation or vibration; and according to physical laws, a force being applied to the summit, the base of the oval is drawn in by all the force being here concentrated. If the bone is but ordinarily strong and the force sufficiently great, the skull is fractured, and the brain itself may escape with comparatively little injury. If the bone is strong and escapes fracture, then the vibrations are transmitted to the brain itself, and thus we may have a most severe injury produced.

In this case we had evidence of deep-seated injury of the brain. We may have facial paralysis from a blow on the side of the face, affecting the facial nerve or portio dura, but here we had a combination of nerve lesions. The double vision was probably due to disturbance of the optic nerve or tract, and when, in addition to this, we had ptosis or paralysis of the levator palpebræ muscle, which is supplied by the oculomotor nerve, and facial paralysis besides, it is at least most probable that the lesion, involving three distinct nerves, was not of peripheral origin, but centric. Apart from the nervous disturbances, there was no evidence of fracture in this case.

If there is fracture of the middle fossa of the skull, we nearly always have hemorrhage from the ear; we may, of course, have such hemorrhage without a fracture, but where there is profuse hemorrhage continued for some time, and after it ceases, a watery flow, then fracture is very probable, though even then not certain. In almost all these cases the watery fluid is cerebro-spinal fluid. Cases also are on record where there have been fissures in the skull allowing the escape of this fluid. In fractures of the anterior fossa, blood, and afterwards watery fluid, may escape through the nose. In fracture of the anterior fossa there is nasal hemorrhage, but, of course, the hemorrhage may occur from other causes. Again, in fractures of the anterior part of the skull, we have another characteristic symptom, namely, intra-orbital ecchymosis or subconjunctival hemorrhage. This is to be distinguished from the ecchymosis caused by a blow—the "black eye"—by the fact that it does not come on immediately, and is not preceded by palpebral ecchymosis. We may have ecchymosis which, beginning in the eyelid, goes to the conjunctiva in a few days. But if we have subconjunctival hemorrhage coming on two or three days after an injury of the head, and before there has been hemorrhage into the eyelid, the blood has probably come through a fissure of the orbit from the brain. It may, however, be due to a rupture of a vessel in the orbit itself, but then it usually comes on at an earlier period. We have here nothing of this kind, and we have no reason for thinking that there has been any fracture, though we have strong reasons for believing that there has been an injury of the brain itself.

We probably have here to deal with some slight laceration of the brain fibres, with a consequent production of lymph, which by pressure has for the time interfered with the functional activity of the affected nerves. The fact that the paralysis did not come on at first, is the reason for believing that it has been due to the pressure of lymph, and not to a rupture of nerve fibres, as in the latter case we should probably have had the symptoms coming on immediately. The ptosis and the facial paralysis did not come on for several days after the accident. The double vision which occurred immediately was probably due to some of the lesions which I have already spoken of as present in cases of cerebral concussion.

The paralysis of the facial muscles and of the levator palpebræ has gradually passed off, in consequence either of the lymph being absorbed or because the brain has become accustomed to the pressure. The hebetude and dulness from which the patient at first suffered have also passed off.

The treatment which has been adopted in both these cases, and which I commonly employ in cases of head-injury, has been the application of cold to the head, and the administration of calomel and Dover's powder. In the first case we treated the first stage of shock by the application of heat, by means of hot-water cans, to the cold extremities, and by the internal use of ammonium carbonate; five grains every hour. When reaction set in, cold was applied to the head. In these cases small doses of opium produce a calming and soothing effect, in addition to their physiological action of producing anæmia of the brain; the use of opium has therefore a double advantage. The calomel is used for its "anticipatory antiplastic" effect. It has a very great influence over all inflammations of serous membranes. Desault recommended the use of large doses of antimony with the view of producing the same effect; he used enormous quantities of tartar-emetic in cases of head-injury, with the view of preventing inflammation. I have always hesitated to use antimony in this way, nor do I believe that it is called for in these cases, as we can accomplish every purpose by giving minute doses of calomel. In these cases, then, you may advantageously use cold to the head, with calomel and Dover's powder internally, and when there is much headache present, you can afford relief by giving bromide of potassium. Our second patient, in addition to these remedies, has lately been taking quinine to improve his general nutrition. As for food, you may use milk—as much as the patient can take. It does no harm even to give stimulants, if the general condition renders it necessary. The fact to be remembered is that you must maintain the nutrition of the brain, and often your attention or want of attention to this point will make the difference between reparative inflammation and suppurative inflammation of this organ. If your patients are starved in the way persons formerly were in these cases, you need not expect that they will get well. You must then, at the same time that you are giving calomel, keep up the general condition and nutrition of the brain—blowing hot and cold, as it were, together—and thus try to prevent the reparative from passing into the suppurative form of inflammation.

Our third patient is a man, who, last Saturday night, being seven days ago, fell from the Paoli bridge, sustaining, beside a fracture of the radius, an injury of the head. The external wound is a comparatively small affair, but, in addition to this, there is a deeper lesion which may possibly involve the skull itself. There were, when this patient came into the hospital, bruises of the face, with profuse hemorrhage from the nose. Dr. Martin succeeded in controlling the hemorrhage, which then came only from the right nostril, by plugging the anterior naris on that side. This answered the purpose for some time, but on Monday the hemorrhage recurred from both nostrils, when we had recourse to plugging both nares, both anteriorly and posteriorly.

The plugging of the posterior nares may be accomplished by the use of the double canula, but it can be more conveniently accomplished by means of Bellocq's sound, which is introduced through the anterior nares until it reaches back of the soft palate, when the end is made to protrude by means of a curved wire. The end is now threaded in the mouth, the cord carrying at its end a plug which is made to enter the posterior naris by the withdrawal of the sound; then the anterior naris can be plugged from in front. The plugs in the right naris, both anterior and posterior, have become loosened and have been removed; but in the left naris the posterior plug is still in position. We do not want to leave the plug too long, nor yet do we wish to remove it before it becomes loose, since its premature withdrawal might reëxcite the hemorrhage. The patient also presents some cerebral symptoms; he is quite dull and heavy, and has been at times delirious. He has lost much blood and is, in consequence, very anæmic; because of this we have adopted special measures for the keeping up of the heart's action. We are using tincture of digitalis as a cardiac tonic; opium to keep the patient quiet, and ergot to occasion contraction of the capillaries and thus prevent capillary hemorrhage. He gets all the nourishment he can take. The bleeding was so profuse that we feared that it might come from a fracture of the skull at the base of the nose. In some cases the ethmoid bone is extensively fractured, and then there is great risk of meningitis following.

We are using here calomel and Dover's powder, and if there should appear any further symptoms of cerebral disturbance, we should use cold to the head. We did not use cold in the beginning, as the patient had lost so much blood that we wished to avoid anything that might chill him.

There is very little danger in leaving plugs in the nares even for a considerable time. Some surgeons have feared that to do so might expose to risk of blood-poisoning, but there is a comparatively slight risk of this. You must by all means control the hemorrhage, and leave the plugs in until they become loose of themselves. They may become very offensive both to the patient and to those around him; and they have the additional disadvantage that the secretions being swallowed may cause disorder of the digestive functions, but even this is better than a recurrence of the bleeding On the whole, our patient is doing well, and there is no reason why he should not recover.

IMPETIGO CONTAGIOSA: ITS INDIVIDUALITY AND NATURE.

BY HENRY W. STELWAGON, M D.,
PHYSICIAN TO THE PHILADELPHIA DISPENSARY FOR SKIN DISEASE; CHIEF OF THE SKIN DISPENSARY, HOSPITAL OF THE UNIVERSITY OF PENNSYLVANIA, ETC.

(*Read at the Seventh Annual Meeting of the American Dermatological Association, Lake George, August 29, 1883.*)

SINCE the first papers[1] on the subject of this disease, by the late Tilbury Fox, in which its clinical features were so well portrayed and its individuality so forcibly presented, numerous observations of other writers have been added, and the accumulated facts all go to prove the correctness of the views advanced by that distinguished observer.

As with most diseases, this affection presents slight differences as observed in different countries, although in the main and essential points coinciding. English observation,[2] following that of Fox, has corroborated the truth and accuracy of his descriptions.

With the Germans, as described by Kaposi,[3] Simon,[4] Geber,[5] Unna,[6] Riegel,[7] and others, the character of the eruption is the same, but the prodromic constitutional disturbance which, according to Fox, ushers in the eruption is rarely marked, and frequently absent, and the eruption is mostly confined to the face and scalp, sometimes extending to the hands and feet, but rarely to the trunk and limbs. In these cases, however, swelling of the submaxillary glands is occasionally noticed, a symptom, to which scarcely any reference is made by writers of other countries.

In the disease as seen in our country, as described by Taylor,[1] Piffard,[2] Foster,[3] Van Harlingen,[4] and others,[5] the antecedent febrile condition is in most instances so slight as to escape observation; the distribution corresponds to that given by Fox, except that the eruption is usually less abundant.

French references to the disease are scant; not infrequently reference is made to contagious pemphigus, ecthyma, and herpes, which refer, in some instances, probably, to the disease under consideration.

The claims of the disease to individuality are generally recognized, although not universally so. The Germans are the main doubters. Kaposi,[6] the present leader of the Vienna School of Dermatology, has in his late treatise almost completely ignored the disease, mentioning it only to state that the cases giving rise to this name belong most probably, either to the domain of eczema, tinea tricophytina, or pediculosis; this in spite of the fact that he had some years previously not only granted the disease a distinct existence, but also, on account of having discovered a fungus in some of the crusts, had designated it by the new name of "impetigo parasitaria." Geber[7] and Lang[8] are disposed to consider it an unusual form of tinea tricophytina. Unna[9] considers it a distinct disease. Riegel[10] looks upon it as a contagious eczema, and suggests that it should be so named.[11]

Pediculi are, admittedly, capable of producing pustulation, but never the characteristic vesicles, vesico-pustules, and blebs of this disease; nor is it at all probable, even if so capable, that all the lesions would be so uniform, or that in several members of a family they would present the same characters. Then, again, itching is almost a constant sign of pediculosis, and is rarely present in contagious impetigo, nor would there be any probability of the disease being at all a definite one with such a cause acting.

[11] Lewkowitsch: Ein Beitrag zur Streitfrage der Existenz der Impetigo Contagiosa oder Parasitaria; Jahrb. für Kindh., p. 303, 1877.

Cases in which the eruption is in places confluent, and confined to the face and scalp, do resemble eczema somewhat, but the character of the primary lesions, their maturation, and indisposition to rupture, furnish sufficient grounds against this disease, without taking into consideration the contagious properties of the affection.

Those cases in which the vesico-pustules grow rapidly larger by extension of the peripheral wall give rise to the view that the disease may be an unusual form of tinea circinata. In these cases, Kaposi agrees with the views of Geber and Lang, who, as stated, consider the disease, in all its phases, of the nature of ringworm. Geber, in substantiation of his view, has reported one case in which characteristic patches of ringworm were present, the other lesions being typical of contagious impetigo; the fungus of ringworm was found, and the apparent identity of the two diseases announced. Lang[1] followed with a report of a similar case.

Any impartial observer reading the reports of these cases would have no doubt that instead of one process, there were two distinct diseases present. In a case in which the lesions were all typical of impetigo contagiosa, Geber found a fungus in one of the crusts resembling that found previously by Kaposi, but considered its presence accidental, to which view Kaposi subsequently yielded. It would be extraordinary to have so copious an eruption as is common in this disease from the fungus of tinea tricophytina, in which all the lesions would present characters so uniformly unusual, so extraordinary, I think, as to be impossible. Moreover, with so much eruption, if the disease were ringworm, there should be no difficulty in detecting the fungus; on the contrary, attempts to do this are always negative, except in cases in which, as in those of Geber and Lang, ringworm clearly coexists, and naturally such patches may furnish the characteristic fungus. Admitting the difficulty at times of discovering the fungus in cases of ringworm of the body, and that the same would be true in unusual forms of it, there never is any difficulty in detecting fungous elements in the hairs when the scalp is affected, and this should be true, as Simon suggested, of patches of contagious impetigo in the scalp, were it a form of ringworm; microscopical examinations are, however, without result. Again, patients with impetigo contagiosa, if inoculated with the fungus of ringworm, should, I think, show resulting patches at least somewhat similar to the impetiginous eruption present, as a tendency to an unusual form of an eruption must be dependent upon the state of the skin or condition of the patient or surroundings, rather than upon any condition of the fungus itself. On the contrary, in cases of this disease in which I made the experiment, and in a few of which, as a result, ringworm was produced, the patches were typical, and showed no tendency whatever to the production of a lesion or patch similar to the coexisting eruption of contagious impetigo. In fact, there is neither clinical nor microscopical proof that the disease is in any way related to ringworm.

American observers recognize the individuality of the disease with, to my knowledge, but one exception. Dr. Hyde,[1] in his treatise recently published, regards the disease as a variety or modification of simple impetigo—an impetigo following in the wake of a contagious disease. After describing the clinical history of the disease, and mentioning the fact that it frequently follows a contagious disease, Dr. Hyde says:

> "The natural conclusion seems to me irresistible. Impetigo contagiosa is merely an impetigo which must first, at least, occur in the skin of a patient who has lately suffered from a contagious disease (varicella, variola, vaccinia). The living matter of the pus shares, to a feeble extent, in the activity with which the protoplasmic elements of such a skin were recently endowed. Thus originated, and in this feeble degree inoculable, such a living pus could readily excite the protoplasm of another part of the body or of another individual not convalescent from a contagious disease to a similar activity. Especially should this be demonstrable in the tender and susceptible skin of a child. As regards any differences which have been named above between the features of impetigo in its non-contagious and contagious forms, these are all non-essential, and due to the difference in the activity of the process."

Is the fact, as Dr. Hyde states, that the disease follows a contagious disease correct and sustained by clinical experience? I think not. Among all the reports of cases, in a few instances only did the disease follow varicella, and I can recall no case in which it followed variola, and in only a small proportion of cases did it seem to have any relationship to vaccination. In the eighty eight cases under my care during the past three years and a half, in one only did it follow varicella, in no instance had variola preceded, and in but six did it follow vaccination, and in these a period varying from one month to a year had intervened.

Postponing a further discussion of its possible relationship to vaccination till the subject of the nature of the disease is taken up, and passing to a consideration of other questions raised by Dr. Hyde's theory, the next point suggested is: Can a pustular disease be so modified by a preëxisting contagious disease, which had some time previously occurred, as to present an entirely different clinical picture? I know of no example or proof in substantiation of this. Admitting, however, that such can take place, can such a modification be possessed of such characters as to propagate itself in its own modified form? If so, then there is a new disease, entirely differing from the original disease, and totally distinct and independent. I do not believe, however, that such can take place; clinical observation is against it, and it lacks both positive and negative demonstration. The clinical features of the two diseases are markedly different, and cannot be easily confounded.

If the disease is not a variety or modification of another disease, and its clinical characteristics are so distinct and different from other diseases, the conclusion must be reached that the process is an independent one, and the individuality of the disease must be admitted. This granted, the nature of the disease demands consideration.

[1] Hyde: Diseases of the Skin, p. 186.

In regard to this point but few observers are in accord; some viewing it as a parasitic disease, others opposed to this, and others again holding aloof and advancing no opinion. The eruption has distinct contagious properties; is inoculable, as well as auto-inoculable; to these facts most observers agree. This being the case, this contagion must be derived from a constitutional or local source. The question of the local source of the contagion, or the parasitic view, will be first considered.

Some points regarding the parasitic theory have been unavoidably touched upon in discussing the individuality of the disease, and a certain amount of repetition may be necessary.

Several observers, most notably Kaposi[1] and Piffard,[2] have attributed the disease to the presence of a fungus which they have discovered in some of the crusts. This view is, however, materially weakened at the start by the fact that in almost all instances the discovered fungus has been different from that discovered by others. Almost every observer has, in fact, been able to demonstrate the presence of a fungus in a few crusts, but many look upon it as accidental, a view which Kaposi, one of the first supporters of the fungus theory, subsequently adopted. Others, again, most conspicuously Unna, consider the disease, in all probability, due to a fungus, but admit that as yet the fungus has not been found. No one has been able to demonstrate a fungus in the contents of the lesions.

It is not at all surprising that fungi have been detected in some of the crusts, for it is well known that fungi may float about in the air, and may lodge upon anything exposed. Take the crusts of any disease, the non-parasitic nature of which is unquestioned, and the same result will be obtained. This I have done with the crusts of eczema and dermatitis, and in them I have occasionally found not only the fungus described by Kaposi and Geber, and that found by Piffard, but also fungous elements of other characters. In all, five hundred examinations were made. The same was done with the crusts of impetigo contagiosa, and with about the same results. In numerous examinations of the contents of the lesions, I was never able to detect the slightest trace of a fungus, agreeing in this with the experience of all other observers. The fungi so far discovered in the crusts are, therefore, in all probability, adventitious, and in no way related to the disease. I may here say that not infrequently I have found micrococci in the contents of the *maturing* lesions, suggested by Crocker[3] as a possible cause of the disease, but these are not peculiar to this disease, and may be frequently found in pustules of other diseases.

In a disease with so copious an eruption as commonly observed in this affection, if it were in any way dependent upon a parasitic cause, there should be no difficulty in detecting the same fungus in several of the crusts, even if not in the contents of the lesion. A failure to do this is in itself against the supposition of a parasitic disease.

The aggregate results, therefore, of microscopic investigations of the disease, have been so far negative, and must be accepted as proving more or less conclusively its non-parasitic nature.

This conclusion is supported by the clinical features of the disease: the prodromic febrile disturbance, the character and progress of the eruption, the definite course, are all in opposition to the parasitic view.

The disease occurs mainly among the poorer classes: this has been looked upon as favoring its parasitic nature. It should have, however, but little weight, as all contagious diseases, it matters not what the contagium may be, are always more common among the poor and neglected.

Another view of the eruption, which is nowhere clearly advanced, although its suggestion is occasionally implied, is that which would consider the disease a general systemic one, and the cutaneous phenomena as its manifestations, resembling in this respect the other eruptive diseases—varicella, variola, and the like, and that the eruption is prolonged by auto inoculation. This view is one, I think, which the writings of Fox in a measure suggest, although it is not distinctly so stated. This observer, in discussing the prodromic constitutional symptoms of the disease, says:[1]

"There is clearly an affection of the system at large before the occurrence of any eruption;" and then again: "There was in many instances smart pyrexia accompanying the development of the disease;" and further: "I noticed in the quasi-epidemic of 1870 how completely the definite course of the eruption was marked by the successive cropping-up of fresh places, in part induced by the inoculation from scratching, and also by the fact that the patient scratched open the pustules before the scabbing had taken place, and so prevented their drying and healing up;" and further says: "The natural course of the disease is a short and definite one."

There are several reasons in support of this view. The fact that there is a slight fever before the appearance of an eruption is a good basis for this supposition. That this is frequently absent, or at least so slight as to escape notice, may appear at first thought to antagonize such a view. This, however, occurs frequently in varicella, and occasionally in varioloid, as well as in other such diseases, the constitutional nature of which is unquestioned. Certain it is that the aggregate experience of observers points to the frequent occurrence of prodromic symptoms, or a period of invasion, especially when the disease occurs in young children. Like varicella and others of the eruptive diseases, it is a disease of childhood, and is frequently epidemic, and at times apparently infectious. The disease does not often recur. There is occasional swelling of the submaxillary glands. The disease is markedly contagious, and, moreover, frequently several children are simultaneously attacked, indicating a specific poison.

[1] Fox (Tilbury): Skin Diseases. Second American Edition, 1879, p. 224.

All these facts are in favor of the view under consideration.

Ordinarily the disease runs a short and definite course, and the clinical picture of it when this is the case is very characteristic of an acute contagious eruptive disease of a systemic nature, due to a specific poison.

It is only in those cases in which the eruption continues to appear for several weeks or even months that a doubt is thrown upon this view of the disease, and a suspicion aroused that the lesions are due to some external agent. The eruption is, however, auto-inoculable, and this may explain the occasional chronic character of the disease, although, to say the least, the explanation is unsatisfactory.

So far as my observations have gone, I incline to this view of the disease, strengthened as it has been by a careful study of the literature of the subject. This theory will explain the typical cases, and I am willing to accept for the present that. in some instances, the cutaneous manifestations are prolonged by the persistence of the auto-inoculable properties of the lesions after the active and essential disease has run its course: in this manner, new patches may be produced for several weeks, this inherent element of the vesico-pustules becoming gradually weaker, and finally its power to reproduce disappearing.

That this is, however, a correct explanation of the disease I am far from convinced; but if we dismiss the possibility of a parasitic cause (and the collective investigations of the disease certainly demand this), then I can think of no other alternative which will explain the disease as well as this, and which has so many grounds in its support.

As already remarked, the greater number of writers hold aloof, and advance no opinion as to the nature of the disease. Several have suggested that in some way it was related to vaccination, as has already been intimated. Fox himself stated that some cases followed this operation. Piffard[1] and Duhring[2] have seen such instances; Hyde also saw such relationship in some cases. Others have failed to recognize any connection whatever, and in many writings on the disease the question is not discussed, and the inference is that in their cases such relationship was not noticed. As before remarked, in my cases a dependence upon vaccination could not be demonstrated.

In addition to clinical observation, Piffard based this view upon the discovery of a fungus in the vaccine crust resembling that found in the crust of contagious impetigo. The fungus was found in a number of vaccine crusts, but only in several impetigo crusts, a fact suspicious in itself. No fungus could be seen in fresh vaccine lymph. It is probable that if impetigo crusts were exposed to the air as long as vaccine crusts usually are, an examination would disclose the fungus in a greater proportion. Dr. Piffard himself did not, however, consider this proof of a relationship conclusive.

There are several grounds against the supposition that the disease follows vaccination. The disease is commonly observed among the poor, and rarely among the well-to-do. Vaccination, on the other hand, is almost universally practised among the better classes, whereas among the poor it is frequently neglected. This being the case, contagious impetigo should not be so rare among the well-to-do, and so common among the poor; in other words, where vaccination is freely practised, scarcely any cases are observed. Again, the disease should be more prevalent during smallpox epidemics, as then vaccination is more common. A study of the literature of the disease fails to show that this was the case; on the contrary, the reports really prove the reverse.

Another point against it is that not infrequently the disease breaks out simultaneously in several children of a family, only one or two of whom had ever been vaccinated.

With these grounds, and the additional fact that in the mass of cases reported no connection with vaccination was observed, the conclusion is inevitable that no such relationship exists.

In summing up my investigations of the disease, as above detailed, the following results are adduced:

1. It is a separate and distinct disease.
2. It is not parasitic.
3. It is not related in any way to vaccination.
4. It is an acute, contagious, systemic disease (exanthema), with cutaneous manifestations having a definite course, and, in all probability, due to a specific poison.

The first three deductions are, I think, well founded; the fourth is merely suggestive.

TWO CASES OF PARACENTESIS OF THE THORAX;

WITH THE UNUSUAL COEXISTENCE OF PNEUMOTHORAX, NOT TRAUMATIC IN ONE, AND PLEURITIC FRICTION SOUNDS FOLLOWING THE OPERATION IN BOTH CASES; WITH REMARKS AND DEDUCTIONS.

BY F. PEYRE PORCHER M.D.,
PHYSICIAN IN CHARGE MEDICAL WARDS, CITY HOSPITAL, CHARLESTON.

(*Read before the Medical Society of South Carolina, October, 1883.*)

I HAVE recently had occasion in my service at the City Hospital to withdraw by the aspirator three pints of sero-albuminous fluid, of a pale straw-color from Mrs. M., a white woman, æt. 61, who was supposed to be suffering from phthisis. I found partial dulness at the base of the left thorax anteriorly and posteriorly, with absolute dulness in the right cavity up to the nipple.

---

[1] Loc. cit.

[2] Duhring: Diseases of the Skin. Third edition. 1882, p. 298.

The needle of the aspirator was inserted July 6th, at a point three and a half inches below the lower border of the scapula, when a portion of the fluid was withdrawn. Three days subsequently the needle was made to enter over a dull area between the sixth and seventh ribs a little anterior to the middle axillary space, when the removal of an additional quantity of fluid rewarded our efforts.

The patient, before the operation, had been compelled to maintain the upright position day and night on account of dyspnœa, which symptom was entirely relieved, and though there is still some dulness at the base of the right lung posteriorly, she is perfectly comfortable. Two weeks after the operation pleuritic friction sounds could be distinctly heard—consequent upon the contact of the pulmonary and costal pleural surfaces. At the present writing, August 21st, there is not the slightest disturbance as regards her chest. She only suffers from a singular tendency to cutaneous hemorrhage from a scratch or a mosquito-bite, or any other irritant acting upon the surface of the body. At an examination made October 1st, some friction sounds could still be heard, but no fluid existed. The accentuation of the pulmonary second sound was still marked.

It has been my invariable rule in operations for paracentesis of the chest-walls, including two for removal of fluid from the pericardium and one from the lungs, to use the hypodermic syringe with a fine needle as a suction instrument to *test* for the presence of fluid. After the point of the needle has been inserted beneath the skin, the piston is drawn back and a vacuum is created, so that immediately as any fluid is reached it is drawn up into the body of the instrument and its existence made known. Then recourse is had to the aspirator. I make such innocuous searches for fluid in almost every region of the body, deadening the sensation of pain by a spray of ether, or the direct application for a half-minute of a smooth bit of ice. Dr. Douglass Purcell (*London Medical Record*) recommends that the ice should be previously dipped in salt.

To show, furthermore, the necessity for *searching* for the existence of pleuritic effusion in persons who are unconscious of its existence, I report the fact that I have to-day used the hypodermic needle in a man who has been up for three weeks, and obtained some fluid by a puncture in the right middle axillary space, and judging from the extent of the dulness, I confidently expect at my next visit to withdraw two or more quarts for the relief of a state of inactivity and "a heavy feeling about his chest"—the only complaints he makes.

CASE II.—Mr. B., white, æt. 44, has been sick five months, during three of which an inmate of the hospital, suffering from Bright's disease with anasarca. I learn since that his illness began with a severe cold, accompanied by pain in the side; and I may remark here that many diseases of the chest ascribed to tuberculosis will be found upon closer examination to have been caused by previous attacks of pneumonia or pleuro-pneumonia; and the prognosis is then always more favorable. Upon a chemical and microscopical examination of his urine, a very moderate amount of albumen—one-fortieth of a test-tube—was found, and many broken tube casts. There was marked intensification of the second sound at the base of the heart. After careful additional examination (July 16, 1883), I discovered that he also had a large quantity of fluid in the thoracic cavity. My colleague, Prof. M. Michel, Drs. M. Simons, Thomas Legare, my son, W. P. Porcher and the house physicians being present, the needle of the aspirator was entered at the back of the left lung, three inches below the scapula, and one pint of fluid obtained. Two measured pints were then drawn from the base of the right lung, the needle being inserted at a point between the ninth and tenth ribs, intermediate between the lower axillary space and the lower border of the scapula. The pale, serous fluid obtained from each side was slightly different in color.

Relief from pain and dyspnœa and diminished swelling of the feet followed the removal of so large a quantity of fluid, which had, of course, interfered materially with the important organs in the thorax. The tendency of pleuritic effusions is to invade the pericardial sac, and, if allowed to remain, they impede absorption throughout the body.

Dr. F. P. Henry, in presenting a case of Bright's disease to the Pathological Society of Philadelphia (THE MEDICAL NEWS, August 2, 1883), stated that the cause of death was œdema of the lungs, which is a common event in this disease; and he urges the important point that the pleural cavity may serve as an outlet for effusions, "which, but for its presence, would infiltrate the lung parenchyma, . . . and that œdema of the lung may perhaps be averted by the timely performance of paracentesis."

He urges that any cause which interfered with a proper expansion of the thorax would lead to congestion of the pulmonary capillaries, thereby favoring pleural effusion.

A few days subsequently, with the especial object of ascertaining whether friction sounds would not be discovered as a result of the operation, as in the preceding case, I found exceedingly well-marked rubbing sounds at points in the left chest between the heart and the middle axillary space. These sounds, listened to by several friends, persisted for several days: they were so exaggerated as almost to be confounded with the rustle of the clothing, and more distinct than any I have ever heard.

This case presented an additional point of interest, which has surpassed everything in my previous experience in hospital or private practice. This was the escape of an enormous amount of air from both sides of the thorax, which passed into the reservoir of the aspirator with the fluid. The presence of a certain amount of crepitation had been noted previous to the operation, but there had been no very marked resonance upon percussion. When we remember that there was never any traumatism, no previous injury to the ribs or chest, and that the possibility of the existence of idiopathic pneumothorax has been widely denied, this case gives a striking refutation to such denial. I have also been enabled in this instance, as well as in several other persons examined for the purpose, to confirm an observation recently reported in The American Journal of the Medical Sciences—*i. e.*, the coexistence of intensification of the second sound at the base of the heart consequent upon the presence of peritoneal fluid, gall-stones, concretions, ovarian cysts, or whatever else produces obstruction in the liver and interferes with the due discharge of blood through the ascending vena cava. As one of the writers expresses it: "There is an ischæmia of the portal and hepatic, and a hyperæmia of the pulmonary system."

Such obstructions (and this man's abdomen was distended by fluid) influence the cardio-pulmonary circulation; the right side of the heart is engorged; owing to the compression, the diaphragm becomes fixed, the lungs cannot expand freely and express their contained blood, hence the flow of blood through the pulmonary artery is impeded. There is revealed at the tricuspid orifice a prolonged first sound and a regurgitant murmur, and the second sound is accentuated over the pulmonary orifice, owing to increased arterial tension in the pulmonary circulation. It is purely mechanical, and occurs even in pregnancy. See papers by Dr. Passerini, in *Gazz. degli Ospitali*, January 3, 1883; also Barié, in *Revue de Médicine*, February, 1883; in *English Practitioner*, August, 1883. The condition of the right cavities of the heart, as seen at the autopsy which we will presently relate, serves to confirm the explanation.

According to some authorities, including Hoppe, intensification of the pulmonary artery second sound at the base was often otherwise explained, indicating, for example, a diseased condition of the left ventricle, markedly of the mitral valve. Dr. E. Hyla Greves states, in the *Liverpool Medico-Chirurg. Journal* for July, 1883, "that the pulmonary second sound is accentuated in cases of chlorosis also, and indicates increased tension in the pulmonary artery." On the other hand, there can be a true cirrhosis of the liver of cardiac origin (M. Ch. Sabourin, 1883).

Mr. B. died August 18. The accumulation of fluid in the abdomen having largely increased, he was tapped, at my request, by the house physician, Dr. I. O. Cobb, two days before his death, and three gallons of serous fluid removed.

At the post-mortem examination, made by the house physician, two or three quarts of fluid were found remaining in the cavity of the thorax, and a small amount in the pericardial sac. There was great hypertrophy of the heart. The left ventricle was very much hypertrophied, the walls over an inch in thickness; the right ventricle was also hypertrophied. The right auricle was very much distended, the left normal. The aortic valve was normal, the mitral being slightly insufficient, with great development of the fleshy columns of the valves, as the specimen exhibits. The lungs were congested and condensed by the pressure of the circumambient fluid, adhesions and pleural bands existing. The fluid was becoming denser, approaching to an empyæmatic condition. The kidneys were somewhat enlarged, red, granular, and nodulated, with the capsules adherent; on cutting into them, some of the pyramids were found to be destroyed. The liver was enlarged.

It is a regret that I did not use earlier and more frequent operations for the removal of the serous fluid in both chest and abdomen. I think that morbid accumulations should be carefully searched for and more frequently and earlier withdrawn.

Dr. Bouveret (*Lyon Médical*, 1883) has noticed an ascites among alcoholists curable by tapping. He brings these cases in relation "with the ascites which Murchison has reported as accompanying hepatic congestion, and Semmola has found to exist in certain cases of interstitial hepatitis, and, finally, with the ascites found in chronic peritonitis by Leudet and Lancereux." Differential diagnosis, he adds, is impossible, and only the progress of the affection can throw light on the nature of the ascites.

I regard paracentesis as often only palliative of pain and disease, yet that it is essential as such. I have had one case of perfect recovery from ascites where the patient was also put on sulphate of copper as a tonic; and in a second case, the man from whose abdomen five measured gallons were drawn was at his work five months afterwards.

In the case of a man with Bright's disease, of cardiac origin, seen with Dr. R. A. Brodie, of this city, and tapped six times, with the removal of more than two gallons in several instances, he has recently walked more than two miles, after having been confined to his room for months, and often compelled to sit up in his chair night and day.

In conclusion, I will relate two unique cases, indicating the necessity for paracentesis, but in neither of which, unfortunately, was the operation performed.

In an autopsy—made within the past few days—of a man with serous fluid in the lungs accompanying great enlargement of the liver, insufficiency of the mitral valves having been diagnosticated, a fibrous mass the size of a bullet was found imbedded in one of the fleshy columns of the mitral. A singular incident occurred in connection with this case: Whilst the muscles of the thorax were being divided, but before the cavity of the chest was opened, a large quantity of fluid was seen to flow in a continuous stream from the mouth of the corpse. This phenomenon was never before witnessed by any one present, including Prof. Michel, who assisted. It could only be accounted for by an accidental communication being forced between the superabundant fluid in the chest into the trachea, though no opening could be discovered.

In another case, which I had occasion to publish during the past year in connection with reports of several cases of paracentesis thoracis, a gardener, who had been in the habit of lying out in the open air, and who was admitted into the hospital suffering from great oppression, pleuritic effusion being diagnosticated, paracentesis was proposed, but the patient refused. Spontaneous rupture through the bronchial tubes from gangrene of the lungs occurred during the night, and the man was suffocated in ten minutes by the deluge of fluid from the pleural cavity.

A CASE OF POISONING BY TURPETH MINERAL; DEATH.

BY A. McPHEDRAN, M.B.,
OF TORONTO, CANADA.

I AM not aware that any instance of poisoning by the yellow sulphate of mercury has been published, or that such a result has ever before occurred from its administration, and deem it, therefore, a duty to report the following case. A medicine that has been so unreservedly commended by so high an authority as Dr. Fordyce Barker, of New York, must be used by many practitioners in both the United States and Canada. Should it occasionally miscarry with even less disastrous results than in the case given below, it is very desirable that such a fact be known to the profession generally, that due caution may be exercised in its administration.

I was consulted in August of last year by a woman for her child, aged five months, on account of a croupy cough which had begun two days before, and was growing worse. There were symptoms occasionally of slight spasm of the larynx, and the mother was apprehensive of "croup." The cough was due to a slight catarrh of the larynx and trachea, with pretty free secretion. The child was healthy and well nourished, though small. Fearing an attack of dyspnœa during the night from spasm of the larynx, it was thought advisable to be prepared to give an emetic, and two powders, three grains each, of turpeth mineral, were ordered, with directions that one should be given as soon as an attack of spasm threatened. The second powder was directed to be given in fifteen minutes if the first failed to produce vomiting. No doubt, however, was entertained of the prompt action of the first powder.

During the night, the mother thought it necessary to make the child vomit, and gave one powder, a little of which was not swallowed, but returned mixed with saliva, so that probably about two grains were taken. A few minutes afterwards, the child seemed greatly distressed, and made fruitless efforts to vomit. The second powder was given in a quarter of an hour, but only increased the suffering without producing emesis.

I was immediately sent for, and, on my arrival, found the child in great agony. The tongue was slightly whitened, and the throat filled with mucus. Shortly afterwards the bowels began to move. The first motion was of normal consistence and dark-yellow color; the subsequent ones consisted of white, coagulated mucus and watery fluid, in which at first could frequently be seen light, yellow particles, which probably consisted of turpeth mineral. The evacuations were very frequent, and soon became almost continuous. The child could swallow nothing, so that little could be done to give relief. An enema was given, but it returned immediately. After about two hours, collapse began to set in. The pain came in paroxysms, during which there were efforts to vomit. The collapse gradually increased, and death took place in eleven hours, with signs of slight convulsions.

These symptoms are identical with those due to acute poisoning by the perchloride of mercury. The lemon-yellow color of the powder precludes the possibility of its being other than the yellow sulphate. A short time previously I prescribed this emetic for diphtheritic laryngitis in a child under two years old. The prescription was filled from the same bottle of the medicine as was used to fill the order in the above case. In that case, four and a half grain doses were given, and each dose caused prompt, easy emesis without any perceptible depression following its action. Full doses were ordered in each case, in the expectation that the most prompt action would be obtained without any increase in the depressing effects. I was led to give the preference to turpeth mineral for the infant from observing how perfectly it met all the requirements of an emetic in the case of the child. My friend, Dr. Cameron, of this city, has since had similar experience with this medicine. He ordered it for a child, and the first dose not producing emesis, a second was given. This also failed to accomplish the object aimed at, but a severe diarrhœa was produced, which terminated fatally.

MEDICAL PROGRESS.

NEPHRECTOMY.—On November 13th DR. RICHARD DAVY removed, by post-peritoneal incision, a large fibro-cystic kidney from a man aged 53. The albuminous urine has ceased since the day of operation, and the patient is doing well. On November 14th Mr. Knowsley Thornton performed nephrectomy by abdominal section on a young woman at the Samaritan Free Hospital, a tuberculous kidney being removed. The abdominal incision was made external to the rectus muscle, as Langenbuch recommends, and, after a principle introduced by the operator, the cut surface of the distal part of the ureter was fixed outside the abdominal wound. The patient is progressing very favorably. This is the sixth case of nephrectomy performed by the same operator; all the patients have recovered, and in every case the strictest antiseptic precautions were employed. A very complete account of the history of surgical operations upon the kidney will be found in the contributions of Mr. Clement Lucas and Dr. W. Walter to the Surgical Section at the recent annual meeting of the Association, together with the subsequent discussion, published in the *Journal*, September 29, 1883.—*British Med. Journ.*, Nov. 24, 1883.

EROSION OF THE INTERNAL CAROTID FROM CARIES OF THE PETROUS BONE.—DR. HESSLER reports a case in which sudden death from profuse hemorrhage from the mouth, nose, and ears, was occasioned by caries of the tympanic cavity causing erosion of the internal carotid. Reference to the literature of the subject shows that other similar cases have been reported. The accident seems to be especially likely to occur in these cases on account of the close relation of the internal carotid to the petrous portion of the temporal bone. The hemorrhage is generally sudden and fatal, and without prodromal symptoms. It may be brought on by a paroxysm of cough.

The prognosis is, of course, very unfavorable, the patient bleeding to death before assistance can be rendered. The only treatment is compression and ligature of the common carotid. Even then hemorrhage may occur from a return current through the anastomosis with the vertebral and the cerebral anastomoses.—*Deutsche Med. Wochenschr.*, August 22, 1883.

Treatment of Fistulæ of Steno's Duct.—Dr. Edouard Martin has recently published a clinical study of this affection, in which he draws the following conclusions:

1. From an etiological point of view, fistulæ of Steno's duct may be classified almost equally as traumatic fistulæ, and pathological fistulæ following abscess and inflammation.

2. Their treatment varies a great deal according to the indications; it is therefore a grave error to choose any one procedure to the exclusion of all others for a distinct application in these cases.

When the anterior extremity of the canal is permeable, cauterization, aided in some cases by dilatation, may effect a cure. When the anterior extremity is closed, it is necessary either to produce glandular atrophy by compression, or by evacuating the saliva externally, a procedure not without inconveniences, though it has given good results in the hands of Louis, Borel, and Julliard, or else to make an artificial duct. For this purpose Martin believes that simple puncture with a large trocar, followed by the introduction of a large drain left *in situ* for a few days, is sufficient in the majority of cases to insure the permeability of the artificial duct. Should this show a tendency to close up, a canulated sound may be passed, or the duct may be dilated by laminaria. Deguise's method of double puncture, with Béclard's, Gosselin's, Trélot's, or Richelot's modifications, should be reserved for exceptional cases.—*Revue de Thérap.*, Nov. 1, 1883.

Treatment of Epithelial Tumors by Arsenical Paste.—M. Garès (*Thèse de Paris*, 1883) recommends the method employed by Laboulbène. The paste is made as follows: ℞.—Arsenious acid, 1 part; sulphate of mercury, 3 parts; calcined sponge, 6 parts; add water sufficient to make a soft paste. After a little ammonia has been applied to the surface of the tumor, a small quantity of the paste is applied; the quantity to be applied varies according to the dimensions of the tumor. The paste is applied by means of a piece of tinder, and secured. There is generally some pain, but not sufficient to cause serious inconvenience until the second day. After a time varying from four to six days, the tumor becomes detached and falls off, leaving a wound which soon begins to cicatrize. The chief advantage of this paste lies in its elective properties, pursuing the ramifications of an epithelioma in a remarkable manner.—*Revue de Thérap.*, Dec. 1, 1883.

Actinomycosis Hominis.—Middeldorpf reports a case of actinomycosis hominis seen at the Freiburg Surgical Clinic. The patient was thirty-five years old; had had symptoms of peritonitis in July, 1882. Then two pelvic abscesses formed, which, when opened, discharged characteristic actinomycoses. In the course of time a gluteal abscess formed, a communication existed between the abscess-opening and the intestine, and later a communication between the intestine and urinary passages. The treatment was symptomatic and the patient recovered. The reported cases of actinomycosis amount to twenty-three.—*Centralbl. f. Chir.*, Nov. 3, 1883.

Chyluria, with Casein in the Urine.—Dr. A. Loison reports the case of a woman affected with chyluria. The amount of fat varied between grammes 3.25 to 4.11 per litre of urine. The density of the urine was normal. Microscopic examination showed the presence of numerous fatty globules, granular masses of precipitated urocasein, and fibrinous clots as large as the head of a pin, and containing blood-globules.

The caseous material which M. Loison called urocasein was precipitable by acetic acid, the precipitant being soluble in ammonia and in the alkaline carbonates, phosphates, borates, and bicarbonates. When dissolved in bicarbonate of soda this material was precipitated by sulphate of magnesia. The alkaline solutions are precipitable by acetic and lactic acids, and by tartaric acid (an excess of this last material redissolves the precipitate).

In an alkaline solution it is precipitated by alcohol, heat redissolving the precipitate. Elementary analysis shows that this casein is analogous to milk casein.—*Ann. des Mal. des Organes Genito-Urinaires*, November, 1883.

Prognosis of Resection of the Vagus.—A. Vogel reports three cases of resection of the vagus.

The first case was one of extirpation of carcinomatous glands in the neck, during which one and one-fifth inch of the left internal jugular and two inches of the left vagus were resected. It was rather remarkable that the left recurrent was not affected until nine days after the operation. Up to this time the voice was loud and clear; then total paralysis of the left vocal chord came on. Vogel thinks that there must have been an anastomotic connection between the right vagus and the left superior laryngeal.

The second case was one of partial extirpation of the larynx, a portion of internal jugular, three and one-fifth inches of the common carotid, and large pieces of the vagus, sympathetic, and hypoglossal nerves. Death occurred ten hours after the operation, from loss of blood.

The third case was one of lympho-sarcoma of the neck; extirpation with resection of the right vagus, a part of the cervical plexus, section of the sympathetic, ligation of the internal jugular and subclavian veins, and vertebral and subclavian arteries. Death occurred in four days from loss of blood. As far as paralytic accidents are concerned, the operation does not seem to be contra-indicated.—*Centralbl. f. Chir.*, November 24, 1883.

The Effect of the Metallic Chlorides on Microbes.—M. Ch. Richet has recently made some experimental studies on this subject.

He used, as a fermentable liquid, sea-water to which a small quantity of pepsin had been added. This liquid is, in a few hours, filled with bacteria. In comparing the metals which, in the state of chlorides, prevented the development of bacteria for forty-eight hours, M. Richet discovered that twenty times as much of the chloride was needed, as was necessary to endanger the lives of fishes.

Mercury has the most powerful action; after this are zinc, cadmium, and copper. Ammonium and potassium, which are energetic animal poisons, have no effect on plants. It is probable that this difference depends on the nervous system, upon which the salts of ammonium and potash are toxic. There are then universal poisons, of which mercury and zinc are the types acting on the entire organism; and poisons of the nervous system.—*Revue Scientifique*, Nov. 10, 1883.

Scarlatinoid Disease.—In his annual report on the condition of the Combined Gloucestershire District for the year 1882, Dr. Francis Bond, the Medical Officer of Health for the district, explains at some length his reasons for classing the mortality from scarlatina, diphtheria, and croup under the head of scarlatinoid disease. It is not, he observes, that typical scarlatina and typical diphtheria are diseases which can be confounded with one another by any person who has once seen examples of them, but that there is so much practical confusion in the intermediate links by which these separable types are connected with one another, and in the tendency both of the profession and the public to call cases of severe sore-throat "diphtheria," though the scarlatinoid nature of such cases is often not difficult to recognize when searched for, that he sees no alternative but to group them under one head, believing them all to have a more or less intimate family relationship to one another in origin, pathology, and sanitary importance. In illustration, Dr. Bond quotes the case of an outbreak which took place at the close of last year, in the parish of Westbury-on-Severn, where upwards of forty children were suddenly smitten by an attack, the precise nature of which it was by no means easy to identify. The only invariable symptom was a more or less congested condition of the throat and tonsils, accompanied in several cases with localized ulcerations, and very rarely with anything like true diphtheritic exudation, though with occasional croupy tone of voice. Had he seen the latter samples of the affection alone, Dr. Bond would have classified them as croup; had he seen those only in which there was a tendency to exudative deposit on the tongue and fauces, he would have been inclined to admit the diagnosis of a medical friend who saw them with him, and who pronounced them diphtheritic. But the absence in the majority of the cases of the characteristic symptoms of specific diphtheria, the presence in the district of unquestionable scarlatina, the want of any conditions to explain an outbreak of specific diphtheria, and the existence about the same time of similar ambiguous cases of the same kind in other parts of the district, all pointed to the conclusion that this was an aberrant and ill-developed form of scarlatina, modified to some extent by obscure local or personal influences. Enlarged experience tends, Dr. Bond says, to confirm in his mind the belief that, though scarlatina generally originates from direct personal infection, and though typical diphtheria often has a purely local origin, these diseases are due to an infection which in all cases attacks the throat, propagates itself mainly from the throat, and which may, in passing from one person to another, undergo such modifications as will give rise in one case to a characteristic outbreak of scarlatina, in another to an equally characteristic attack of diphtheria, and in a third to a mongrel type of affection which it is difficult to refer dogmatically to either of these diseases, or identify by any other name than bad sore-throat, and which is, in fact, a connecting link between them. Practically, the outcome of this view is, he thinks, to observe with the greatest suspicion any case of sore-throat, more especially in young persons, and to assume that it is scarlatinoid in nature unless good reason can be shown for regarding it otherwise.—*Med. Times and Gazette*, Nov. 17, 1883.

Lupus of the Larynx.—A paper on this subject, by MM. Chiari and Riehl, appears in the *Vierteljahrs. f. Dermatol. u. Syphilis*, 1882, page 663, and *Centralbl. f. klin. Med.*, No. 41, 1883. A review of the present literature of the subject goes to prove that the absolute diagnosis of the condition is only to be made when some affection of the skin accompanies it, and when the possibility of syphilis, tubercle, and carcinoma can be excluded with certainty. Of sixty-eight cases (twenty-six males and forty-two females, all suffering from lupus of the skin or of various mucous membranes) investigated by the authors, only six could be definitely diagnosed as lupus of the larynx. The following appears to be the most usual mode of onset. Small excrescences of the size of hemp-seeds, some isolated and others in groups, appear upon the epiglottis, and, later, upon the ary-epiglottic folds. Similar outgrowths may form on the vocal cords, or may even extend into the trachea. These nodules are seated upon a slightly hyperæmic mucous membrane, and tend to increase both in prominence and in superficial area. They may end in resolution, a slight scabbing taking place, followed by cicatrization, with shallow depressions of the mucous membrane; or ulceration may occur, of very long duration, often accompanied by glandular swellings in the neck, and leading to deep cicatrices, in which fresh nodules are very prone to recur. Unlike lupus of the nose, there appears to be but little tendency for laryngeal lupus to attack the cartilaginous structures. The symptoms, of necessity, depend upon the part of the larynx invaded. Women would appear to be more liable to the affection than men. Scrofulous or tuberculous diatheses do not seem to have any influence either upon the origin or the course of the disease. From tubercular disease of the larynx it differs in its proneness to attack the epiglottis, and thence to spread downwards, and in the scarring about the healed nodules or ulcers. From carcinoma it is distinguished by the absence of the cachexia and by the age of the patient, and further, by its tendency to disintegration rather than proliferation. The differential diagnosis from the syphilitic affections is less easy. The character of the ulcers themselves forms the most marked point of distinction; the sharply defined rounded edge, and the surface covered with yellowish secretion peculiar to the syphilitic ulcers, will often serve to determine their nature. In some cases, however, the course of the disease and its amenability to treatment are the only means of coming to a correct diagnosis. The prognosis must invariably be very guarded. Complications such as perichondritis or even stenosis of the trachea have been observed, although only in a very small proportion of the cases. Treatment must be general, especially by cod-liver oil, and local, by caustic remedies such as iodoform or nitrate of silver.—*Medical Times and Gazette*, November 10, 1883.

Turpentine in Diphtheria.—The antiseptic treatment of diphtheria by turpentine has recently been introduced in Germany by Bosse, of Domian. It is given in the same manner as in cases of phosphorus poisoning, that is to say, as pure turpentine, highly rectified, in doses of a soup-spoonful twice a day to adults, a dessertspoonful to children of more than five years of age, and a teaspoonful to young infants. Milk and wine are given abundantly at the same time. The administration of it causes a sensation of burning in the stomach, epigastric pressure, vomiting, and the passage of stools strongly impregnated with turpentine odor.

This use of turpentine was suggested by the experiments of Koch, which showed that it had an action on the problematic bacilli of diphtheria. But the treatment itself is much more than problematic.—*L'Union Méd.*, November 20, 1883.

Bismuth as an Antiseptic.—Kocher has recently published a further observation in favor of the antiseptic use of bismuth.

The patient was a small boy, who was brought to the hospital at Berne, early in October, on account of a wound from a firearm. The ball had penetrated the abdominal cavity, perforating the cartilages of the seventh and eighth ribs and the wall of the stomach, which was distended with food, the latter being extravasated into the peritoneal cavity. Laparotomy was performed, and the wound brought together by a catgut suture, being completed by a fine silk suture. The peritoneal cavity was disinfected with a solution of subnitrate of bismuth, two per cent. Six days afterwards, the sutures were removed, and twenty days later the patient was well.—*L'Union Méd.*, November 20, 1883.

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

Address, HENRY C. LEA'S SON & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA, PA.

SATURDAY, DECEMBER 22, 1883.

THE DWIGHT LIFE INSURANCE CASE.

FOR several weeks, public attention has been attracted in an unusual degree, to the Dwight Life Insurance Case, proceeding at Norwich, New York. The prominence of the citizen, whose death involved a large sum of money, the mystery surrounding the dying man's last moments, the supposition on the one hand of fraud, and the fatality of the events as believed on the other, have combined to awaken the keenest interest on the part of the medical profession and the public. The secular press having supplied the material to satisfy the curiosity of the public, as medical journalists, we have now to place before our readers the medical aspects of this remarkable medico-legal investigation.

The late Col. Dwight, of Binghamton, New York, a few months before his death, secured policies on his life, in various companies, aggregating upwards of three hundred thousand dollars. Having recently been discharged from his debts under the existing Bankrupt Act, Dwight was unprovided with the means to pay the premiums on his policies, and hence made an arrangement for quarterly instalments. He had paid one quarter only when he died. His death was peculiarly timely. The proceedings in bankruptcy had just been concluded, and in a few days the second quarterly instalment of the annual premium would come due. Various circumstances connected with Dwight's illness and death were peculiar, the will, which disposed of the insurance money, is a remarkable document, and the numerous beneficiaries under the will appear to have been selected for the testator's bounty with other than merely friendly interest: hence it can hardly be surprising that the insurance companies suspected fraud, and resisted payment of the insurance money. The executors of Dwight brought suit to compel payment, and hence the legal contest which has just terminated by the defeat of the insurance companies.

There are several medical and medico-legal questions connected with the case which cannot fail to interest our readers. Dwight was, in some respects, a remarkable man; his malady was obscure; the cause of death was involved in much doubt, notwithstanding an autopsy was held. The trial developed many singular opinions on the part of witnesses to fact, and also on the part of the experts. To present an intelligible view of the case, it is necessary to clear the ground by some preliminary statements.

Dwight was forty-one years of age, six feet two inches in height, and weighed, when in health, two hundred and twenty pounds; he had, moreover, immense strength, activity, and endurance, and he possessed many of the moral qualities of "Col. Sellers." After very harassing pecuniary troubles, ended in the bankrupt court, he was greatly fatigued and much exposed on a hunting expedition which immediately followed. He fell sick, and the symptoms, as given by Dr. Burr, his physician, were "sleeplessness, entire want of appetite, loathing of food, vomiting frequently of contents of stomach—mostly drinks that he had taken." He then improved, and on November 1st was reported as "dressed and sitting up." The next day, on rising to open the door of his room, he "suddenly became faint, and fell back on his bed unconscious. The symptoms were those of a congestive chill. Stimulants and other restoratives were employed, and in the course of an hour he was able to speak." As there is no evidence of fever present at any time, this theory of a pernicious intermittent seems strangely at variance with this fact, and no less irreconcilable with subsequent developments.

On the 9th of November, or one week after this, Dr. Burr reported the onset of the "expected chill," but he says, "we prepared for it yesterday, and late in the evening administered Magendie's solution of morphia, both internally and hypodermically." "The doses of morphia were renewed at two o'clock A. M.," as some pain had occurred. The second paroxysm of the supposed pernicious intermittent, was not attended with more characteristic symptoms than had been witnessed in the first. Some depression of the powers of life came on after the "preparations" to prevent it had been made, but the symptom of chief importance, for the relief of which morphine in repeated doses had been given, was severe pain in the hypochondriac regions.

After this Dwight again improved, and on the 16th of November, the day of his death, he was "very comfortable," according to Dr. Burr, and expressed himself in the evening of the same day as feeling "unusually comfortable." During this day large doses of Magendie's solution of morphine were administered—one of these doses being one drachm of the solution, or two grains—and at 9 P.M., an amount, which was not definitely remembered, was given subcutaneously. Not less than three grains, certainly, had been taken during the day and evening, some portion of it hypodermatically. It is stated that morphine had been given freely during his illness to procure sleep—the more freely, since Dwight, whilst not an opium *habitué*, was extremely insusceptible to its action. On those days when the "congestive chills" were expected, and to procure sleep on the night previous to the first fainting fit, he received large doses of morphine.

Notwithstanding the statement which we find in the report of Dr. Delafield, made to the Insurance Company, that "no poisonous symptoms were produced" by the large doses of morphine, it is certain that the pulmonary and circulatory systems were characteristically affected. All the world knows that morphine in full doses, especially when given subcutaneously, is a vascular sedative. It is this power which renders it so valuable an agent in acute serous inflammations. The sedative action is made up of two effects; lessened activity of the cardiac-motor ganglia; contraction of the peripheral arterioles. Fluid extract of gelsemium had also been given during the last two weeks of Dwight's life—a practice which necessarily increased the cardiac depression. There were conditions developed at the autopsy which rendered this treatment peculiarly hazardous.

Dr. Delafield, who made the first post-mortem examination, found changes in the intestinal glandular apparatus and in the spleen, indicative of the prodromal stage of typhoid, and the heart was small and its muscular tissue "somewhat degenerated." The post-mortem also disclosed chronic pachymeningitis, and a small hemorrhagic extravasation in connection therewith. The opinion of Dr. Delafield as to the mode of dying seems to us wholly sound. The attacks supposed to be congestive chills, he says, "were due to sudden feebleness of the heart; in the second attack, the heart ceased to act." In this result the agency of the morphine is obvious. Although Dwight's brain was rather insusceptible to the narcotic impression, the heart was in a condition to be depressed by the enormous doses required to force sleep. In the words of Dr. Burr, "he suddenly without any premonition sank away and died."

The question of suicide entered largely into the theory of the mode of dying adopted by the experts and the counsel for the insurance companies. Before we consider the means by which Dwight was supposed to effect his purpose, we must dispose of the influence which certain moral questions and personal characteristics had in determining his actions. The reason he had for taking so great an amount of insurance, may have been, to secure large sums of money to his family and friends, by a supreme fraud. When we reflect on the enormity of the crime, on his hopeful disposition and self-confidence, especially on the large enterprises which he had in view, it seems more rational to interpret his conduct by the light of other motives. From this point of view the large insurance was intended to bridge over the period between the present impecuniosity, and that successful enterprise with "millions it it," which, as the testimony shows, he had entered upon. The disclosures of the post-mortem render it probable that he was in the incipiency of one of those forms of mental derangement characterized by expansive ideas. Pachymeningitis accompanied by a hemorrhagic extravasation is so common a condition in some forms of insanity that we can hardly doubt its agency in this case A large life insurance was a natural conception of a mind now about to enter on gigantic schemes of money-getting.

The most important and, indeed, only real evidence of suicide was afforded by a peculiar indentation and a corresponding line of discoloration around the neck, extending from both sides upwards and backwards, as if made by a cord. There was no proof of hanging. On the contrary, the testimony of several witnesses to the final cessation of Dwight's breathing is conclusive against the theory of suicide by strangulation. What, then, produced this appearance of the neck? The explanation offered by the undertaker is, probably, the correct one. After death, the flexing of the neck caused by the support under the head, and suggillation, the tissues being fixed in this positon by a packing of ice, produced the appearance of which so much use was made by the experts of the insurance companies. Dr. Swinburne, of Albany, was the original author of this strangulation theory, supported it by his testimony at the coroner's inquest, and, undoubtedly, impressed his views successfully on the insurance companies' experts. There was no injury to the hyoid bone, to the larynx and trachea, but some evidences of death by asphyxia were certainly present. Strangely enough, no attention was paid to this condition as a result of morphine narcosis. We have already alluded to the effect of this narcotic, when the condition of the heart was under consideration; but the post-mortem appearances indicate that respiratory failure probably preceded by a few seconds the arrest of the heart, for this organ was nearly emptied of blood, and the lungs were congested and inflated.

It is the misfortune of our present system of jurisprudence, as regards expert testimony, that the medical men summoned on one side assume the position of partisans, and testify only to facts that are regarded as favorable to the side on which they are retained. The theory of strangulation suited the interests of the companies seeking to establish fraud, and it would have been fatal to their cause to admit the agency of the repeated doses of morphine in inducing death. That respiration was deeply embarrassed is shown by the testimony of the person who sat up with Dwight on the night of his death. Ten minutes before breathing finally ceased, this person sitting in the room adjoining, heard Dwight "gasping for breath."

Reviewing now the case in its entirety, we believe that the decision at which the jury arrived is supported by the medical evidence, and that the accusation of fraud is unjustified. If the lesions demonstrated by Dr. Delafield at the first autopsy seem inadequate to explain the fatal termination, the enormous doses of morphine administered on the last day of Dwight's life, by way of "preparation" for the expected "congestive chill," are quite sufficient. He had suffered from a pachymeningitis, and there had occurred a recent extravasation at the site of the old exudation; the intestinal glands manifested the appearances of the prodromal stage of typhoid; the spleen was enlarged and softened, and the forces of the body were reduced by several weeks of illness: under such circumstances, is it surprising that, having received three grains of morphine within a few hours, death should have occurred with all the phenomena of respiratory paralysis? The insurance companies should profit by such an experience, and eminent experts should view all sides of similar cases, and become judicially minded if they would retain any of the influence belonging to the scientific character in presence of court and juries.

THE CONVERSION OF TUBERCLE INTO AN INERT FOREIGN BODY.

In an elaborate memoir just concluded, which has appeared in the *Revue de Médecine* (Nos. 9 and 10, 1883), MM. Parrot and Martin have studied the action of various destructive agents on the tubercle parasite. The problem which they set themselves to solve consisted in the discovery of some agent which will convert tubercle into an inert, and therefore harmless, foreign body. We can hardly experience a feeling of surprise and disappointment that the problem still remains insoluble. The progress of pathological discovery only postpones to a still more remote future a therapeutical remedy, and he must be unquenchably sanguine who can hope from our existing resources to find the agent which can safely effect the destruction of the tubercle parasite *in situ*.

If MM. Parrot and Martin have not discovered a cure, they have, at least, so far narrowed the field of inquiry as to demonstrate the inutility of some supposed remedies, and to indicate the work to be accomplished by the remedy of the future. Their research has also tended to establish the specificity of tubercle by showing its power of resistance to the various destructive influences. So little impressionable is the tubercle parasite that no agent now at our command will act destructively on it that does not, at the same time, affect the living tissues injuriously. The agents employed by them were salicylic acid, sulphate of quinine, corrosive sublimate, carbolic acid, creasote, bromine water, and peroxide of hydrogen. In the quantity suitable for administration, none of these exercised any influence on tuberculous virus. The only agent capable of effectively destroying it is heat of 212° F.

From this point of view, tuberculosis is the result of pullulation of a living organism. It does not live necessarily on the surface, and may exist for a long time wholly deprived of oxygen. MM. Parrot and Martin found, indeed, that some tubercle matter, immersed in almond oil, and kept from all possibility of the access of air, preserved its activity for several months. After a time, indeed, its infective property is lessened, but it is found that by repeated inoculations its activity is restored. Also, when immersed in alcohol for several days, the infective property is enfeebled, but by successive inoculations in animals, its normal power is regained.

These facts indicate how difficult is the attempt to procure a remedy which shall accomplish the destruction of tubercle infection. The system of attenuation of virus found by Pasteur to render some kinds finally sterile cannot be applied to the tubercle parasite. Antiseptics, as far as known to us, are powerless in any degree of strength within the limits of safety. The body is a culture ground in which the parasite finds the material of its development, and its pullulation causes the appearances to which we apply the term tuberculosis. Thus under our eyes proceed the ravages of a parasite which we are unable, in the present state of our knowledge, to destroy or render inert.

BISMUTH AS AN ASEPTIC DRESSING.

In a paper, read at the Twelfth Congress of the German Surgical Association, Riedel, of Aix-la-Chapelle, stated that his experience with the dressing of wounds with subnitrate of bismuth supported that of Kocher, who first called attention to it. He thought that the aseptic property of the remedy was due to the incessant disengagement of minute quantities of nitric acid, through which it acted as a mild caustic upon the tissues. He had, however, found it powerless in abscesses and in erysipelas, and, in consequence of its producing adhesions, he advised that it should not be used in operations upon the chest and abdomen.

In the discussion which followed, Kocher stated that bismuth was not a germicide, but that, by forming an albuminate with the tissues, it converted the latter into a soil which was unsuitable for the development of minute organisms. Von Langenbeck, of Wiesbaden, and Hahn, of Berlin, were warmly in favor of the dressing. Like all other agents, however, the use of bismuth is now and then followed by accidents. Kocher had known enteritis, nephritis, and stomatitis to be set up, and Israel, of Berlin, narrated a case of extirpation of carcinomatous axillary glands, in which an acute gangrenous stomatitis developed, and small nodosities remained in the vicinity of the cicatrix, which were due to deposits of the salt.

From these observations it appears that bismuth does not sustain the hopes which were anticipated when it was first introduced. Arsenic, with which it is largely contaminated, may possibly account for the aseptic properties which have been attributed to it.

MICRO-ORGANISMS IN NORMAL FECES.

An important series of observations has recently been undertaken by student of medicine Berthold Bienstock in the Clinical Laboratory of the Royal Medical Clinic at Breslau, and reported in the *Deutsch. med. Wochenschrift*, Nov. 21, 1883.

It will be remembered that in Cohn's classification there are four principal groups of bacteria, or cleft-fungi: 1. Micrococci or spherical bacteria. 2. Micro-bacteria or short-rod bacteria. 3. Desmobacteria or filamentous bacteria. 4. Spiro-bacteria or screw bacteria, one of the genera of which is the *spirochæta obermeyeri* or the spirillum of relapsing fever.

Now, of these groups, Mr. Bienstock has found constantly present in normal feces, a bacillus or long-rod bacterium, a genus of the desmo-bacteria. To this same genus belong the bacillus of anthrax, the bacillus tuberculosis, and others. The genus bacillus, according to Koch, is the only one capable of resisting the solvent action of the gastric juice. All the remaining genera are destroyed by gastric juice in from twenty to thirty minutes.

No less than five different varieties of bacilli were found by Bienstock in feces, distinguishable from each other partly by their mode of growth and culture, and partly by their properties.

It is impossible for us to follow Bienstock in his description of these varieties, of which one, found capable of breaking up albuminous substances, was conspicuously absent from the intestinal contents of suckling infants, whose only food was milk; while the same stools carefully collected were capable of developing the purest cultures of a second bacillus, which was found catalytic of carbohydrates. But the conclusion of the investigator that each fermentative process in the act of digestion has its own excitor in the shape of a bacterium, just as anthrax, glanders, and tuberculosis possess their specific fungi, adds a result to the investigation of micro-organisms which, if confirmed, seems likely to lead to important practical results. Shall we live to see the day when a bacterium may be prescribed for one variety of indigestion, or for the solution of a certain kind of food, and another for the digestion of an aliment which would otherwise resist conversion into absorbable peptones or creamy chyle?

In connection with Koch's recent researches upon cholera in Egypt, during which he has noted a bacillus in the intestinal walls, these discoveries are also of importance.

THE INDEX MEDICUS.

The publisher of *The Index Medicus* again places before the profession a statement of the status of this periodical, from which we learn that the mere annual cost of production is not less than $5000, and that the maximum returns from subscriptions at $6 per annum have not exceeded $3600. It is therefore evident that to maintain this publication, which has now really become indispensable to all who are engaged in medical research, it is necessary either to have a largely increased subscription list, or the same list with an increased subscription price.

To the credit of the profession of this country and its future scientific work, this publication should not be allowed to stop. The burden of supporting it would not be felt by individuals if every medical society would take a copy at $10 per annum, or if the wealthier societies would subscribe $50 apiece as a guarantee fund, as has been done by two of the Philadelphia societies. The question of what is to be done to support this invaluable publication must be decided at once, and we hope that every physician interested in the advancement of his profession—and who is not?—will endeavor to authorize a subscription by his medical society at its next meeting, and in default of that, if possible, forward his own subscription to Mr. F. Leypoldt, 31 Park Row, New York. It would be a misfortune for the publication of *The Index Medicus* to be allowed to cease.

REVIEWS.

The Pathology and Treatment of Venereal Diseases. By Freeman J. Bumstead, M.D., LL.D., etc., and Robert W. Taylor, A.M., M.D., etc. Fifth edition, revised and rewritten, with many additions by Dr. Taylor. Illustrated. 8vo. pp. 906. Philadelphia: Henry C. Lea's Son & Co., 1883.

This admirable book, which has been long enough before the medical public to need no special recommendation, is undoubtedly the best book on the subject that has appeared on this side the Atlantic, and one of the best that has appeared anywhere. As years have rolled by, it has reached successive editions, constantly assimilating the conclusions of scientific investigators all over the world, and never falling behind the advance guard of its own department of medicine. This last edition keeps up the reputation which its predecessors acquired. It comes revised, added to, and improved. The characteristic features of the original are not changed, but there has been a development like that which is looked for in sound organisms, and which speaks well for the organism and well for its surroundings. The one is shown to be healthy, the other propitious.

It is not possible, of course, nor would it be worth while, to attempt to make a complete review of a book so large, which is already so well known. But of a few matters here discussed, it may be well to say a little. In the first place, it is interesting to find that the authors speak with no uncertain sound in regard to the dual and distinct nature of the chancroidal and syphilitic poisons. Prolonged experience has only confirmed the views that they have before published. They still sanction the old notion that a tree is fairly to be judged by its fruits, and that as no one has ever been shown to have acquired syphilis from one who had nothing but a chancroid, therefore, it is reasonable to assume that the chancroid must belong to another category from the chancre—the initial lesion of syphilis. They point out the danger of judging venereal sores by their appearances alone, however useful and reliable these may at times be.

In the introduction we find the same reference that was made in the last edition to the investigations of Prof. Jones, who in 1878 announced the discovery of evidences of the existence of syphilis among the aborigines of America, as shown by the finding of bones in a state of syphilitic disorganization in ancient burial places in certain Southern States. This the authors seem inclined to accept, though they do not do so entirely. So far as we are aware, these claims of Dr. Jones have not had the attention which they deserve. They are of enough consequence to the cause of science that they should be either established or disproved.

Passing from the general to the special, we note a few points in regard to the treatment of the subject of gonorrhœa. The first of these is that the strong views of Fournier, in regard to the preponderance of the subjective element in the acquirement of gonorrhœa, are endorsed by implication. This suggests a query which could be best answered by those who have large practices in this specialty, namely, whether or not the majority of cases of gonorrhœa are found in those who, on account of youth or inexperience, or intoxication, are most impetuous and ardent in their sexual acts? It would seem that this would have some influence in deciding whether Fournier is right or wrong in this matter. We observe, again, what is always to be commended, that a proper use of the word "incubation" is made, and the reader who may need it is warned that he must not understand by this term a period of inactivity, or latency, but one in which the effects of inoculation are not yet manifest. Ricord used to say: "The period of incubation is only a period of inobservation."

Considerable space is devoted in this book to the endoscope—more perhaps than it would be worth, if it were not for the fact that it might in skilful hands be made to contribute much more than it does to clearing up the pathology of the urethra. It is, however, an instrument which but few practitioners will ever use. Those who wish to use it should not fail to examine the excellent papers of Grünfeld, to which reference is here made.

The chapter on stricture of the urethra would detain us too long were we to stop at it; but we may note, in passing, the unwillingness to accept the dictum of Dr. Otis in regard to the relative dimensions of the body of the penis and the urethral canal. An unwillingness which we think is shared by most of those who have investigated the matter for themselves. Not that there is nothing in what Otis has claimed, but that the rule he laid down is not as universal as he supposed.

Sexual hypochondriasis is treated of admirably, though briefly; and wise and honorable advice is given as to its treatment. There is no attempt made, in this connection, to make capital out of men's fears, or to be entertaining at the expense of true delicacy. The words of Sir James Paget are quoted more than once, and the spirit of his writings on this same subject is imitated.

In the chapter which treats of the chancroid there is a condemnation of the practice of touching suspicious looking sores on the genitals with "*lapis infernalis*," which one might suppose was not needed in these days of modern enlightenment, were it not that one is constantly finding that men considered to be enlightened still do this very thing. The comment of the book on this is: "I feel tempted to apply to this indiscriminate and senseless mode of practice the adjective which, in Latin, is given to the '*lapis*' employed."

In the chapter on the nature of syphilis, there is a somewhat indignant denial of the recently repeated claim of Dr. Otis, that Bumstead and Taylor have adopted his peculiar views as to the nature of the syphilitic virus, and the process of its absorption and distribution through the system.

In another place, we find an excellent and useful chapter on certain cutaneous affections of the genitals, which are sometimes thought to be of venereal origin. Some of them—scabies and phtheiriasis, for example—are, in fact, of venereal origin occasionally; but the error which the authors point out of considering them always so, and of supposing that others, such as tinea versicolor, are manifestations of syphilis, is made often enough to call for this notice in a systematic work on the venereal diseases proper.

The authors discuss in detail the still mooted question whether or not a father can transmit syphilis, by inheritance, to his offspring. To this question they give an answer in the affirmative. On the other hand, they deny the possibility of the communication of syphilis through the utero-placental circulation. In regard to the second of these propositions, we think the arguments fair and conclusive. In regard to the first, we think there might have been more space given to argument without disadvantage. The whole subject of hereditary syphilis is involved in a certain degree of darkness even yet, and we doubt whether it will be cleared up until the terms employed in speaking of it have a universal and inflexible meaning. Then there is still the question whether it is syphilis itself, or a derivative, which is inherited.

In speaking of the treatment of syphilis, we find the authors saying: "The therapeutic effect of iodine and its compounds upon syphilitic symptoms is in direct ratio to the duration of the disease." This is the usual view, and it is made stronger by the endorsement of this book; but it is a view which Sigmund abandoned before he died—so much so that he rather recommended the use of the iodine preparations for the early and more sthenic manifestations of syphilis, and the mercurials for the late and atonic manifestations. The authors speak in the highest terms of the administration of the erythroxylon coca as a tonic in the anæmic and cachectic stages of syphilis.

The concluding chapter contains a brief review of the question of syphilis in relation to marriage. This chapter might well have been made longer and more detailed, adopting more fully the form of the conclusions enunciated in Fournier's book on the same subject.

And now, as we think of this book as a whole, we revert to the expression with which our review begins, and repeat that it is in every way admirable, a credit to its authors and a credit to its publishers. Not the least instructive part of it is formed of the excellent woodcuts and colored plates which it contains. The paper and typography are of the best quality, and the binding is of the sort to send across the ocean, to show our British cousins how a good book should be bound.

ANATOMY, DESCRIPTIVE AND SURGICAL. By HENRY GRAY, F.R.S. With an Introduction on General Anatomy and Development. By T. HOLMES, M.A. (Cantab.). Edited by T. PICKERING PICK, Surgeon to St. George's Hospital. A new American from the tenth English edition. To which is added LANDMARKS, MEDICAL AND SURGICAL. By LUTHER HOLDEN, F.R.C.S. With additions by WILLIAM W. KEEN, M.D. Imp. 8vo. pp. 1023. Philadelphia: Henry C. Lea's Son & Co., 1883.

THAT Gray's *Anatomy* should have reached a tenth edition is a fact which speaks more loudly in praise of the practical utility of the work, both to the student and practitioner, than any mere words can do. In this new edition several of the sections, and notably that upon the peritoneum, have been enlarged and rewritten, new plates have been added, and the whole work has been brought to correspond with the most recent discoveries in anatomy and histology. Like the last two editions, this contains Holden's admirable "Landmarks, Medical and Surgical," and is a model of excellence in typography and engraving. Whilst its bulk renders it less useful in the dissecting-room than some of the smaller manuals, it is an encyclopædia of anatomy which every practitioner and student should have at hand for frequent consultation.

SOCIETY PROCEEDINGS.

NEW YORK SURGICAL SOCIETY.

Stated Meeting, November 27, 1883.

THE PRESIDENT, ROBERT F. WEIR, M.D., IN THE CHAIR.

DR. W. T. BULL read a paper entitled

REMARKS ON THE TREATMENT OF IRREDUCIBLE HERNIA BY OPERATION.

With the confidence inspired by success with antiseptic wound-treatment many surgeons have been encouraged to revive operations which had been discarded, and to perform them with success. Among such none have attracted more notice than the operation for the radical cure of hernia. Various methods of operation involving the incision and subsequent suture of the structures concerned in ruptures have been adopted, and have yielded a varying degree of success. Leaving out of consideration minor modifications, these methods, which have been termed "Modern Radical Operations," may be reduced to three, viz. (Steele and Marcy): 1. Closure of the abdominal aperture of the hernia. 2. Closure of the neck of the sac by ligature or suture (Nussbaum). 3. A combination of the two procedures (Czerny).

Reports of operations and a number of papers have accompanied the experience of nine years, and we can form a good notion of the value of these operations by studying the elaborate statistics compiled by Dr. Leisrink, of Hamburg.[1] It will be sufficient for my purpose to call attention to the results of the operation for all cases not strangulated, *i. e.*, reducible and irreducible. Of these there have been operated on by one or the three methods, two hundred and two cases (one hundred and sixty-nine inguinal, twenty-five femoral, eight umbilical and ventral) with fifteen deaths, which gives a death-rate of only seven and two-fifths per cent. Nine deaths were due to septic poisoning, which represent a death-rate of four and three-tenths per cent. from this cause. The percentage of relapses, or cases in which no cure was obtained, is large. Details are not given in all cases, but of those reported there are found twenty and one-ninth per cent. of relapses. Thirty-two patients experienced relapse. A decided improvement was claimed in eighty per cent. Of the patients operated on for inguinal hernia, sixty per cent. were irreducible.

These figures show that the operation is attended with danger (seven per cent. mortality; four and one-third per cent. deaths from sepsis), and that it fails to effect a cure in twenty per cent. of the cases, while at the same time it holds out decided hope of improvement. It can, therefore, hardly be recommended to patients with hernia that can be controlled by truss. These persons are comparatively comfortable with a truss, and their condition far from dangerous, if they exercise proper care; and if any operation is attempted for their cure it should be one free from danger, such as the cure by Heaton's method of injection. The subjects of irreducible hernia, on the other hand, or at least a large majority of them, suffer frequent inconvenience, and are in constant danger of serious accidents. If the hernia contain intestine, they are generally unable to wear a truss, and have dragging pain on exertion, and frequent intestinal disturbances. They are liable to inflammation of the protruded viscera, or to the occurrence of strangulation of additional intestine. With an omental hernia some persons can wear a truss, especially if the pad be "concaved;" but they rarely do this with comfort. Without its support there is generally a feeling of weakness, inability to make more than moderate exertion without pain, and there is just the same liability or danger of the accidents of strangulation or inflammation.

These are the cases for which I believe the modern operations are desirable, and should be recommended when the simpler measures, such as rest in bed, restricted diet, repeated taxis and compression of the hernia, have failed. I have operated on all the cases which have come under my notice in the past three years, and with success. They are three in number.

---

[1] For the literature of the subject we should consult "Die Moderne Radical Operation des Unterleibbrüche," by Leisrink, Hamburg: Leopold Voss, 1883.

1. Irreducible inguinal omental hernia. Excision of omentum, ligature, and excision of sac. Recovery.

A housekeeper, æt. 47, in good general health, was sent to me by Dr. Gibney for an irreducible inguinal hernia of the left inguinal region of six weeks' duration. The rupture had existed for ten years in a reducible condition, and had never given any annoyance till it became fixed, when the presence of a truss became unbearable, and she had pain in making moderate exertion. Several ineffectual attempts to reduce it without anæsthesia had been made. The swelling was over the site of the external abdominal ring on the left side, of the size of a small egg, doughy in feel, dull on percussion, tender on pressure, and contained no fluid on puncture. General health unaffected. After four days' rest in bed, with poultices applied at frequent intervals, the tenderness disappeared, and the swelling became softer. An attempt to reduce it under ether did not succeed, and an operation was recommended. On March 8, 1882, she entered the St. Luke's Hospital in the same condition as before. Under ether, and with the "spray," the sac was opened by an incision three inches in length, and found to contain a mass of omentum adherent to the sac at some places. At the neck of the sac it was as large as the little finger. It was drawn down, tied with a carbolized silk ligature, cut off, and the stump returned to the abdomen. The sac was then pulled down, its neck sewed up with fine catgut, and the rest excised; the wound united by a few catgut sutures and one silver wire with lead plates. Peat and carbolic acid dressing. Recovery was interrupted by a retention of secretion in the wound, which gave rise to slight fever, local tenderness, and vomiting on the third day. These symptoms disappeared promptly on relieving tension by opening the skin wound, and the entire wound healed by granulation under carbolic acid compresses, without further general or local disturbance, in four weeks. Six months afterwards, though the woman had discarded the truss given her on leaving the hospital, there was no sign of return and no unpleasant symptoms.

2. Irreducible inguinal omental hernia, extending into the labium majus. Excision of omentum, ligature and excision of sac. Recovery.

A widow, thirty years of age, and a seamstress by occupation, had been prevented from going out of the house, and at times even from moving about the room, for six months before she was sent to me from the Hospital for Ruptured and Crippled. The rupture appeared three years before in the left inguinal region, as large as a pea, and gradually increased to the size of a man's thumb, without ever being reduced. It gave her little trouble till about six months before I saw her. At this time she consulted a trussmaker, who made repeated efforts to fix a truss over the swelling, which he called a "gland." She could bear no pressure, and was unable to move about without pain. The swelling was three inches in length, extending from the external abdominal ring into the labium of the left side; irregular in its outline, soft to the feel, dull on percussion, irreducible, but giving an impulse in coughing at the upper part, and tender on moderate manipulation. General health good.

An operation was recommended, which was performed at St. Luke's Hospital, April 6, 1882. This operation was without spray, but with other antiseptic measures. The incision, three inches in length, exposed the peritoneal sac, which was opened and found to contain a tongue-like process of omentum, which was atrophied opposite the neck of the sac. This was tied with carbolized silk just about its thinnest part, cut off, and the stump returned to the abdomen. The hernial sac was then isolated, drawn down, its neck ligated with catgut, and the wound in the superjacent tissues of the labium extended through the greater part of the labium majus. Six sutures were put in the upper part of wound, which was now four inches in length, the lower part being placed in apposition by small peat-bags (with iodoform). Large peat and iodoform dressing. The wound healed under two dressings, except a narrow granulating strip, which was cicatrized by the twelfth day. A truss with a light spring has been worn since, though there is no protrusion and the patient feels perfectly well.

3. Inflamed irreducible scrotal hernia (epiplocele). Drainage of sac. Recovery. Antiseptic treatment with spray.

A laborer, aged forty, came to the Chambers Street Hospital suffering from abdominal pain and vomiting, which had begun twenty-four hours before admission. He called attention to a large scrotal hernia of the right side, which had been irreducible for five years. How long it had existed he could not tell. The hernia was of the size of a cocoanut, and covered the upper third of the thigh. There was no tension and the finger could be passed into the abdominal aperture on its upper surface. The surface was smooth and tympanitic over the lower part, was dull and doughy above. It was *not* decidedly tender. There was no impulse, and no impression could be made on it by taxis, but "gurgling" was produced. The man could not tell whether it was any larger than it had been for years past, but thought it got larger while he was at work, and before the vomiting began. He had slight abdominal pain, no tympanites, pulse 100, temperature 99° F., surface warm. He had been constipated for several days, but it was his habit, and he paid no attention to it. He stated, too, that he had had several attacks like this before, lasting two or three days. At the expiration of twelve hours morphine had been injected hypodermically three times, and ice applied to the tumor, and his condition was about the same. He had, however, vomited several times, but only the contents of the stomach.

Fearing the approach of strangulation I decided to attempt taxis under ether, and this failing, to operate. Taxis was tried for fifteen minutes without success. An incision three inches long was then made, and the tissues external to the sac divided. Taxis was again tried unsuccessfully. There seemed to be, however, no constriction about the neck of the sac, for the finger could be passed into the abdominal ring. The incision was extended, the sac opened and found to contain some turbid serum not offensive. A loop of large intestine slightly congested (it was barely changed in color) and distended with gas, and some small intestine not congested, forming a mass as large as a big fist, which was adherent to the bottom of the sac. It was held in a club-shaped mass by adhesion of the serous coats at its narrowest part. These bands and the adhesions to the sac were torn through, and about twenty carbolized silk ligatures applied to bleeding points. Both loops of intestine were then replaced. The abdominal ring admitted all the fingers, and the tissues overlying the sac in its vicinity were adherent and thickened. I, therefore, did not ligate the sac, for fear of injuring the spermatic cord, nor attempt its extirpation, in order not to extend the wound into the cellular tissue of the scrotum, but a counter-opening was made at the bottom of the sac and the wound sutured with silk, two drainage-tubes being inserted. Lister dressing. There was but slight shock from the operation. The wound healed entirely in four weeks with but moderate suppuration and slight fever (101.5° F.), but there was marked local peritonitis from the sixth to the tenth day. The bowels moved on the second and fourth days naturally, and there was no more vomiting. The man was discharged at the end of two months, wearing a Heaton bandage, and has not been heard from since.

It will be noticed that I have followed only the one method, that of ligature and excision of the sac, and that is the only one, from what I have read of the operations of others, that I should be willing to recommend. The apertures cannot be first pared and then sewed up without increasing the risk of the operation, and from what we know of the liability to ventral hernia after wounds of the muscular parietes, there is no reason to believe that we can effectually close up an orifice surrounded by aponeurotic structures. I see no objection in the attempt to *diminish* the size of the orifice in this way, but I believe it of doubtful efficacy. I should think it wiser to adopt the *safest* operation for an irreducible hernia, which will make it reducible. A truss will then control it, and at a later date I should endeavor to diminish or to close the abdominal aperture by the injection method.

While the statistics quoted above give one a general idea of the risks of the operation, it will be apparent to all that these will vary with the conditions of each individual case. A small omental hernia in a woman is a safe thing to cut into, and a large intestinal hernia in a man a very dangerous one. In the same way, the ligature or the excision of the sac in one case may add a trifling nick, in another, a very great one; drawing down the peritoneal pouch, cutting it across, and causing it to unite, is the chief object to be accomplished. The remainder can be left (and drained) if its removal would leave a wound with many chances of septic infection; if not, it should be excised.

I have spoken of this operation only in irreducible hernia. It is proper, however, to state, before closing, my convictions as to its employment in strangulated cases. Leisrink's tables show the mortality after operations for strangulated hernia to be as follows: Of one hundred and eighty-six cases there were thirty-three deaths, giving a mortality of seventeen and two-thirds per cent. This compares most favorably with the rate of mortality in the days before antiseptic surgery was adopted; for the statistics of Luke, Malgaigne, Textor, South, and Gosselin show a death-rate varying from thirty-two per cent. to twenty per cent. As to the duration of the strangulation, the modern operations with antiseptic treatment show: twenty-three cases operated within fifty hours, two deaths, eight and two-thirds per cent. mortality; twenty-one cases operated after fifty hours, seven deaths, thirty-three and one-third per cent.; while with the older methods we find (Gosselin's statistics) twenty-five cases operated on within fifty hours, eight deaths, thirty-two per cent.; forty-one cases operated on after fifty hours, twenty-three deaths, sixty five per cent.

This indeed convinces me that it is safe enough to add to the ordinary operation for strangulated hernia the measure I have referred to above. In other words, I would urge ligation or suture of the peritoneum at above the neck of the sac in every case of strangulated hernia, and excision of the sac besides, or its drainage, according to the circumstances of the case.

DR. CHARLES K. BRIDDON said that several years ago, during his term of service in the New York Dispensary, a colored child, eleven or twelve years of age, was brought there with an inguinal hernia on the right side as large as the child's head. It was irreducible, and had been so for a long time—perhaps had existed from birth. Only a portion of the contents of the sac could be reduced, and when so reduced there remained a band apparently passing from the upper portion of the sac to its fundus, which was supposed, both by himself and by Dr. Gurdon Buck, to be a long band of adhesion. Dr. Briddon operated, exposed the sac, and found that it was a hernia of the cæcum. There was no meso-cæcum. The cæcum had simply slipped down behind the tunica vaginalis, and into that sac a portion of the small intestine had descended which could be reduced, but the irreducible portion was composed of cæcum. The portion which was thought to be a band of adhesion was the vermiform appendix. With considerable difficulty this was dissected free, and the entire contents of the hernial sac were reduced into the abdominal cavity, and a pad was applied. On the following day the hernia was in the same position as before the operation, having been rendered so by a fit of coughing. There was so much tenderness that he hesitated about reducing it and allowed it to remain. An abscess formed in the scrotum which gave discharge to a small quantity of the fluid portion of the fecal matter, but nothing solid; and it continued to discharge for years afterwards. The child was not at all benefited by the operation.

He had performed the operation referred to by Dr. Bull, that of tying the neck of the sac, and always resorted to it in strangulated hernia, but had his doubts as to whether it had been of service. In cases in which he had tied it high up, there had always been a necessity for the use of a truss afterward. He had also several times tried to approximate the columns forming the external ring, but without any benefit. On one occasion he excised the sac, but should never make that attempt again. It was a serious operation in a case of irreducible inguinal hernia, which was followed by a great amount of constitutional and local reaction. He thought the operation proposed by Dr. Bull, that of tying the sac and leaving the rest open to heal by granulation, was the best method to be adopted.

DR. A. C. POST presented a specimen of

UNUNITED FRACTURE OF LEFT THIGH, A HAND'S BREADTH ABOVE THE PATELLA; RESECTION; FRAGMENTS UNITED BY WIRE SUTURES.

On the 2d of July, 1883, I was on a visit to Charlotte, N. C., and saw J. M. Roark, a man fifty-one years of age, who had been injured by the explosion of a boiler on the 24th of June, 1882. He had a compound fracture of the left thigh, a hand's breadth above the patella; also a compound fracture of the left arm near its middle, and sundry contusions of different parts of his body. He had recovered from all his other injuries, but the fracture of the thigh remained ununited. His general health was good.

Condition, July 2, 1883: The limb is shortened about five centimetres. The upper fragment overlaps the lower on the outer side, and there is very free motion between the fragments.

Operation, July 2d: The patient being etherized, I made a free incision over the anterior and outer surface of the upper fragment, divided the periosteum, and worked carefully on the surface of the bone with a blunt instrument, and, after a long and persevering effort, succeeded in turning out the end of the bone and removing it with a saw. The portion removed was a little more than three centimetres in length. The lower fragment was very deep and difficult of access, but I succeeded at last in exposing it sufficiently to pass a chain saw around it, and to remove its extremity, which terminated in a rounded point. The portion removed was a little less than three centimetres in length. It required much effort to bring the sawn surfaces of the fragments into contact. I drilled two holes in each segment, and wired the segments together with annealed iron wire. A plaster-of-Paris splint, previously prepared, was applied to the dorsal and lateral surfaces of the limb. Carbolized compresses were placed between the lips of the wound, which were simply drawn towards each other, and secured by a roller bandage. Over this a plaster-of-Paris bandage was applied.

3d.—The patient had been somewhat restless and uncomfortable during the night, but I found him in a very fair condition. Pulse 84 and of good volume; tongue clean. I did not disturb the wound.

4th.—Pulse 108; temperature 101¾°; dressed the wound; made a large fenestra in the plaster bandage: removed the compresses; washed the wound with carbolic acid, one to forty; dusted the surface with iodoform; applied lint wet with the carbolized lotion to the surface of the wound, which was in a good condition; interposed, between the skin and the edges of the fenestra, lint moistened with carbolized oil, two scruples to one ounce.

5th.—Condition improved; pulse 96; temperature 100¾°; wound in good condition; very little discharge; no odor; dressed as before.

6th.—Still improving; pulse 102; temperature 100°; same dressing.

7th.—Pulse 95; temperature 100°; all symptoms continue favorable.

8th.—Pulse 90; temperature 99.6°; wound looks well; moderate suppuration; no odor; bowels constipated; ordered cathartic enema.

A few days after the last report I came on to the North, and I have not seen the patient since that time. Last month I received a letter from his physician, Dr. J. P. McComb, of Charlotte, giving me an account of the further progress of the case. This letter is dated October 16th. He writes, "The bone has united, and the wound is almost healed. He cannot bend his knee much, but it is improving. He is walking on crutches. The limb is shortened about three inches. There is a large callus all around the limb. He is very grateful for his prospects of a good leg."

ADENO-OSTEO-CHONDROMA OF THE SUBMAXILLARY GLAND.

Dr. Lange presented portions of a tumor removed from the neck of a man twenty-three years of age, which had developed within about five years to the size of a hen's egg. In histological composition it was adeno-chondroma with formation of true bone in small places. The operation was performed about three months ago, presented no difficulty, and will probably not be followed by recurrence of the disease, the tumor belonging to a rather benign species.

ACUTE PYÆMIA OF URETHRAL ORIGIN.

The President presented kidneys and heart illustrating acute pyæmia of urethral origin. They were removed from the body of an apparently healthy man, twenty-five years of age, who had been subject to gleety discharges traceable to stricture. He had had instruments passed from time to time during the summer and in the autumn. Last Sunday his attending physician introduced a sound, No. 23 French, which passed into the bladder without violence, and with no more difficulty than had been produced on all the other occasions. A few drops of blood escaped. On Monday the man was seized with a severe chill. When Dr. Weir saw the patient he had a temperature of 105° F., and he supposed it to be due to malaria, as he knew that the patient had suffered formerly from such chills, which had invariably yielded to quinine. The temperature, however, remained high, and within forty-eight hours afterwards he began to develop joint pains and effusions. He complained of no distress in the bladder, but said that once or twice he had noticed that the urine was very slightly tinged with blood. The man became so delirious that he was removed to the hospital, where he died twenty-four hours afterwards. Before death evidence of pericarditis and endocarditis was detected, and the opinion was formed that it was pyæmic. At the autopsy multiple infarctions with grayish centres were found in the cortex of the left kidney, the right being comparatively unaffected. Pericarditis and recent valvular disease, with excavation at base of one of the cusps (ulcerative endocarditis), were found, and infarctions in the centre of the substance of the heart. The rapidity of the course of the case was especially interesting. Dr. Weir had not seen in acute pyæmia heart lesions so distinctly marked as in the present instance. There were no lacerations of the urethra, but evidences of croupous cystitis were present.

The Society then proceeded to the transaction of miscellaneous business.

OBSTETRICAL SOCIETY OF PHILADELPHIA.

Stated Meeting, December 6, 1883.

The President, R. A. Cleemann, M.D., in the Chair.

Dr. W. Goodell exhibited two

CYSTS OF THE PAROVARIUM,

and remarked: Both patients got well; he, indeed, had never lost a patient from whom he had removed a parovarian cyst. In both cases a correct diagnosis was made previous to the operation. One interesting diagnostic point was the complete absence of the *facies ovariana.* The color in the cheeks was good, and the countenance was free from the anxious expression present in cases of ovarian tumor. One tumor had existed for ten years, the other for one. Another important point in the differential diagnosis is not only the flaccidity of the tumor, but its variable degrees of flaccidity. Upon inspection, it is seen to reach to the sternum, and seems to occupy a large portion of the abdominal cavity, but when the hands are placed upon its sternal edge, it can be compressed to the level of the umbilicus. An ovarian cyst, on the contrary, is hard and uncompressible. Exceptions to this rule are very rare, that is, either a tense parovarian cyst, or a flaccid ovarian one. A third important distinguishing point is the long time—ten years in one case—which the tumor existed, and further without marked deterioration of health. After being tapped, these tumors usually refill, but occasionally they do not, and a cure is thus brought about. The fluid withdrawn has been in every case limpid and generally colorless, but it has sometimes had in his experience an emerald tint. These tumors are generally free from serious adhesions, but if, in an operation for the removal of one, adhesions should exist where for any reason their forcible separation would be unadvisable, or the cyst were intraligamentous, he would not hesitate to leave the adherent portion of the cyst-wall or the whole cyst itself, after making a big hole in it, as the fluid it secretes is bland and unirritating to the peritoneum.

Any one examining one of these cysts for the first time, would consider it to be of ovarian origin: for it is only by patient search that the ovary can be found spread out over the cyst-wall. The microscope will decide with certainty in any otherwise doubtful case. The tumor is covered with a beautiful network of veins.

When a cyst of the parovarium exists on one side, the ovary of the opposite side is usually found to be diseased, and should be removed. In these cases the remaining ovary was seen to be enlarged, and the site of a small ruptured cyst was pointed out. The Fallopian tube was also enlarged, and the terminal vesicle of the Fallopian tube, or the hydatid of Morgagni, was enlarged and cystic. This hydatid sometimes attains the size of an orange, and often ruptures spontaneously without any bad effects. A few years ago, one of these small cysts ruptured while he was making an examination of the patient to ascertain its character.

DR. GOODELL exhibited a

CANCEROUS WOMB REMOVED PER VAGINAM.

In view of the very large mortality of the operation for the removal of the womb for the radical cure of uterine cancer, he had been unwilling to perform it. In most of the cases where the disease had been seen early enough by him to give a chance of success, the patient had been unwilling to take the risk. On one occasion when every preparation had been made to operate, the patient had a convulsion, and an examination of the urine showed a high proportion of albumen, in consequence of which he refused to operate. About a month ago, Dr. Chas. W. Dulles called on him in consultation to see a patient in whom the carcinomatous condition was limited to the anterior lip. The womb was movable. The case was put frankly before the patient, and all its dangers pointed out. The choice of them being given to her, she decided, after due consideration, to take the risks of the radical operation. The operation was not as difficult as he anticipated.

The first step in the operation was to scrape away all cancerous tissue, and to sear the remaining surface with Paquelin's cautery. The vagina was then thoroughly cleansed. A stout thread was passed through the cervix to draw down the womb, instead of using a volsellum, the handles of which would be in the way. A circular incision was made around the cervix, and the tissues were stripped up anteriorly and posteriorly to the reflection of the peritoneum, and laterally to the insertion of the broad ligaments. Finally, the peritoneum was opened, and the womb retroverted into the vagina by means of the obstetric crochet passed over the fundus. A strong thread was now passed through the body of the uterus, by means of which to manipulate it more easily. A ligature was now passed around the broad ligament of the right side, and secured it *en masse*, and a second double ligature was passed through it, and tied on opposite sides. This side of the broad ligament was then divided, the uterus drawn down, and the ligament of the left side secured in a similar manner, and divided. The vaginal wound was closed and dressed with iodoform and cotton. A frank peritonitis set in on the third day, and proved fatal on the fourth. The result made him doubtful whether the operation is ever justifiable; he indeed felt disposed to avoid it whenever possible.

DR. E. E. MONTOGMERY inquired about the feasibility of using the galvanic wire écraseur to divide the broad ligament, keeping the wire at a low red heat, and dividing the tissues slowly, and avoiding the necessity for a drainage-tube. Another method which he had been revolving in his mind was, by means of the galvanic knife, to dissect out the uterus, leaving the peritoneum intact, thus imitating, to a certain extent, the operation of Dr. Marion Sims, of scraping and the use of zinc chloride.

DR. GOODELL thought that Dr. Montgomery's galvanic wire would get too hot as the loop became small, and would then divide rapidly like a knife, and incur the danger of secondary hemorrhage. He feared that the steam generated by the hot wire would penetrate the peritoneal cavity, and have an irritating effect. He has a galvanic cautery-battery, but has not used it since the introduction of Paquelin's benzoline cautery, as he finds the latter far more handy and manageable. He thought Dr. Montgomery's suggestion of shelling out the uterus a good one.

DR. MONTGOMERY exhibited, through the courtesy of Dr. W. H. Warder, the

UTERINE APPENDAGES

which had been removed from a young lady for the relief of dysmenorrhœa, which had resulted in physical and mental failure. Menstruation had commenced at the age of fourteen years, had always been painful, and had developed hysterical manifestations. Bathing at the sea-shore had at one time stopped the periods for three months; after this her health failed; her mind had been seriously affected for the last three years, and she would run away, or do herself some violence at the menstrual periods if not closely watched. Examination: the uterus enlarged and tender; there was profuse leucorrhœa. The os uteri was dilated, and the uterine cavity scraped and cauterized with carbolic acid and bromides, etc., used internally, but no improvement resulted. The ovaries were removed today through abdominal section; catgut ligatures were used. The ovaries are very much enlarged, and contain small cysts. The abdominal wound was closed with silk sutures, and covered with an impervious dressing of collodion, cotton, etc.

HYSTERO-EPILEPSY AS A COMPLICATION OF PREGNANCY.

DR. WILLIAM H. SHIPPS, of Bordentown, N. J., sent the following contribution:

Briefly defined, hystero-epilepsy is a term applied to an abnormal neurotic condition in which are manifested certain phenomena characteristic both of hysteria and epilepsy. Out of two hundred and seventy-six patients confined at La Salpetrière Hospital, Paris, under treatment for various nervous affections thirty-two were diagnosticated by Beau, a careful observer, as suffering from this disease. Among this number the malady assumed either a distinct or combined form, hence he very wisely groups the cases into two classes. In the first, the hysterical seizures and epileptic fits remain distinct, one from the other; to this form he adapts the term given by Landouzy, and designates it as hystero-epilepsy with distinct crises.

In the second class, and the one of which this article furnishes an illustration, the hysterical and epileptic seizures are coeval, both developing at the same time; to this form the name of hystero-epilepsy with combined crises has been given. The object of this paper is, not to enter into a consideration of the disease as it is met with in general practice, but simply to examine it as a complication of pregnancy, a standpoint from which fortunately we are rarely called to view it.

During the early part of March, 1883, I was called to attend a woman said to be in a fit. Arriving at the house, I found, lying on a bed, a young woman apparently seventeen or eighteen years of age, of fairly vigorous physique, who was striving against the united efforts of two or three neighbors who sought to prevent her doing herself bodily harm in the violence of her struggles. Examination showed entire loss of consciousness, eyes open and staring, pupils widely dilated, frothing at the mouth, which was then tightly closed, pulse full and bounding. Inquiry elicited that during the day she had been visiting a friend, herself the subject of some spasmodic affection, and whilst in her company became greatly exercised by some trivial occurrence, and in this state of excitement returned home, which place she no sooner reached than she was seized with a convulsion. Her husband informed me that she was in the third month of pregnancy, and that prior to this morning had on one or two occasions attacks somewhat similar, though of less severity. I at once injected hypodermatically one-third grain of morphine, which in a short time was followed by a total disappearance of all spasmodic action, a state of stupor supervening from which in the course of three or four hours she aroused apparently as well as ever. On the day following, I was called to see her and found her in a state of high nervous excitement, sobbing and deploring the presence of some impending danger which she, in her imagination, insisted was threatening her. In a short time the stage of muscular contraction, loss of consciousness, stupor, etc., took the place of the hysterical symptoms, finally terminating as before in a return to her normal condition.

Without attempting to follow the case step by step, taking in all its details, and noting the many and peculiar phases through which it passed, it is interesting to note that prior to September 23, 1883, covering a period of two hundred days, not a day passed without the occurrence of one or more paroxysms. At times the hysterical phenomena would be most marked and usher in the attack; then again the epileptic fit would take the precedence, always, however, accompanied by the undeniable imprint of the dual disease hystero-epilepsy. In the inter-paroxysmal period she enjoyed for the most part average good health.

On the morning of September 23d, I was asked to see her in an attack of more than usual gravity. When I reached the house she was profoundly unconscious, and had been so for several hours. The time for her approaching labor being near I made a vaginal examination, but found no evidence of commencing uterine action. I ordered a hot mustard bath, mustard to the extremities, and bromides the moment she should be able to swallow. In the evening, when I again called, her condition was apparently unchanged. I then ordered a blister to the nape of the neck and left the patient, to return early in the morning. At 7 A.M., a messenger called stating that the woman was now perfectly rational, and, to all appearance, in labor. I at once responded and found that she was having bearing down pains of moderate intensity at intervals of five or ten minutes, mouth of womb dilating, vertex presenting. I remained by the woman's side until 3 45 P.M., when the child, a healthy female weighing nine or ten pounds, was born. The labor did not differ from ordinary labors, except that it was only by the utmost vigilance that the woman was prevented falling into one of her accustomed attacks. After the birth of the child, I gave it to the mother, at the same time remarking to her, that, as she valued the life of the child, under no circumstances to allow herself to have another convulsion. She promised faithful obedience, and up to the present has not shown the first indication of her old trouble. It should be mentioned that during the entire period the patient was under observation, she had daily taken large doses of the bromides and other nervines, without any effect save perhaps in ameliorating the number and violence of the paroxysms. The case is interesting on account of the rarity of the disease as a complication of pregnancy; its persistence throughout the entire period; its resistance to all remedial measures, and the final disappearance of all symptoms after the termination of labor.

Two queries very naturally present themselves: What was the exciting cause of the attacks? Would the induction of premature labor in this and similar cases be justifiable?

In answer to the first query, I attribute the attacks to an action upon the brain and spinal cord, reflex in its nature, and developed or excited by the fœtus in utero.

The happy termination of the case would seemingly offer a negative to the second query; but better judgment will, I think, suggest the wisdom of the operation, and the danger of refusing to employ what theoretically at least offers the only chance of relief; at all events, in a similar case I would most certainly have recourse to the operation, and expect from it the best results.

CORRESPONDENCE.

ACTINOMYCOSIS IN ANIMALS.

To the Editor of THE MEDICAL NEWS.

SIR: In your report of the Detroit Meeting of the American Public Health Association I am represented as denying "that the recognition of the actinomycoccic character of the disease (of the jaws of cattle) was of so recent a date as claimed." Your readers will naturally infer that I deny the priority of Bollinger's demonstration of actinomycosis. Nothing could be further from the truth. What I do deny is the claim put forth by Dr. Belfield in his paper, that he was the first in America to demonstrate the existence of the actinomyces in this disease. The fact is that ever since Bollinger published his observations, I have taught the true nature of the disease to my classes, and in February last, in connection with a diseased herd about which I had been consulted, I brought the matter before the Medical Society of Tompkins County, N. Y., exhibiting a number of microscopic slides of the fungus and stating the known facts as to its development in the bodies of men and animals. The following note from the Secretary of the Society gives quotations from the minutes of the meeting in question:

"ITHACA, November 26, 1883.

"PROF. JAMES LAW.

"DEAR SIR: In answer to your inquiries, I here transcribe from minutes of a meeting of the Tompkins County Medical Society, held February 21, 1883, at Ithaca, the following record:

"'Prof. Law favored the Society with a clear statement of the nature and symptoms of actinomycosis occurring in various animals, and sometimes in man, and exhibited to us the cells of the fungous growth under the microscope.'

"Respectfully,
"S. P. SACKETT,
"Sec. of Tompkins Co. Med. Soc."

About the same date I showed the slides of actinomyces to several of my colleagues in the natural history department, to Dr. Wey, Jr., of Elmira, and others.

In a recent case about which I was consulted by a former student now raising stock in Montana I advised the excision of the fungus as far as possible, and the thorough treatment of the sore with iodized phenole. The result is given in this letter.

"FORT BENTON, M. T., July 22, 1883.

"PROF. JAMES LAW.

"DEAR PROFESSOR: I have been meaning to write you for some time on the result of my operation on the big-jaw. Immediately on the receipt of your letter I decided to try the experiment of cutting it out. The disease had run pretty long, and I was astonished to find it had eaten a cavity from the lower edge of the bone up along the teeth, about two inches wide at the upper edge, and in places cavities three-quarters of an inch deep. I had nothing but ordinary scalpels, and found it impossible to do it properly. I scraped the bone as well as I could, and painted it with carbolic acid and tincture of iodine. And here was the trouble: the blood and saliva were running so freely that they carried the medicine into the mouth, and the cow was continually sucking through the wound and swallowing. For a long time I thought she would die, as she became a mere walking skeleton, seldom lying down. I thought this was due to the burning of her stomach with the iodine and the acid. I found, by feeling, that the fungus was growing anew, and I painted it thoroughly again with iodine, being careful not to get it into her mouth. Since then she has picked up wonderfully, the wound has healed up, the disease is apparently killed, and the cow is getting fat. I am confident now that I can cure it if taken in time, and am very glad I made the experiment. I had no means of preserving any of the fungous growth, but send some of the fragments of bone that were in it. . . . .

"Resp'y, your old pupil,
"EDWARD C. RUSSEL."

The fragments sent proved as I had expected, that the *big-jaw* of Montana was identical with the already familiar actinomycosis of New York.

I state these facts not because the question of priority in demonstrating the actinomyces in America is a matter of any great importance when the pathology of the well known disease had been once discovered by Bollinger, but because of the statement in Dr. Belfield's paper, that American veterinarians were still ignorant of the true nature of the malady, and looked on it as a scrofulous affection—a mistake into which I regret to see you also fall, notwithstanding my prompt repudiation at the Detroit meeting. As further illustrating the fact of the prior recognition of the actinic fungus in America, I may state that Professor Taylor, of the Agricultural Department at Washington, has for a length of time recognized the actinomyces as growing in the lungs of dogs, and has cultivated the same artificially.

This susceptibility of the dog to the attacks of the fungus, which has been corroborated by Vachetta (Osteochondro-sarcoma macrocellulare con Actinomyceti alla mandibola inferiore d'un Cane, *La Clinica Veterinaria*, 1882), implies, as in man, the probable implanting of the disease from another source than grain, as neither of these genera consume grain in the uncooked condition. The dog can in no sense be called a graminivorous animal, so that the theory of Dr. Belfield, that the disease is peculiar to such subjects, is no longer tenable.

Though much remains to be learned as to the mode in which the germs are implanted in the tissues, the notorious predilection which they show for the vicinity of carrion's teeth, for the tongue, and for the pharynx strongly suggests that at the outset they usually secure a foothold in the morbid products of a sore, or in the partially devitalized tissues that are undergoing inflammation, and that once fairly seated their invasion of new tissue advances steadily in the products of the resulting peripheral inflammation. In a case which I saw in the Chicago Stock-yards, through the courtesy of Drs. De Wolf and Belfield, the disease extended on both sides of the upper jaw, around a pair of molars which had made an imperfect eruption, and which still remained so far beneath the level of their fellows that the enamel had not been worn off their tables. Between these teeth and the next adjacent ones were cavities filled with the débris of food. In the majority of cases that I have seen, diseased teeth or alveolæ have been a prominent feature. This, taken with the fact that the malady so often starts in the jaws of the young, about the period of the second dentition, suggests a frequent etiological connection with dental disease. When actual disease of the teeth has not already existed, there is still the presumption that the actinomyces had become lodged in the cavity left after the evulsion of the deciduous tooth, and before the growth of the permanent one, seeing it could then make its way so easily through the irritated and inflamed periodontal membrane into the osseous tissue beneath. In other cases, doubtless, the germ makes its way through the superficial abrasions which are so liable to happen about the mouth in vegetable feeders.

The precise measure of the danger to man must be determined in the future. We must ascertain by experiment the temperature at which the fungus is destroyed in cooking; also in what medium it lives out of the animal body, and its consequent opportunities for entering the body in food, water, and air. The discovery of the fungus already in over thirty human bodies, the frequency of the disease in such a large class of quadrupeds, and the especial liability of the herbivoræ (ox, horse, goat, swine, rabbit) implying the probable growth of the fungus on vegetable products, invest the disease with an importance which must command the attention and investigation of sanitarians. There is reason to believe that the malady is indigenous to certain districts. I have known it to attack three successive generations of cattle living in the same place. Again, in certain herds, I have seen as many as four or five individuals suffering at the same time. Yet I have not, so far, been able to trace any etiological connection with a particular geological formation, nor with any peculiarity of the flora. Its connection with grain-feeding is probably quite as much owing to injuries to the teeth and gums from the flinty seeds, as to these being the true vegetable habitat of the fungus. This is the more probable since we find the disease on the pastures of Texas and Montana in cattle that have never seen grain, and in the distillery stables at Peoria and elsewhere, among cattle drawn from the pastures in question, and fed grain only as distillery swill, which has been subjected to a boiling temperature.

Respectfully,
JAMES LAW,
Professor of Veterinary Medicine.

ITHACA, N. Y., November 28, 1883.

OBITUARY.

THOMAS STORY KIRKBRIDE, M.D., LL.D.

DR. THOMAS S. KIRKBRIDE, Physician-in-Chief and Superintendent of the Pennsylvania Hospital for the Insane, died on Monday morning, December 17th, after a protracted illness, at his residence, within the grounds of the institution which, for over forty years, he had faithfully served.

Dr. Kirkbride's habitually vigorous health sustained a severe shock four years ago in a prolonged illness, from the effects of which he only partially recovered. About two years ago, he had a second illness, from which again he rallied, and last winter he was able to resume a considerable portion of his ordinary duties. In the spring, he was again, however, prostrated, and never rallied to any hopeful extent. During the last few weeks, there have been periods of temporary improvement, and he has even been able to drive in the Hospital grounds. On December 14th, he had a severe chill, and gradually relapsed into coma, from which he never rallied.

Dr. Kirkbride was born on July 31, 1809, near Morrisville, Bucks County, Pennsylvania. His ancestor, Joseph Kirkbride, came to this country from the parish of Kirkbride, County of Cumberland, England, with William Penn, being connected with the Society of Friends, as have been his descendants down to the present generation. He received his academical education at Trenton, N. J., and graduated from the Medical Department of the University of Pennsylvania, in March, 1832, the subject of his thesis being "Neuralgia." In the following April he was appointed resident physician to the Friends' Asylum for the

Insane, in which position he served for one year, when in March, 1833, he was elected resident physician to the Pennsylvania Hospital, where he remained two years, after which, settling in Philadelphia, he engaged in private practice, devoting himself principally to surgery, and at this time he was physician to the House of Refuge, the Institution for the Blind, and the Magdalen Asylum.

In October, 1840, without solicitation on his part, Dr. Kirkbride was elected Physician-in-Chief and Superintendent of the Pennsylvania Hospital for the Insane, a new institution on the west side of the Schuylkill River, then nearly completed, and to which it was intended to remove the insane from the old hospital at Eighth and Pine Streets. The new hospital was opened on the 1st day of January, 1841, since which time he has had the care and management of it. By constant improvements and additions to the original building this institution, which was then only capable of receiving a hundred inmates, now accommodates upwards of five hundred. In 1854, the original building having become crowded, Dr. Kirkbride recommended the erection of a new one on the grounds of the institution, which comprised a tract of one hundred and thirteen acres, and he urged the complete separation of the sexes as though in two distinct institutions. He further recommended that the building proposed should be erected through an appeal to the public, which, accordingly, was made, and with entire success, the building being completed wholly with private contributions, exceeding in the aggregate $355,000. This new building was a third of a mile distant from the other. It was erected in accordance with his own carefully prepared plans, and is so admirably adapted to the purposes for which it was intended, that it has been a model for similar buildings which have been subsequently erected. The new building was opened in October, 1859, and since that time the Pennsylvania Hospital for the Insane has consisted of two separate departments—one for men and one for women—each having a capacity for two hundred and fifty patients, and entirely distinct from each other in all their arrangements, though with the same physician-in-chief and the same board of managers. The success of this experiment, which he inaugurated, has been complete, and has led to the adoption of the plan in other institutions.

As an authority in mental disease, Dr. Kirkbride enjoyed the highest reputation, and his name was so identified with the great institution of which he was the physician-in-chief, that "Kirkbride's" has become in this country the popularly used synonym of the English "Bedlam." He was a careful student, and possessed marked executive ability. His faithful devotion to the interests of the institution confided to his care has frequently elicited the admiration of its managers.

Dr. Kirkbride was of square build and medium height, with a firm mouth, penetrating eye, and a charmingly benevolent face, which was expressive of his great modesty, spotless integrity, and rare virtue. He was endowed with a wonderful tact in the management of the insane, and he was able quickly to win the affections of even his most wayward patients, and his forbearing gentleness and wise firmness enabled him to exert the best influences upon all who came under his care.

His writings have given him a high reputation. His "Propositions relative to the Construction of Hospitals for the Insane," first adopted by the Association of Medical Superintendents of American Institutions for the Insane, has been repeatedly reaffirmed by them, and were published in 1854, with notes and additions, under the title of "The Construction, Organization, and General Arrangement of Hospitals for the Insane," of which a second edition was called for in 1880. In his annual reports Dr. Kirkbride, year by year, discussed at length, nearly every subject connected with the treatment and care of the insane, and they constitute a series of great value to the student of mental diseases.

No man in the United States has devoted himself more entirely to the care of the insane than Dr. Kirkbride. From the day of his appointment to the superintendency of the Pennsylvania Hospital for the Insane, his whole thought was given to whatever would tend to relieve the mental disorder of those placed in his care, and everything which could in any way assist in that work was laid under tribute from the firm belief he entertained that nothing should be overlooked, for a reason clear to every one that small things often have a great influence in turning the current of thought and diverting to happier or more gloomy thoughts as the incident may itself determine. No one can read the very able, conscientious, and practical reports which have emanated from him during more than forty years without being fully convinced that his whole energy was given to his work, and the results of that work are shown in those reports, and in his work on the "Construction of Hospitals for the Insane," which places the reader in possession of practical conclusions and sound deductions from long experience, which can be relied on while the shifting sands of theory are blown away.

The wonderful changes which have been effected in the last forty years in the treatment of the insane may, in great part, be attributed to his labors and his influence on his brethren connected with the different institutions. The amount of restraint used at that early date was greater than even those who write so much on the subject know, and Dr. Kirkbride's efforts to change that condition of things were earnest and persistent, and, while not a believer in absolute non-restraint, so zealously advocated by some whose experience is infinitesimal when compared with his, he yet held firmly to the opinion, as he did to all that he had formed cautiously and deliberately, that restraint should be used only when the condition of the case, and the benefit of his fellow-patients, really demanded it, or, in other words, on the same principle that a surgeon would apply a splint to a broken limb; and the truth was strongly expressed by Dr. Bucknill, of England, that while Dr. Kirkbride believed in restraint, he rarely used it.

Dr. Kirkbride was one of the founders of "the Association of Medical Superintendents of American Institutions for the Insane," and for eight consecutive years was its President. He was also a Fellow of the College of Physicians of Philadelphia, an Honorary Member of the British Medico-Psychological Association, and a member of the American Philosophical Society. His wife and six children survive him.

NEWS ITEMS.

BALTIMORE.

(*From our Special Correspondent.*)

The Johns Hopkins Lectures on Municipal Hygiene.—The last lectures of Dr. J. S. Billing's interesting and instructive course on *Municipal Hygiene*, have now been delivered at the Johns Hopkins University. It is to be hoped that the important matters which he discussed will not be overlooked by the health and other municipal authorities, and that many evils to which he called attention, will soon be remedied. Below is an abstract of the last four lectures.

Schools and Education.—School-regulation, a most important subject in municipal hygiene, should be under the supervision of the city; legislation on this point being just as appropriate as against the overcrowding of steamers, tenement houses, etc. The dangers of school-life to health, both in public and in private schools, are of three kinds: 1. Those connected with the plan and location of the school building. 2. Those connected with the course of studies. 3. Those connected with the spread of contagious diseases. Those of the first class are due to insufficient size of building for the number of pupils, to insufficient ventilation, and bad light. In school building, these points and security from fire are most important things. Many children, especially Germans or of German descent, have eyes slightly abnormal, which abnormality is often increased by school-life. Many think that the number of abnormal eyes is increasing; and though the increase is supposed to be due to better methods of diagnosis and increased attention to the subject, the balance of evidence lies on their side. Shortsightedness is more common in city schools than in those of the country; this is probably due to the greater amount of study done at night, especially with the ordinary flickering gas-flame in the city. In schoolrooms the light should come from the left side, or, much better, from both sides. In regard to *ventilation*, each student should have thirty feet of pure air per minute to keep the air in the schoolroom pure. To supply this steadily and without draught, requires special arrangements, careful supervision, and a great amount of fuel (to make up for the great amount of heat lost in escaping air). The desk should be of proper height for the child, and the seat should properly support its back.

The duty of municipal authorities to provide for these requisites cannot be avoided on the ground of insufficient appropriation. The *elementary schools should first be provided for*, and then money may be spent upon schools for higher education, but not before. An important fault in our methods of education, is too much study at home. The teacher should instruct, and not simply hear the pupils recite. It is now acknowledged that the object of school-education is not so much to teach facts, as to instruct them how to think, and ascertain facts, etc. The evils from excessive study fall most heavily on girls between the ages of thirteen and seventeen, in whom they often only appear a few years afterwards. The principal diseases which are communicated by schools, are diphtheria (especially in America), scarlet fever (most important in England), and measles. It is found that there is a regular increase in the number of cases of diphtheria when schools are opened and a decrease at their close. These diseases are not only communicated through the air, but also directly by drinking from the same cup, eating the same apple, putting pencils in mouth, etc. The way to avoid these is by employing constant skilled medical inspection, as is done in Brussels, where there has been no epidemic, though there have been in neighboring cities since the system has been introduced. This inspection should not be confined to the public schools, but also to private, day, and boarding schools.

Food, Markets, etc.—The health of a community depends on the quantity, quality, and regularity of its food supply. To bring just enough diversified supply of food for a city is accomplished, not by any deliberate exercise of human wisdom, but by men each interested in himself, but who unconsciously combine to effect an object, the vastness of which is bewildering to contemplate. Our supply of *meats* is good and ample, and there is little danger in eating them. The germs of infectious diseases which might be communicated by them are killed by thorough cooking (as is that of tuberculosis, too, in all probability). There is great danger, however, to cleanliness in having many private slaughtering houses. The way to obviate this is by having a public abattoir, either managed by the city or by a firm with power granted by the city. In Boston, the leading butchers took the first step in establishing one. *Vegetables*, by not being always brought to consumers in a fresh state, cause various diseases of the digestive organs. *Milk* is one of the most important articles of food, and one most liable to carry disease. Being a fluid rich in all elements of nourishment, it becomes an excellent culture fluid for germs. A drop of polluted water can fill a can of warm milk in a short time with the germs of various diseases. Great epidemics have been traced to milk which may have been rendered dangerous by adulteration with water, by rinsing cans with bad water, or by having been in the house of a dairyman whose family was suffering from a contagious disease. The flow of milk usually stops in diseased animals. Milk of a tuberculous cow sometimes causes tuberculosis in a child or an animal raised on it. The high rate of mortality among infants is due to want of proper food (mothers' milk or its next best substitute, fresh unskimmed cows' milk, sweetened and diluted). In tenement-houses in New York, infants of three months are often fed on the food of the rest of the family. It would be well to put some one firm in charge of all skimmed milk and prohibit all others from selling it, so that this article of food would not be taken from the poor, who are unable to procure other milk. *Oleomargarine* (when made from pure, sweet fat) and *glucose* are both useful and healthy. *Spices* and *coffee* are very often adulterated, but seldom objectionable from a sanitary point of view. That there is not much danger from *canned food* can be seen from the rare cases of poisoning reported, and the vast number of cans used. The salts of tin are not poisonous in small quantities, and in large quantities they would be unpleasant to the taste. A few cases of lead-poisoning have been reported (one, by the way, in The Medical News for September 8, 1883, by a Maryland physician; but since, Dr. Billings has had those cans examined and analyzed under the supervision of Prof. Remsen, and no trace of lead could be found in the contents). It is well known that there is danger of poisoning from wall-paper with arsenical colors, which is now, however, much less common than formerly. The effects are often slight ailments, mistakable for other things. On the other hand, there is no danger to the inmates of a room of lead-poisoning in freshly painted rooms, though there is to the painter. A source of great danger are the *adulterated drugs*, which may deceive the physician by their action and cause him to make an erroneous diagnosis, at times to the injury of the patient, or even his death.

Jurisprudence of Hygiene.—In sanitary legislation the interests of the many conflict with those of individuals. Who shall yield or compensate the others? It may seem as if the State were interfering with liberty when she bids the householder to ventilate his drains in a certain way; the physician to keep record of and report deaths, etc. But it is not. The State has the right of eminent domain, *i. e.*, to take private property for public use when necessary; to demand service of individuals, and to furnish compensation for the same. The State has police powers by which she prohibits the storing of gunpowder, regulates the height of buildings, and the location of hospitals for contagious diseases, etc. Upon the plea of nuisance, she can interfere in privileges established by ancient customs, etc.; and she has the right to avail herself of the light of modern science. The power of cities to do the same is limited by considerations of cost. Many of our cities are so burdened with debt that they say they cannot afford to spend money on sanitary improvements; but since these soon pay for themselves in money and labor saved and distress avoided, this plea can rarely be admitted as an excuse for permitting unsanitary conditions to remain. In this case, appeal must be made to the State. Law and equity are two distinct things. The common law says that the use of one's own property to the injury of the right of another is a nuisance; but it does not say what amount of discomfort. The importance and utility of a business have great weight in judging the question. As regards public health, the common law may be summed up "So to use thine own that thou dost not injure another;" but the remedy comes too late; pecuniary damages cannot compensate for ruined health and lost lives. In sanitary legislation, definitions of nuisances, descriptions of modes of procedure against them, should be as precise as possible. The State ought to provide for a full record of times and number of births, marriages, and deaths; for the gathering and dissemination of knowledge relative to the preventable causes of disease and death; for good drainage and sewerage; for the supervision of dead human bodies, cemeteries, etc.; and where needed for quarantine authority, and should give discretionary powers to boards of health of acting promptly and fearlessly, for subordinating private comfort to public safety, and for making all needful expenditures to avert and alleviate pestilence. The word quarantine is now used in two different senses: (1) the detention for a fixed time as a test of the presence of contagious diseases in suspected vessels (which carried to extreme is non-intercourse), and (2) maritime inspection to secure clean and healthy ships, which requires a short detention. Against smallpox, quarantine is of little value, except in compelling vaccination. If the community is vaccinated, and it should be constantly vaccinated and revaccinated, this is unnecessary, and if unprotected it is no preventative. Quarantine against *cholera* is efficacious, except when the disease has already a foothold. Since cholera appears here two years after it appears in Europe, it is highly probable that *we will have it here in a few years*, for it promises to appear in Europe next year. Our streets should be disinfected above and below the surface; all causes of soil pollution removed, etc., so that our cities are clean, when they will run little danger. To get a perfectly satisfactory quarantine, coöperation is necessary, not only between States, but among nations; yellow fever can be better kept away from this country if we inspect at Havana and other West India seaports, than at our own harbors. We have no simple preventatives against measles, scarlet and typhoid fevers, but by immediate notification and proper isolation much can be done.

Health Departments and Health Officers.—A single health officer for a city succeeds better than a board. Health officers should not be engaged in private practice, which, in various ways, would interfere with the proper exercise of his duties. The appointments should be made for not less than six years, and the compensation should be not less than $3000, and in large cities at least $5000 per annum. The appointment should be made by city officials. Competent medical men who are willing to give up a good practice to become health officers are few. We have not, as yet, men who are especially educated for that purpose, but we hope soon to have such provisions here, and to be able to send men from the Johns Hopkins University, with requisite guarantees as to fitness for such work. There are great difficulties in public hygiene; one great difficulty is ignorance—both want of information, which is easily removed, and misinformation, which is very difficult to clear up. If a man is about digging a cesspool near a well you can easily convince him of the danger, but it is difficult to show a man who has been drinking water from a well in the neighborhood of a cesspool, that there is danger, for he has used it for so many years without harm, and it sparkles and tastes so well (often from the salts dissolved from the cesspool. Another objection is the increase of taxes, cost, etc. This ignorance is being very slowly removed by the press, lectures, etc., but the best place is in the primary and normal schools.

Statistics should be kept of private premises, and this can be best done by clubs, entirely separated from city authority, such as that of Chicago.

Yellow Fever in Mexico still prevails, there having been twenty deaths from this disease at Acapulco during the last week of November. At Manzanillo all industries are in a state of decadence due to the scourge, which Assistant Surgeon Main states still continues to be the reigning terror—agriculture particularly is paralyzed. The necessities of life are scarce, almost amounting to a famine. To this is added the calamity of a strike among the day laborers and seamen in the port. Assistance has been sent there, and funds are being collected for sufferers at all the ports of the Republic—about $20,000 have so far been collected. President Gonzalez advises all places of interment of those dying of yellow fever, be covered two inches deep with unslacked lime, to prevent the exhalation of miasmatic poison. At Vera Cruz there are a few sporadic cases of yellow fever, from which it spread to Orizaba, where a good quarantine was kept up till the 20th of October, but was raised on the supposition that all danger had passed. It broke out in a malignant form, became epidemic, and was still prevailing on the 23d of November. The Governor of Sinaloa was among those attacked with yellow fever, but recovered.

Yellow Fever in Havana.—Total deaths from yellow fever at Havana, Cuba, for the week ending December 8, 1883, reported by Sanitary Inspector Burgess, is stated to be twenty-three.

The Cholera in Egypt.—The State Department is in receipt of a communication from the U. S. Consul-General at Cairo, Egypt, giving an account of the cholera epidemic in Egypt, which he obtained in a letter from His Excellency, Dr. Salem Pasha, President of the Egyptian Sanitary Council, in answer to an official request for the same. The report is accompanied with detailed statistics, fixing the number of deaths from cholera, officially reported from the 22d of June, 1883, to the 1st of September, 1883, at from 48,000 to 50,000 persons. A translation of the closing portion of the letter referred to is herewith given:

"As to the total number of mortality, the Council of Health is engaged in collecting precise statistics, and from those already obtained, the number of victims can be stated at from 48,000 to 50,000.

"As the Department is doubtless already informed by telegraphic despatches, and from other sources, the cholera, after having completely disappeared, again, about twenty days ago, reappeared at Alexandria, from which there have been officially reported from three to twelve deaths daily. In other parts of Egypt the epidemic seems to have completely disappeared, and the general health of Egypt has resumed its normal condition.

"In transmitting to your Excellency these official statistics, I deem it my duty to add that it has been found, upon a more careful verification, that the Official sanitary bulletins published during the prevalence of the epidemic were very erroneous, owing principally to the want of proper organization and sufficient number of agents in the Sanitary Department. As one example of these errors, on the twenty-fourth day of July, the sanitary bulletin fixed the number of deaths in Cairo at 465, when, from other reliable sources, notably the police statistics, the deaths exceeded 1200.

"It is generally believed, in well-informed official circles, that the final result of inquiries, especially in the remote villages, will establish the number of victims from cholera during a period of nearly four months, from between 65,000 and 70,000.

"It will be interesting at another time to note the economic effects of this terrible destruction of life upon the prosperity of this unfortunate country.

"In many villages of the interior, a majority of the laboring population has died, and, in some instances, nearly entire communities have disappeared, so that not sufficient effective hands remain to cultivate and harvest the crops."

The deaths from cholera at Calcutta, for the week ending October 27, 1883, are reported to have been 20 out of a total of 243.

College of Physicians of Philadelphia.—At the December meeting of the College *the Annual Report of the Library Committee* was presented, showing that there have been added to the library this year—

2186 volumes,
2107 pamphlets,
2862 numbers of journals.

The total number of volumes now in the library is 26,359. For the ensuing year, the Library will be kept open, except on Sundays and legal holidays, from ten o'clock A. M. to five P. M.

There are in the collection 3381 duplicates, and particular attention was called to this fact, inasmuch as it affords a rare opportunity to other libraries, of augmenting their list at comparatively small expense.

The Report of the Committee on the Directory for Nurses showed that the number of nurses registered

December 1, 1882,			209
Added during the year,.		104	
Lost by striking from roll,	6		
Lost by withdrawal,	4	10	
Net gain,			94
Present number,			303

Total number of nurses furnished during the year, 733—an average per month of 61, as against 49 for last year.

Largest number (February),	84
Smallest number (August),	34
Sent outside of the city, but within the State,	63
Sent to other States,	59
Wet nurses furnished,	17
Of registered nurses, there are males,	39
" " " females,	264
Graduates of training schools,	60
Non-graduates,	243

Many physicians take great trouble and waste much valuable time in hunting up nurses personally; or, having obtained a good nurse through the Directory, they transfer her from one patient to another directly, instead of through the Directory. Were they to use the Directory they would obtain the *same* nurses, and add to the income of the Directory, and so to the appropriation to the Library.

It is the desire of the committee to make the Directory also a bureau for all needed information for the sick; and they have in contemplation measures by which, if any one desires to obtain boarding in the country, or at the seaside, for cases of whooping-cough, or for recent cases of measles, scarlet fever, or diphtheria; and for information concerning all appliances for the sick, such as invalid-chairs, wheel and other crutches, bed-rests, fracture-, water-, or air-beds, etc., he may obtain the object he seeks at the Directory.

The amount given to the library during the last year was $200, and for the present year, $300.

Dr. Albert H. Smith will sail from Liverpool on December 22d, after an absence from home of six weeks. Dr. Smith's friends will be greatly gratified to learn that his health is much improved. While in London he was under the professional care of Sir Henry Thompson, who entertains the opinion that under appropriate treatment he will get perfectly well.

Dr. Smith has just paid a brief visit to Edinburgh, where he was the recipient of much hospitality, and was so fortunate as to see Keith perform one of his brilliant ovariotomies.

Health in Michigan.—Reports to the State Board of Health for the week ending December 8, 1883, indicate that intermittent fever, rheumatism, and influenza have increased, and that bronchitis, erysipelas, and diphtheria have decreased in area of prevalence.

Including reports by regular observers and others, diphtheria was reported present during the week ending December 8th, and since at fifteen places; scarlet fever at twenty-three places; and measles at nine places.

Obituary Record.—At Boston, on December 16th, Calvin Ellis, M.D., Jackson Professor of Clinical Medicine in Harvard University.

Dr. Ellis was educated at Harvard and received his degree in the arts in 1846, and in medicine three years later. He was one of the attending physicians to the Massachusetts General Hospital for a number of years, and Dean of the Harvard Medical Faculty.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM DECEMBER 10 TO DECEMBER 17, 1883.

Campbell, John, *Lieutenant Colonel and Surgeon.*—Having completed the duties pertaining to the office of the Medical Director of the late Department of the South, to proceed from Newport Barracks, Kentucky, to New York City, and assume the duties of Attending Surgeon in that city.—*Par. 12, S. O. 284, A. G. O., December 12, 1883.*

Clements, Bennett A., *Major and Surgeon.*—Relieved from duty as Attending Surgeon, New York City, and detailed as member of Army Medical Examining Board, now in session in New York City.—*Par. 12, S. O. 284, A. G. O., December 12, 1883.*

McKee, J. C., *Major and Surgeon.*—Assigned to duty as Medical Director, Department of the Columbia.—*G. O. 31, Department of the Columbia, December 3, 1883.*

Williams, John W., *Major and Surgeon.*—Leave of absence on surgeon's certificate of disability granted in S. O. 157, November 12, 1883, Department of the Columbia, extended five months, on surgeon's certificate of disability.—*Par. 6, S. O. 286, A. G. O., December 14, 1883.*

Shufeldt Robert W., *Captain and Assistant Surgeon.*—Now on sick leave, relieved from duty in the Department of the East, and assigned to temporary duty in the office of the Surgeon-General of the Army.—*Par. 12, S. O. 284, A. G. O., December 12, 1883.*

The Medical News *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the News *should be addressed to No. 1004 Walnut Street, Philadelphia.*

ORIGINAL ARTICLES.

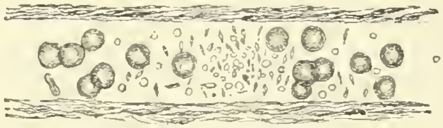
THE THIRD CORPUSCLE OF THE BLOOD.

BY WILLIAM OSLER, M.D., F.R.C.P. LOND.,
PROFESSOR OF THE INSTITUTES OF MEDICINE IN MCGILL COLLEGE, MONTREAL.

IN addition to the red and white corpuscles, there are in the blood granular bodies of various size, from that of a red corpuscle to masses ten to twenty times as large. These were first described by Max Schultze, and they may be called very appropriately, as I have been in the habit of doing for years, "Schultze's granule masses." In healthy adults they are not abundant as a rule, though exceptionally in persons in apparently good condition they abound. In all cachectic states the granule masses are large and numerous. They form notable features in blood specimens from cases of chronic phthisis, cancer, and wasting diseases generally; also in leukæmia and symptomatic anæmia; but it is not a little remarkable that in pernicious anæmia they are scanty, or even absent. In the lower animals the masses are met with in variable numbers. The blood of the young contains them in larger proportion than in adults. The new-born rat, kitten, rabbit, or guinea-pig may be used with advantage for their study. So common are they in the blood of hospital patients that it is not to be wondèred at if mistakes have arisen concerning the signs of their presence in certain diseases. Thus, in *The Lancet* a few years ago, a gentleman described them under the heading of "a new feature in leucæmic blood," regarding them as specific or characteristic elements.

I have been told of a somewhat prominent London physician, connected with one of the special hospitals for chest diseases, who found them so constant in the blood of phthisical patients that he regarded them as peculiar to the disease, until advised by a colleague of their wide distribution. The most extensive observations upon their presence in disease were made by Dr. Reiss.[1] The common opinion regarding them has been that they represent degenerated white blood-corpuscles, or a granular detritus resulting from their decay. I first showed that they were composed of distinct corpuscles, and that the masses did not preëxist in the blood, but were formed at the moment of withdrawal by the aggregation of the corpuscles. At the edges of large groups, the disk-like corpuscles can be distinctly seen, and in the sulphate of soda solution, such as used for mixing the blood in hæmocytometer work, the corpuscular nature of the masses is quite clear. But what led me to this point was the fact of the impossibility of supposing that masses of the size of some of these could pass through the capillaries. Reiss felt the same difficulty, and suggested that in some cases they might produce embolism. In the blood of the new-born rat they are most abundant, and the subcutaneous tissue was employed to investigate the condition of the masses within the vessels. It was then found that they do not preëxist as aggregations in the blood, but are in the form of isolated corpuscles floating free with the other forms. By far the simplest way of demonstrating the isolated corpuscles in the vessels is to snip a small bit of the subcutaneous tissue from a young rat, and examine in salt solution.

FIG. 1.



In a small artery or vein, there will be seen with the red and white cells small, pale corpuscles about one-fourth the size of the red ones, often in extraordinary numbers (Fig. 1). A drop of blood from the tail of the same animal will show numerous granule masses, at the edges of which the corpuscles can be seen. The corpuscles swell in water, and become pale: dilute acetic acid renders them more distinct; they stain with carmine and methyl-violet. The corpuscles are discoid, pale, structureless (Fig. 2),

FIG. 2.

and often undergo peculiar alterations in shape, elongating or presenting two or three fine hair-like extensions. They measure from $\frac{1}{8000}$ to $\frac{1}{12000}$ of an inch. The largest I have measured was $\frac{1}{5000}$; and the smallest are from $\frac{1}{15000}$ to $\frac{1}{20000}$.

The facts above given are from my paper before the Royal Society in 1874, which was published in the *Proceedings* for June 18th of that year. A considerable part of that communication was taken up with describing the changes in form which the corpuscles undergo when kept for some hours at the temperature of the body, and examined in blood-serum; but the corpuscles were described and figured, and a true explanation given of the structure and formation of Schultze's granule masses. These bodies are undoubtedly the same as those described by Zimmerman[1] as elementary corpuscles which he found when blood was let flow into a solution of a neutral salt; after the subsidence of the colored elements, the supernatant serum contained, in extraordinary numbers, small, round, colorless corpuscles with weak contours.

---

[1] Reichert u. DuBois Reymond's Archiv, 1872.

[1] Virchow's Archiv, Bd. xviii.

In 1877-79, Hayem, of Paris, investigated these bodies very carefully, and by special modes of preparation and examination was enabled to isolate them and prevent their aggregation into masses. He called them hæmatoblasts and believed that they represented embryonic red corpuscles.

From this time on, until last year, little or nothing new concerning these bodies is met with in medical literature, when in a series of papers in the *Centralblatt f. d. medicinischen Wissenschaften*, and more fully the November number of Virchow's *Archiv* (Bd. xc.), Prof. Bizzozero, of Turin, described anew the corpuscles and advanced important views concerning their connection with the process of thrombosis and coagulation. His account of the corpuscles, which he calls "Blutplättchen" (blood-plates), differs in no essential particular from that which I had already given, and his figure of them in a small bloodvessel (Pl. V., Fig. 2, Virchow's *Archiv*, Bd. xc.) is similar to my original one reproduced here in Fig. 1. The observations upon the connection of the corpuscles with thrombus formation are novel and important. When a vessel-wall is injured, or when any foreign body is introduced, the earliest observable phenomenon is the collection of the blood-plates on the wounded spot or on the foreign substance. The white corpuscles appear later and are much less numerous. The blood-plates rapidly change, becoming fused or united together and converted into a granular substance, and this dissolution or disintegration appears intimately associated with fibrin formation. In a portion of a vessel sutured between two ligatures the blood remains fluid so long as the blood-plates retain their normal form and appearance.

The influence which Schmidt and others attribute to the white corpuscle in coagulation, Bizzozero believes is due to these smaller elements. Certainly no such rapid disintegration of the colorless corpuscles takes place, as is spoken of by some writers. Under favorable conditions they may retain their vitality, as shown by amœboid movements, for twenty-four or thirty-six hours after withdrawal, and many hours after coagulation has occurred. If freshly-drawn blood is whipped with a bundle of threads, the "blood-plates" first adhere to them, and afterwards a few white and red corpuscles. If the threads are then, before fibrin is deposited, washed in salt solution, they will, when placed in a suitable liquid (proplastic of Schmidt), induce coagulation, which, as Bizzozero has shown by other experiments, cannot be attributed to the few red or white corpuscles adhering to the threads. Several facts have come under my observation which corroborate the views of the learned Italian professor. I have been struck with the density and richness of the fibrin network in blood specimens in which Schultze's granule masses were abundant. As is well known, the distinctness with which the fibrin filaments can be seen in blood slides varies very much, and I think the variations will be found to have a close connection with the abundance or paucity of these elements. As one watches the process of coagulation, the filaments first seen are invariably in association with small granules—which represent disintegrated blood plates—or larger Schultze's masses. In cases of extensive atheroma of the aorta, the thrombi which form in the small breaches of the intima may consist entirely of these corpuscles, and in aneurisms they occur on the surface of the fibrinous laminæ. So, also, in the vegetations of endocarditis, these little corpuscles are found associated with the fibrin layers so commonly deposited in these structures.

So far as I can make out, the corpuscles here described are different from the invisible corpuscles of Professor Norris, of Birmingham. The origin of the corpuscles remains a problem—one of many connected with the blood which await solution at the hands of histologists.

To conclude: 1st. There is in mammalian blood a third corpuscular element, one-eighth to one-half the size of the red corpuscle. It can be clearly seen in the bloodvessels of the living animal or in the vessels of freshly removed bits of tissue. It may be called appropriately the third corpuscle, or "blood-plate," though the latter expression is not a very satisfactory one.

2d. In blood withdrawn from the vessels these corpuscles aggregate together and form the well-known granule masses in which the corpuscles rapidly degenerate and lose their outlines. These masses, first described by Max Schultze, should be known by his name.

3d. There is evidence to show that the third corpuscle plays an important *rôle* in coagulation.

THE USE OF THE OLEATE OF ACONITIA AS A LOCAL ANODYNE.

By HOWARD A. KELLY, M.D.,
OF PHILADELPHIA.

Amid the hosts of claims continually being urged on all sides for remarkable specific effects from the use of various drugs, principally new, I have long hesitated before publishing any observations of my own not based upon extended experience. But the effects obtained from the external use of the oleate of aconitia in the following case are so remarkable that I feel justified in presenting them. The results noted in this case tally so exactly with the well-known physiological action of the active ingredient of the salt (aconitia), that its usefulness in the particular instance before us might readily have been inferred on the strong basis of *à priori* reasoning; there is, therefore, the greater hope that its value in all similar cases may approach that of a specific effect—*i. e.*, under like circumstances producing identical results.

While a resident in the Episcopal Hospital, in 1882, Dr. W. H. Bennett, then chief of the medical wards, put into my hands a pamphlet published by Dr. Squibb, of Brooklyn, giving a detailed account of the preparation of the various oleates, and at his instance I secured several of the preparations, and used them in the wards with the view of determining their therapeutic value. After many trials in all sorts of atypical cases, with varying success, the case about to be recorded was made the subject of a test of the value of the oleate of aconitia with most gratifying results.

I had admitted a short time previously a man of about forty years of age, with a large, rapidly growing aneurism of the ascending arch of the aorta. At first, the tumor could be distinctly seen pulsating in the first and second intercostal spaces of the right chest, above the clavicle, and above the sternum as big as a hazelnut. Within two months, it had grown to the size of a cocoanut, bulging from the right upper chest, a large, dusky-red, pulsating tumor, displacing ribs and sternum, which could not be found, and occupying the whole right side of the neck, tilting the head to the opposite side, and rendering it almost immovable.

All the ordinary signs common in such aggravated cases were present; the voice was suppressed and hoarse, and a paroxysmal cough and severe attacks of dyspnœa frequent. The breathing was never whistling, nor were any auscultatory sounds heard suggestive of a limited constriction of a large bronchus. The right pupil was smaller than the left, but the difference was no greater than I have very frequently observed in the healthy subject, or could at the time demonstrate in at least a dozen various cases in the ward.

The rapid growth of the tumor was accompanied by agonizing, tearing, clawing, and burning pains, occurring in paroxysms at any time of the day or night, and lasting for hours at a time. The pain was chiefly localized over the shoulder, the outer and posterior aspect of the arm, and the right side of the neck, extending up in front of the ear.

The palliative effect of two or three drops of the oleate of aconitia, of two per cent. strength, gently diffused over this area, was absolute. Paroxysms coming on were checked, and fully developed paroxysms were instantly arrested. In from five to eight seconds after the application, he felt a pricking "like pins and needles," and in twenty seconds the pain had disappeared, leaving a slight numbness.

The poor fellow's enthusiasm for the drug was well expressed one day when, as I was entering the room, he cried out: "Oh, Doctor, I was just praying you would come, and bring those drops." And during my absence, he was extremely solicitous that "the other Doctor" should know just where to find them in case of need. The results were as complete and satisfactory with the last application as with the first.

I cannot assert that the pains returned less frequently after the use of the drug, but the relief afforded by a single application lasted for hours, or until a new paroxysm developed. No constitutional effects were ever observed in this or any other case under my charge, although six, eight, or ten drops were at times used.

I have heard eminent authority declare (and prove by his practice that he believed) that *electro-puncture* was justifiable in these cases, if on the sole ground of its partial palliative effect to the distressing pains. If that is *all* we are to expect from electro-puncture, what a valuable substitute we may have here.

This patient died finally in a paroxysm of dyspnœa, without any rupture of the sac. At post-mortem examination the lost ribs were found eroded and enclosed with the thick sac wall, the sternal extremity of the clavicle was found in detached, honeycombed pieces at various points in the anterior wall, while the remainder of the clavicle projected free into the interior of the sac. The whole brachial plexus was surrounded with hardened masses of inflammatory thickening, and included within the posterior wall of the sac.

The cases in which the oleate of aconitia has found its greatest use have been well-marked examples of trifacial neuralgia, and the following, under the care of my friend, Dr. Geo. E. de Schweinitz, in which he made use of a few drops of this drug, which I gave him at his request, is in every way so satisfactory that it is well worth adding to the list.

He furnishes me with notes to the following effect. A widow, of about thirty-five years of age, had suffered extremely for two years from well-marked attacks of tic douloureux, occurring four or five times every month. She had been under all manner of recognized appropriate treatment, including, iron, arsenic, strychnia, phosphorus, belladonna, quinine, iodide of potassium; electricity, epispastics, rubefacients and anodyne applications were also faithfully pushed. Under the continued use of phosphorus and nux vomica, with the instillation of a solution of eserine, a half grain to the ounce, into the eye, for an unaccountable increase of tension, the disease was markedly controlled, attacks recurring not oftener than once a month. Nevertheless, their severity was not diminished, and in two of these attacks the oleate of aconitia was used, and complete relief was afforded in from three to five minutes by three drops of the two per cent. solution gently rubbed into the skin. The result was most satisfactory to Dr. de Schweinitz, and to the patient appeared little less than magical.

323 South Seventeenth Street.

TREATMENT OF DENUDED SURFACES.

By M. H. CRYER, M.D., D.D.S.,
of Philadelphia.

Some twenty years ago, it was noticed by horsemen that when race-horses were chaffed or galled by saddle or otherwise, ointments and other applications very often failed to restore the skin to the affected parts. For this purpose, the best remedy was found to be the dust which collects upon the curry-comb during the cleaning of a healthy animal, blown thickly into the sore.

During the past summer, fresh evidences of the efficacy of this treatment have been brought to our attention in such a manner as to merit notice. One case specially should be mentioned, that of a horse with a large discharging abscess just below the crest of the right ilium. After curing the abscess and fistula, it was found that the parts at the opening had so sloughed away as to leave a space some three and a half by four inches in diameter uncovered by skin. The owner having made several unsuccessful attempts to get the parts to heal over, thought he would have to resort to skin-grafting, the surface being in a healthy plastic condition.

Before resorting to this expedient, however, the treatment above spoken of was brought to his attention. Having other horses in his stable in perfect health, it was suggested that the epithelial cells from these, being almost pure, would, no doubt, accomplish a cure. After cleaning these horses, therefore, the dust from the currycomb was thickly blown into the uncovered ulcer two or three times a day, forming a temporary covering of almost pure dermoid tissue. The animal salts in the dust acted as a stimulant and astringent, and in two days after the first application, there was marked improvement around the edges of the parts affected. In twenty days, the parts were covered with new skin on which there were evidences of a copious growth of hair, which has now—two months from the beginning of treatment—attained almost the normal growth and appearance.

A modification of this treatment may be of benefit in restoring denuded parts caused by ulcers, burns, etc. It is certainly worthy of a trial. We are assured of a successful issue in minor cases, and we should not hesitate to apply it in even graver lesions, where skin-grafting is usually demanded.

It is safe to conclude, from the number of cases brought to our attention of a similar character, that the apparently dead dermoid cells either become in part revivified by being brought into contact with the highly plastic material of the ulcer, or produce a covering to the young formative material of the skin so nearly natural as to induce their full physiological action.

REMOVAL OF AN EXTRA-VESICAL URINARY CALCULUS.

BY JAMES L. DICKEN, M.D.,
OF LA FONTAINE, IND.

I WAS consulted on the 22d day of October, 1882, by I. F., of German parentage, born in the United States, aged thirty-three years, height five feet ten inches, weight 225 pounds; stout, robust, and healthy, and a blacksmith by occupation, who represented that, when seven years old, he was in an edge-tool shop, and was standing near a grindstone, which was in motion, and operated by his father, that the crank caught in his pantaloons near his privates, and before his father could throw the belt in order to stop the motion of the stone, he was thrown several times around, lacerating the parts, and tearing the penis entirely away from the body. He said the wound healed after throwing off some gangrenous sloughs, leaving the scrotum and testicles in a normal condition, as evinced by his sexual propensities being as vigorous as usual.

For a time, the urine passed out through the wound, but finally a fistulous opening made its appearance about one inch above and a half inch to the right of the wound, when the urine ceased passing through the wound, and had ever since passed through this fistulous opening.

At the site of the wound was a cicatrix which gave no signs of a penis ever having been attached at that point. Situated above this fistulous opening, and extending over and above the pubes, apparently beneath the skin and superficial fascia, was a calculus, apparently about the size of a turkey's egg.

A sound could not be made to enter the bladder from the opening through which the urine passed, but the calculus could be distinctly felt. He had entire control of his urine—could retain or void it at will.

He was exceedingly anxious not only to have the stone removed, but to have also a protuberance or kind of artificial penis formed, through which he could pass his urine without subjecting himself to the annoyance or inconvenience of having to use a tube to carry the urine away from his person every time he had occasion to micturate. I unhesitatingly promised to remove the stone, and to do what I could in relieving him of his inconvenience in urinating.

Accordingly, on the 25th day of October, 1882, in the presence of and assisted by Drs. N. W. Scott and C. L. Dicken, I performed the operation. The hair was closely shorn from the pubes, after which he was anæsthetized with chloroform and ether.

I then made two parallel incisions four inches long, and one inch and a half apart, extending from above the pubes down to the point where the penis should have been, connecting them at the top by a Λ incision. I dissected the strip included between the incisions, together with the tissues between it and the stone down to the point indicated, intending to fold it upon itself, and make an opening near the middle, through which I could pass a catheter, and extend it through the urethra into the bladder, and, after removing the stone, stitch the folded portion on each side around the catheter, leaving it *in situ* to serve as a continuation of the urethra till the edges were entirely united, hoping to form a kind of artificial penis. I intended also, after removing the stone, to bring the parts together from which the strip had been dissected, which I could have readily done, as the integument was quite loose, especially after the stone was removed.

When I had dissected the strip fully down, I was greatly surprised to find beneath the portion removed a full-grown penis, with glans, foreskin, frenum, and meatus, all in their normal condition, with the exception of the penis, which was somewhat shortened from the injury received at the time of the accident, and its cramped position for the last twenty-six years. I removed the stone; cut off the strip that I had intended to make a penis of; passed the catheter into the bladder; drew the penis out around it, and dissected the attachments from the penis which had formed at the time of the injury. I carefully washed out the cavity from which the stone was removed, and brought the parts together by interrupted sutures and adhesive straps, leaving the penis hanging out at the point from which it had been driven twenty-six years previously.

A compress was applied, which was also held down by adhesive straps. The wound healed readily, and in three weeks after the operation, the gentleman came to my office, and exhibited himself, showing that when his penis was erected it was three inches in length, and he was confident that it would yet elongate under proper training; at all events, it answered him much better than the goose-quill he had been using so long. The stone was of the phosphatic variety, and weighed five and one-fourth ounces Troy weight.

HOSPITAL NOTES.

HOSPITAL OF THE UNIVERSITY OF PENNSYLVANIA.

(Service of Louis A. Duhring, M.D.,)

PROFESSOR OF DISEASES OF THE SKIN IN THE UNIVERSITY OF PENNSYLVANIA.

Reported by Henry Wile, M.D.

THE "ELASTIC SKIN MAN."

This individual is a study of interest and presents a peculiar dermatological condition which is extraordinary. The subject is a man thirty-five years old, a native of Nuremburg, apparently healthy, and with a skin that appears normal until touched, when one notices some abnormal peculiarity. It is movable, extensible, and elastic on the head, trunk, and extremities, in fact, over the whole general surface. Taking hold of the skin it may be drawn out; as for example, seizing the skin over the sternum, it can be drawn over almost his entire face, or that between the scapula over the back of his head. The distance to which it can be drawn from the surface depends upon the amount of skin grasped. The skin is extremely soft, and none of the movements give him the least pain. The condition is congenital. Pulling out the skin and holding it in front of a light, the circulation of the blood in the skin only is beautifully seen. The condition is supposed to be due to an absence of the subcutaneous connective tissue, but it is a question whether the subcutaneous connective tissue is not present and attached to the fasciæ of the muscles instead of to the corium.

The elasticity is shown by the fact that on drawing out the skin and letting go, it flies back. It is more elastic in some directions than in others—more when drawn transversely to the natural lines than parallel with the lines. As far as my information extends the case is almost unique, there not being another case on record except that of a Spaniard about two hundred years ago.

The forehead wrinkles naturally, and notwithstanding the amount of manipulation that the skin has undergone, it is exceedingly sensitive. This condition exists in lower animals, and particularly in dogs, cats, and rabbits. There is a condition known as dermatolysis, which is analogous to that found in this man; but in this disease there is a state of marked hypertrophy, while here the skin is normal as to structure. As to its classification, it may be placed with dermatolysis.

MEDICAL PROGRESS.

Iodine, Externally and Internally in Amenorrhœa and Dysmenorrhœa.—It is rare, says Chéron, that amenorrhœa and dysmenorrhœa are not complicated by lumbo-abdominal neuralgia which adds to the painful state of the utero-ovarian apparatus in these affections.

Tincture of iodine freely applied, every two or three days, over the region of the kidneys, acts very much in the same manner as the application of heat, that is to say, it stimulates the centres of vaso-motor innervation of the lumbar portion of the cord, and of the sympathetic, and at the same time tends to relieve the congestion of the genital apparatus. By this congestion the normal uterine flow is interfered with, being retarded or suppressed.

The tincture of iodine alone will suffice when the lumbo-abdominal neuralgia is not internal. If the neuralgia is internal, Chéron employs the morphinated tincture of iodine: Tincture of iodine 30 parts, sulphate of morphia 1 part. Used internally, iodine is, of all the emmenagogues, one of the surest in its action, more particularly in cases of corpulent persons with very white skin, in whom the lymphatic type is predominant. Iodine may also be employed with good effect in the following formula, whatever may be the cause of the menstrual trouble: Tincture of iodine 1½ parts, tincture of aconite 2 parts, syrup of tolu 400 parts. S. Dose, one, two, or three teaspoonfuls before each meal, or one spoonful for three days, two for three days, and three for as long a time as may be desired.—*Revue de Thérap.*, Dec. 1, 1883.

The Salicyl Treatment of Acute Rheumatism.—There was a discussion on this subject at the fifty-sixth Versammlung deutscher Naturforscher und Aerzte at Freiburg.

Professor Baeumler reported one hundred and seventy-nine cases, ninety-two males and eighty-seven females. Treatment with salicylate of soda produced the result that the fever lasted but a very short time The salicylate preparations, he said, had a specific action in acute rheumatism, though in some cases the disease was only mitigated. For the prevention of relapses the remedy must be used for a longer time and in smaller doses.

Dr. Emmerich, of Nürnberg, has used ergot with salicylate of soda, as recommended by Schilling, with the result of preventing the severe cerebral and aural symptoms.

Professor Weil spoke of his method of using the drug at the Heidelberg clinic. At first he gives, hourly, grs. viij of salicylic acid—later, when the pain has subsided, he used salicylate of soda in solution, in smaller doses. An obstinate case of endocarditis was successfully treated by the salicyl treatment. A patient attacked with acute rheumatism after typhus fever, and treated by salicylate of soda, had very severe dyspnœa. Weil asked whether albuminuria had been observed as a consequence of the salicyl treatment.

Professor Baeumler has seen slight attacks of collapse after the use of the salicylates, redness and cyanosis of the face, and dyspnœa. Great dyspnœa he had seen only once in a pregnant patient, convalescent of pleurisy with effusion, to whom ʒj of salicylate of soda had been given on account of facial erysipelas. He had never seen albuminuria follow the use of the drug.

Professor Riegel thought that salicylic acid acted especially by increasing the blood pressure. He has once seen dyspnœa with cyanosis after large doses of the drug, and thought it due to cardiac dyspnœa.—*Deutsche Med. Wochenschr.*, November 14, 1883.

Encysted Peritoneal Effusion.—Dr. G. C. Roy reports the following case.

S. S., male, aged about twenty-two, was first seen on April 8, 1883. About a year ago he violently ran against the shaft of a cart on a dark and cloudy night, which hit him in the region of the liver and rendered him insensible for an hour. The part swelled up and was painful, and he came on the fourth day to the dispensary for treatment, when the left lobe of the liver was found enlarged, and a fluctuating swelling, supposed to have been the result of a hæmatoma, occupied the central site of the enlargement. Under aconite and antimony, the inflammation gradually subsided, and the improvement continued under iodide of potassium; when no more was heard of him until his second appearance, about two months after the accident, with a swelling larger than before, but painless and without fever. The only inconveniences complained of were weight and discomfort after meals. It was then taken for a chronic abscess, and aspiration was proposed, when the patient took fright and ceased further attendance until the date of the present report. This time the abdomen was bulged out at the upper part and standing in relief—the tumor extending down to the level of the umbilicus, and to the left an inch beyond the median line; it was tense and fluctuating. There was no fever, and he was very much emaciated and anæmic. The lower part of the abdomen was free from any fluid accumulation, and tympanitic. Urine scanty and high-colored, and free from albumen.

On the 9th April it was tapped with a fine needle, and one hundred and twenty-eight ounces of fluid were withdrawn. The fluid resembled that of a hydatid in many particulars, being slightly opalescent, of specific gravity 1009, containing abundance of chlorides and a faint trace of albumen, which increased however in subsequent reaccumulations. The patient was ordered iodide of potassium, gr. v. t. i. d.

By the 29th it filled up again to its original size, and sixteen pints of fluid were evacuated.

The third operation was performed on the 14th May, and the fluid measured fourteen pints. This time two drachms of strong tincture of iodine were injected without causing any pain or smarting.

The tumor filled out again, and he presented himself on the 29th May to have it emptied. He was very much emaciated, and was getting a little fever for the first time. There was no anasarca or jaundice.

Twelve pints of fluid were evacuated, the latter portion being semi-puriform, and two drachms of tincture of iodine were again injected into the sac. The specific gravity of the fluid had risen now to 1015, with abundance of albumen, and under the microscope there were numerous leucocytes and pus cells in the field. I must not omit, however, to state that before the introduction of tincture of iodine the fluid presented under the microscope innumerable long, rod-like substances, the exact nature of which I could not determine. These disappeared and gave way to pus cells after the injection of iodine.

He returned a fortnight after, worse than ever, and almost *in extremis*. At his urgent request, I opened it this time with a scalpel, and introduced a big drainage-tube to keep up a permanent discharge. The fluid was more purulent in character, but devoid of fœtor. He was sent home with a worse prognosis, but the disease now took a favorable turn. For a week every thing went on as hopefully as possible, when the putrefaction of the contents aggravated the fever and threatened septicæmia. He got over it, but ceased further attendance, when I heard he had succumbed; but to my surprise he presented himself two months after, with the tube still *in situ* and discharging. He had gained some flesh and strength, and was able to walk about. His fever had left, and he had good appetite. He was kept under observation for ten days, when the sac was daily syringed out with a weak chloride of zinc lotion. He was discharged with the tube very much shortened, as there were evident signs of the cavity contracting rapidly. It is now six months from the date of his first operation, and he is now well in every other respect, and his liver has become much reduced in size. —*Indian Medical Gazette*, Nov. 1883.

RESECTION OF WOUNDED BLOODVESSELS.—The following case, reported by DR. W. BAUM, differs in its clinical history from that published by Tillmanns (*Berlin. klin. Wochens.*, Bd. xviii., No. 3) in that in this case resection was performed on three bleeding vessels.

H. S., æt. thirteen years, was brought to the Stadt-Lazareth in Danzig, on July 5, 1883. One hour before, while cutting a wooden shoe, the knife slipped, and went into the left thigh. Profuse hemorrhage occurred, but was almost immediately checked by digital compression. Dr. Suchanneck, on seeing the patient, enveloped the limb with a rubber-bandage from the toes upward to the wound, and then applied an Esmarch's tube above. The patient had lost but little blood, the senses were entirely clear, and the strength and pulse were far better than would have been supposed after so severe a wound. After being taken to the hospital, the bandage was removed from the leg, and the wound was seen to be about three-fifths of an inch long, with smooth borders on the inner surface, and very near the middle of the thigh.

After cleaning and disinfecting the leg, Baum extended the wound on both sides. The edges were scarcely ecchymosed, and it was only necessary to remove a few clots in order to see the vessels clearly. The femoral vein was first brought into view, a conical clot closing up the wound in its wall; when this was removed, some bleeding occurred, which quickly ceased on the application of a ligature below and above the wound: the piece between the ligatures was now cut out, about four-fifths of an inch. This resected piece showed two smooth perforations through the anterior and posterior walls, each four-tenths of an inch long. The femoral artery, being wounded, was treated in the same manner. A musculo-articular branch being also wounded was resected, after which, the Esmarch's tube being removed, the wound remained bloodless. The edges of the wound were now brought together, the whole extremity enveloped in an antiseptic dressing from the toes to the hip-joints, and the limb placed in a horizontal position.

The temperature went up to a little above 100° Fah., and during the first few days the patient complained of a slight amount of pain in the limb, but it was not so great as to interfere with his sleep. On the morning after the operation, the toes were somewhat colored, and the last phalanx of the great toe seemed to be anæsthetic, but this entirely passed away by the following day. On August 2d, the patient was discharged, with perfect use of the leg.

Baum also reports the case of a man, æt. 46, who had carcinoma of the penis, with thick carcinomatous glands in the groins. The penis was removed by the écraseur, and the glands in the left groin extirpated. The femoral artery and vein were so involved with the carcinomatous glands that pieces one and one-fifth of an inch were resected from each. About a week afterwards, the glands on the right side were extirpated. No accident occurred, and the patient recovered.—*Berliner klin. Wochenschr.*, October 22, 1883.

ANTIQUE THERMAL ESTABLISHMENT.—There have recently been discovered, at Malon-le-Haut, in Beziers, the perfectly preserved remains of a thermal establishment dating from the first years of the Roman occupation.

Malon le-Haut is still much frequented as a thermal establishment.

THE MEDICAL NEWS.
A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

Communications are invited from all parts of the world. Original articles contributed exclusively to The Medical News will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

Subscription Price, including Postage,
Per Annum, in Advance, ... $5.00.
Single Copies, ... 10 cents.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

Address, HENRY C. LEA'S SON & CO.,
Nos. 706 & 708 Sansom Street,
Philadelphia, Pa.

SATURDAY, DECEMBER 29, 1883.

ANNUS MEDICUS 1883.

About this time retrospection is in order. Each of our readers will no doubt give a few moments of the last hours of the dying year to reflections on his own individual work for the past twelve months and on its net results, and in like manner a few notes on the world's medical work for the same period seem appropriate and desirable.

It has not been an epoch-making year in medicine. There are no startling discoveries, no great International Congress, nor any marked new departures to chronicle; the stream has flowed on quietly, vexed a little into ripples and foam on a few shallow places as usual, but, upon the whole, giving to the journalist, whose business it is to watch it, very satisfactory indications of progress and of power.

In medical literature there has been a slight but distinct increase in quantity; the majority of the numbers of *The Index Medicus* for the year contain from four to eight pages more matter than usual. The high birth-rates of the last four or five years in medical journalism have continued, the total number of new medical journals appearing during the year being fifty-five, and the number which have ceased to appear being fifteen.

In general professional work for the advancement of medical science, one of the most noteworthy features is the effort which is now being made in Great Britain, Germany, and the United States, to organize systems of collective investigation of disease. The fact that coöperative work is a necessity in order to secure a sufficient amount of data for useful reasoning in regard to many obscure points in disease, has long been known, and occasionally referred to by medical writers and teachers; but it is only now that we have reached the stage when it seems feasible to set to work on this line of research.

Investigations connected with the germ theory of disease have continued to attract public attention more than any other features of biological work. The fact that a bacillus is invariably present in true tubercle seems now to be pretty firmly established, and practical use is being made of this for diagnostic purposes. Friedlander's researches on the micrococcus of certain forms of pneumonia indicate a distinct advance in our knowledge of the relations of micro-organisms to disease.

The announcement of the discovery of the specific germ of yellow fever, and of its successful cultivation and inoculation, has been made by Dr. Domenigo Freire, of Brazil, but his results have not been confirmed, and a healthy scepticism prevails as to whether they ever will be.

The care required in such researches, and the caution which should be exercised in drawing conclusions from a limited series of observations, are well illustrated in the report made by Dr. Koch of the results of the investigations made by the German Commission which visited Alexandria during the past summer to seek for the cause of cholera. This report is a model of its kind, and sets forth clearly the initial difficulty which besets researches into the intimate pathology of most of the spreading and infectious diseases of man—viz., the possibility of producing specific effects upon some animal by the cause of the disease, in order to have at command some test of the presence of this cause in a suspected fluid—whether this be a direct pathological product or the result of culture of suspected organisms.

An interesting addition to our knowledge of the effects of micro-organisms is the fact that the peculiar action of jequirity, the new remedy for granular lids and chronic thickening of the conjunctiva, have been found to be due to a peculiar bacillus.

In surgery, the principal triumphs continue to be scored in the field of abdominal surgery. Exploratory operations for diagnostic purposes, the removal of tumors of all kinds, the dilatation of the pyloric orifice of the stomach, etc., illustrate the readiness with which the surgeon now opens the peritoneum and deals with the viscera in ways that but a short time ago he would not have dreamed of.

Setting this class of operations aside, nothing remarkable has marked the progress of gynecology and obstetrics. The supply of new forceps, pessaries, and specula, has been rather below than above the average, and the cervix uteri appears to be enjoying a period of comparative quiet.

It has been a year of low mortality throughout the greater part of the civilized world. How far this is due to practical sanitary work, and how far it is due to the fact that we have had a comparatively cool summer, with a corresponding diminution in infant mortality, especially in cities, are questions which we cannot discuss within the limits of this note. At all events, the interest in sanitary work appears to be increasing among the general public, and the new profession of "Sanitary Engineer" appears to be an established addition to the various occupations open to educated men.

In the matter of medical education, matters are not yet perfect. The bill to reorganize the system of medical examinations in Great Britain, which was introduced into Parliament as the result of the very elaborate inquiry made by the Medical Acts Commission in 1881, failed to become a law, owing to circumstances which enabled a very small minority to block the wheels of legislation; but there is every reason to think that it will pass at the next session with comparatively little change. In the United States, the example set by Illinois in dealing with the worst of the quacks through the agency of the State Board of Health is being followed in other States, with the result of transferring the most offensive and unscrupulous charlatans to those States which have not as yet adopted measures of self-protection. We are still awaiting the organization of the medical department of the Hopkins University in Baltimore to provide the facilities for higher medical education which are needed in this country. The latest information which we have is that this school will probably be organized in 1885. Meanwhile, the medical schools in our large cities are flourishing, and there does not seem to be the slightest danger of any deficiency in the number of practitioners required to meet all demands.

We have had a little cholera scare during the year, and, although no cases are now reported in Egypt, it is very probable that the end is not yet. From the history of the progress of previous expansions of this pestilence, it is by no means improbable that we shall hear of it in Europe next year, in which case this country will be in serious danger. Yellow fever has prevailed to an unusual extent in Havana and in Vera Cruz, and we have had a touch of it in Florida and Alabama, but, fortunately, it has been found possible to limit its spread. Smallpox has prevailed in epidemic form in Baltimore and New Orleans, and cases are still reported in several of our large cites, but vaccination has been carried out with very considerable completeness, and although winter favors its spread, we have probably no reason to fear any serious outbreak of this disease in the near future.

Turning now to our losses, the list of the dead of the medical profession is perhaps not quite as long as usual, but it includes some distinguished names and old friends. Van Buren and Sims, Farr and Hilton-Fagge, Cloquet and Lasegue, Von Sigmund and Von Bruns, Pacini and Alvarenga, have finished their work and gone each to his own place. The medical department of our little army has been so unfortunate as to lose two Surgeon-Generals during the year—General Barnes and General Crane. But the ranks are closed up—so far as the general public can see the vacant places have been filled, and the column moves on as usual.

PULSATING PLEURAL EFFUSIONS.

Pulsation in pleural effusions, a phenomenon hitherto little understood because insufficiently studied, has been made the subject of an admirable critical investigation by M. Comby, in the November and December numbers of the *Archives Générales de Médicine* for the current year. Having had the opportunity of personally observing no less than four patients presenting this condition, M. Comby was led to collect the recorded cases. In addition to his own, he was able to find only twenty-three cases, several of which amount to little more than bare mention, a notably small number in view of the fact that pulsating empyema is alluded to in most systematic works on diseases of the chest. The first recorded case is that of Baillou (1570). In all these cases (with the exception of one which appears to have been, not a pleural effusion, but a localized abscess) there was long-standing, large, pleural effusion of the left side. After a period of latency, pulsations synchronous with the ventricular systole are perceived over a more or less extensive area of the wall of the chest in the left side, near the base. These movements are often overlooked until the chest-wall, yielding to the internal pressure, bulges with the formation of one or two pulsatile tumors. These tumors are of varying size, from that of a nut to that of an orange, and are soft, fluctuating, and reducible. Their seat is in front, at the level of the præcordial region, or at the base of the chest posteriorly, a few inches from the vertebral column. In two instances they occupied the left lumbar region.

The author regards the repeated statement that the pulsations are expansile in character as an error of observation associated with the error of diagnosis, to which it corresponds, the absence of true expansile pulsation being, in fact, an important point in the differential diagnosis between these and aneurismal tumors. Auscultation discovers at the seat of the pulsation a double *bruit*, analogous to the heart-sounds, without murmur or thrill. The respiratory murmur, vocal resonance, and vocal fremitus are absent. These tumors, moreover, are observed to diminish at the moment of inspiration, and to advance with expiration. The left chest is commonly enlarged, the intercostal spaces are widened, and the tissues in the region of the tumor are sometimes œdematous. The heart is displaced to the right, but is not hypertrophied, nor does it show other lesions dependent upon the pleural disease. In some of the cases slight pericardial effusion was present. In several instances the pulsation of the tumors was stronger than the cardiac impulse, and progressively augmented in force as the chest wall yielded. The spontaneous or the surgical evacuation of the fluid is always followed by disappearance of the pulsation, but in all cases the signs of pneumothorax at once appear. The heart tends only slightly to resume its normal position and the lung refuses to expand.

The term *pulsating empyema* is justified by the constant purulent character of the effusion. Pulsation occurs only in pleural effusions that are essentially chronic, and have lasted long enough to flatten and destroy the lung. Hence the prognosis is fatal in all cases, save those in which the pulsation appears in a circumscribed empyema or local abscess in the immediate neighborhood of the heart.

The affections from which we should discriminate this condition are: pulsatile pneumonia, pulsatile cancer of the lung, and aneurism of the aorta; and the diagnosis rests upon those signs which indicate the existence of a massive left pleural effusion associated with the pulsating tumors. Nevertheless it should be cautiously determined, lest a coexistent aneurism of the aorta be present.

The necropsy reveals the lung compressed, hard, fibrous, elastic, impermeable to air, and apparently but slightly vascular. It is flattened against the pericardium and adherent to it. Laennec pointed out the fact that solidification and compression of the lung favor the transmission of the heart's impulse rather than its sounds. Pulsating empyema is due to the forcible transmission of the cardiac impulse by a lung sclerosed and adherent to the pericardium.

We have dwelt upon these facts at some length for two reasons.

First, because the condition always presents the same general characters, whether it arises in subjects disposed to phthisis or already tuberculous, or suddenly in previously sound individuals. A period of long duration characterized by the signs of large pleural effusion constitutes the first stage. During the greater part of this period the lung is capable of again expanding, and the judicious interference of the surgeon may result in cure. The appearance of pulsation marks a second stage, that of complete destruction of the lung and its conversion into a fibrous mass incapable of regaining its functions. Recovery is not now to be hoped for. The evacuation of the pus is followed by pneumothorax; the pus reaccumulates; pulsation recurs; and the former condition is reëstablished.

Second, the lesson in practice is of the plainest nature. The structural changes in the lung which underlie the phenomenon of pulsation in empyema are the result of *prolonged* compression. The period of latency in some cases has been one, two, even three years. A far shorter period than this, a period measured perhaps by as many months, is enough in some individuals to compress the lung beyond all hope of rehabilitation. In cases treated without delay empyema cannot become pulsatile.

The rule of practice in pleural effusions may be thus formulated: so soon as there is reason to suspect the existence of pus, make an exploratory aspiration; so soon as pus is known to be present in an adult, perforate the chest-wall and establish permanent drainage.

RESECTION OF THE FEMUR FOR PSEUDARTHROSIS.

Among the operations which the surgeon undertakes with misgiving, if not positive dread, is that of resecting the ends of the fragments for non-union of fracture of the thigh-bone. The procedure is difficult of execution, especially if an attempt be made to connect the freshened ends by means of wire; the subsequent treatment is most trying to one's patience, the failures to effect union are discouraging, and the mortality is by no means inconsiderable. These remarks are the more particularly applicable to the operation as performed in what may be termed the preantiseptic period, since the statistics of Bérenger-Féraud indicate that, of 52 resections done up to 1871, 9 failed, 11 died, and 32 recovered with good union.

That these unfavorable results may be greatly modified by the employment of antiseptics is conclusively shown in a paper contributed to the *Archives Générales de Médicine*, for December, 1883, by Dr. Mathieu. Of the 18 cases which he has collected, including one of his own, 1, or 5.5 per cent., died, 4, or 22.2 per cent., failed, and 13, or 72.2 per cent., were successes. In one of the failures, the result might have been anticipated, as the resected extremities were united with catgut. These figures indicate that the antiseptic resection of the ends of the bone in false joint of the femur is worthy of extended trial after the failure of less severe measures.

VIRCHOW AND THE INFECTIOUSNESS OF TUBERCLE.

In the discussion which followed the reading of a paper by Falk, on "Inoculation Tuberculosis," before the Berlin Medical Society, on November 21, 1883, the illustrious Virchow gave at some length his views upon the much discussed question of the infectiousness of tuberculosis, and the relation of the bacillus to it.

Prof. Virchow holds that, from the experiments reported by the author of the paper, we are not justified in claiming for the bacillus tuberculosis infectious properties in the strictest sense. The term "infection," which he was the first to introduce for a large group of diseases, was intended to indicate an agency capable of producing a series of processes which agree in having a transmissible dyscrasic basis, and in that they infect the entire body. The harmful influence is not local, but works prejudiciously throughout the entire organism. Since fungi have been introduced into the category of the infections, where shall we draw the line between those which are infectious and those which are non-infectious? Is thrush an infectious process? Or is favus? The difficulty is that infection and contagion are used as though they were synonymous, while to Virchow they are entirely distinct. To him intermittent fever is infectious, but not contagious; itch is contagious, but not infectious.

As to tuberculosis, Prof. Virchow calls attention to the fact that long before the bacillus was thought of, there was acknowledged to be a form of tuberculosis in which infectious phenomena were apparently present—that is, in the so-called acute miliary tuberculosis. But no one thought there was also a specific poison at the seat of the local alteration. It was admitted that the local processes operate prejudiciously as such, but it was not believed that a toxic infection of the organism is associated with them, affecting the functions of other organs.

Again, it is proposed to compare pyæmia with tuberculosis. But in this disease we must separate the results of the embolus itself from those of other toxic agencies adhering to it, or coexisting with it. Emboli are at times non-irritant and non-infectious, at others irritant and infectious. These facts are not to be overlooked, nor our previous knowledge thus ignored. Until it has been proved that the tubercle bacillus has a general toxic action, or so long at least as we have any reason to believe its action is purely local, we dare not regard it as infectious.

It is evident, from his statement, that Virchow is not a believer in the modern doctrines of tuberculosis, and that for him the bacillus has no causal relation to the disease. He is still a believer in caseous pneumonia. In reply to the question, "Is not caseous pneumonia also a tuberculosis?" he said any one may so term it if he pleases, but to call a process tubercular in which there is nothing tubercular, seemed to him not justifiable. If, again, the question is asked, "are not tuberculosis and cheesy pneumonia both the effect of the bacillus?" even if answered affirmatively, it does not follow that cheesy pneumonia is tubercular. It is difficult for many pathologists to accustom themselves to consider the same thing from two points of view—from its causal and its intrinsic significance. Tubercle is a small nodule. Cheesy hepatization is no nodule, but frequently a diffuse infiltration of lung tissue. If both are caused by the same bacillus, one might, from a causal standpoint speak of them as *bacillar*, but certainly not as tubercular. To take an analogous example, in syphilis there are many anatomical modes of expression. There is the nodular product known as the gumma, but no one would think of speaking of the gumma as identical with syphilitic erythema. Nor would we speak of the syphilitic bubo as identical with syphilitic exostosis, although both are the result of syphilis.

Whatever may be the final solution of the question, we cannot fail to see in these remarks of Virchow the words of a master—of one who has given a lifetime to the study of pathology in its broadest sense, and not to a single field of inquiry, the study of which is so apt to narrow the horizon of the investigator, and to cause him to overlook all facts bearing upon the subject, except those he has himself noted.

TUBERCULOSIS AS THE RESULT OF THE INOCULATION OF INDIFFERENT SUBSTANCES.

It will be remembered that as far back as 1868 Dr. Wilson Fox, in conjunction with Dr. Burdon-Sanderson, published the results of an elaborate series of experiments, which went to show that tuberculosis could be produced by the inoculation of non-tuberculous matter. In view of the recent observations of Koch, Dr. Fox thought it desirable that his own investigations should be repeated. He accordingly asked Dr. Dawson Williams to do so, and at the meeting of the Pathological Society of London, held December 4th, Dr. Williams communicated his results, from which it appears that the results were entirely negative, and the evidence, therefore, was all against the theory that tuberculosis could be produced in any other way than by infection with tubercular matter.

In the discussion which followed, Dr. Wilson Fox said that he now felt that there must have been some fallacy in conducting his own experiments. He was unwilling that his former observations should still be quoted in opposition to the doctrines of Koch, and those who had more recently been working on the subject; and that therefore he felt bound to come forward, and make known the modification which his views had undergone concerning the specificity of tuberculosis.

This public retraction, while withdrawing one of the strongest arguments against the acceptance of the views of Koch, reflects, also, the highest credit upon Dr. Wilson Fox, who has thus frankly acknowledged that the laborious experiments which he had carried out, and which he had thought established important results are now without weight in the settlement of an important pathological question.

INFLUENCE OF DIABETES UPON THE FEMALE GENERATIVE ORGANS.

THE depressing effect of diabetes upon the generative functions of males has long been known. Recently HOFMIER (*Berlin klin. Wochenschrift*, 1883, No. 42) reported the case of a young woman aged twenty, who had come under treatment for pruritus vulvæ, which was found due to diabetes mellitus. Examination discovered the uterus quite small, scarcely two inches long, and the ovaries, under the expert examination of Schroeder, by aid of etherization, were found very much atrophied. As this young woman was otherwise healthy and vigorous, it was thought that this atrophy might be the result of the diabetes.

REVIEWS.

IMPOTENCE IN THE MALE. By WILLIAM A. HAMMOND, M.D., etc. 8vo. pp. 274. New York: Bermingham & Co., 1883.

IT is by no means an easy thing to review a book like this, for, however scientific it may be, it has a flavor of nastiness about it which makes its study more or less like other disgusting matters, which one avoids as much as possible, and gets through with as quickly as he can. It is, of course, important that the medical man who will be thoroughly furnished shall have accurate notions in regard to the causes, phenomena, and treatment of impotence. But opinions appear to differ as to the amount of detail which is essential to a proper understanding of the subject. Sir James Paget, for example, in his *Clinical Lectures* uncovers the unclean thing for a little while, speaks a few earnest words about its debasing causes, judiciously indicates the combination of moral and physical treatment best calculated to overcome it, and leads his reader back into a less trying atmosphere again before the sense of nausea becomes unendurable. The author of the present book, on the other hand, spreads before the reader a long series of cases, in which example follows example of pederasty, masturbation, unnatural sexual indulgence, the trials of impotent husbands, the confessions of weak moral teachers (who, it is to be hoped, will never hear of the book and learn how it all looks in print), the vagaries of sexual monomaniacs, and the ravings of absolute lunatics. If this book be designed to be a text-book—which appears to be the case—and not a collection of curiosities, we think it would have been the better for a little of the disposition which appears in Sir James Paget's method of handling the same subject. To speak plainly, we think the author has made a mistake in dwelling too much on details which are by no means so instructive as they may prove interesting. We fail to see the advantage to the intelligence, and we think we can see a positive disadvantage to the moral sense of too prolonged a contemplation of the impurities into which men have fallen. The sad fact that men thus fall, is now sufficiently established, and its consequences are pretty well understood, and there is no need to dilate much upon either at the present day.

Another feature of this book which we think demands notice, is the lack of any evident reprobation of the various forms of lust which it describes. On page 112, we are told that masturbating *twice a day* (Italics ours) for a boy of fifteen years, "or even one of any age, was pernicious excess." But nowhere does the author lay stress upon the fact that this unfortunate habit, to which so many boys become addicted before they have any idea of its true nature, is, as Sir James Paget says, "a filthiness forbidden by God, an unmanliness despised by men." The same absence of a proper moral tone seems to be observable in the author's references to fornication; and it even seems a reasonable inference from what he says on pages 198 and 199 that he looks upon it as a justifiable prescription to certain patients. Finally, we will conclude our criticisms with expressing our disapproval of both the matter and the manner of the story on pages 82–84.

It is pleasant, now, to turn from what we cannot approve, to what we find excellent in this book. It contains many facts both curious and interesting, and many suggestions which cannot fail to prove valuable to those who read its pages for instruction. The methods proposed for the treatment of the various forms of impotence are simple and rational, and almost all are entirely within the reach of every practitioner. The way the author uses electricity may not commend itself as strongly to others as it does to him; but the hygienic and medicinal remedies are of the greatest value. The author's experience appears to have been, what we could well suppose, very great. From it he has gathered a mass of facts, and drawn a series of deductions, of much value. These he has set down in a pleasing style, and his publisher has given them the benefit of the best work of the bookmaker's craft. With so much to admire, it is a pity that the book should call for the sort of criticism we have felt it our duty to apply to it at the beginning of this review.

THE INCREASE OF INSANITY IN THE UNITED STATES, ITS CAUSES AND SOURCES. By FOSTER PRATT, M.D. Kalamazoo, Michigan: 1883.

THIS paper, which was read at the recent meeting of the American Public Health Association, should elicit the closest scrutiny. It is an attempt to show that the main cause of this increase is to be found in emigration. The author distinctly formulated the contents of the paper in a part of the preamble and resolutions he offered to the Association. It read thus: "*Whereas*, It also appears that the increase of the aggregate of the insane, and of the increased ratio of their production, are caused mainly by the immigration from Europe of persons inheriting the insane tendency, and also by the transmission to their children, born on our soil, of their mental, moral, and physical defects."

In the first part of his resolutions he further emphasizes this view, and seeks to give force thereto by massing together allied, but yet distinct classes, by speaking of "the large number and undue proportion, according to population, of insane criminals and paupers among our foreign-born population," and of "the coming of these foreign defective and criminal people to burden our resources, and to deprave, by the transmission of their defects to their children, the mental, moral, and physical qualities of our present and future people."

The paper not only attempts to sustain this view, by its reference to paupers and criminals as assisted by foreign officials, but also uses this remarkable language: "Officials of European municipalities, having charge of their poor, *believe in the law of heredity. They understand its effects, and the poor family, rich in children but tainted with an insane heredity, and likely or liable to become a public charge, is shrewdly selected by these wise officials to leave their country for their country's good.*" (Italics ours.) Here is a distinct allegation. To prove it, it is not enough to show that some beadles, or poor-house officials, have, in a few instances, been guilty of aiding thriftless persons to emigrate, although this needs to be established by incontestable evidence, and in enough instances to show that it is a crime which has been tending towards a concealed system. Although the terms pauper, criminal, and insane are made throughout the paper to aid and abet each other, these are not to be taken as one. The distinct averment is that those "tainted with insane heredity are shrewdly selected by these wise officials." It would scarcely do to aver that persons insane on starting were sent, since such a statement would at once require the production of names and occasions. The only approach to this assertion is that "the social crank, the religious crank, and the political crank, all come—some voluntarily, and many involuntarily." If the paper had been one before a social science congress, in which it had been claimed that our interests required that poor and thriftless emigrants should be refused, it would have been in order to present the reasons. But it will be noticed that on the main point, that of the selection of "insane heredity to send here," or that involuntary social, religious, and political cranks were sent, we have neither names, dates, nor places, and no proof offered.

The fact of the greater ratio of insane among the foreign population is of itself worthy of study, and has not been overlooked. The reference to Mr. Wines, the accomplished social statist and statistician in charge of this part of the census, shows his appreciation of the fact and of the reasons therefor. He learns, as do we all, that it is well to exhibit the relative ratio. But when we come to speak of causes it is not correct to compare the whole population of the United States, with what, as a rule, must be the poorer classes of population when there is emigration. If to-day 100,000 of our poorer classes, those on day labor in the country, and those in the tenement-houses of our cities, should start for Australia and settle there, it is certain from the proportion of defective and insane that we always find among such classes, that in a few years there would be found more cases of insanity than among the long-settled residents. This does not prove selection and intent.

In the very start, the handling of the statistics is not fair for the purpose for which they are used. The result comes from a variety of influences and conditions as alluded to by Mr. Wines. Those too who have had occasion to get statistics as to the poorer classes coming to asylums find it very difficult to get all the facts so that many are put down as *foreign* insane, whose parents only were foreign-born, and in whom no such heredity has been traced. We have no doubt of the industry, the ability, and the earnest presupposition of the author. What we now ask, is that he place in the hands of the various consuls of European nations representing them in this country or of their ministers at Washington, the names, and date and place of arrival of those who, "tainted with an insane heredity, are likely or liable to become a public charge," and "who have been shrewdly selected by these wise officials." Also the names of the various "cranks" officially or "involuntarily" sent. Even, if only the names of five or ten can be sent at a time, let it be within the next six months, so that the facts may take the form of close evidence before the next annual meeting, and be in the shape of testimony.

Surely it is fair to have the accused see and make answer to the evidence. We suspend judgment on the paper now, but when such evidence is furnished, we believe both home and foreign governments will unite in preventing this official selection of "poor families, rich in children, but tainted with an insane heredity," to send to "the land of the free." And when that allegation is shown to be true, the author will deserve the ardent thanks of the friends both of sanitary and social reform.

Sepulture: Its History, Methods, and Sanitary Requirements. By Stephen Wickes, A.M., M.D. Large 8vo., pp. 156. Philadelphia: P. Blakiston, Son & Co., 1884.

The object of this book is to attract attention to the importance of a proper regulation of the burial of human dead in this country, and more especially in the large cities. In pursuing this object the author has collected a number of interesting facts in regard to the various methods of disposing of the dead which have been in use in different lands and at different times. He has also narrated a number of cases in which the effluvia from burial places has appeared to be the cause of illness or death. He concludes from the evidence before him that rural cemeteries, properly regulated, and permanently extra-mural, afford all the protection that is necessary to the health of the community. Cremation, he thinks, would be proper if hygiene demanded it; but the question of its adoption is not urgent in this country.

SOCIETY PROCEEDINGS.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Special Meeting, December 21, 1883.

The President, S. Oakley Van Der Poel, M.D., in the Chair.

As the time for the stated meeting for December occurred this year on Christmas eve, a special meeting was held on the 21st, in place of it. The minutes having been read and approved, the report of the Comitia Minora, recommending the election of several candidates for resident membership, was read, and the recommendation adopted; after which the resignations of three members were read, and, on motion, accepted.

Dr. H. J. Garrigues then read a paper on

THE PREVENTION OF PUERPERAL INFECTION.

He said in the outset that he had no wish to emulate the author of a brilliant paper which had recently been read before the Academy of Medicine, and would, no doubt, attract very wide-spread attention. All that he wished to do was to state in as simple a manner as possible, without any reference to pathological theories whatever, how he had recently been enabled to avoid the dangers of puerperal infection in his service at the Maternity Hospital on Blackwell's Island.

Many years before Pasteur had propounded the germ theory, or Lister had revolutionized the whole practice of surgery, Semelweis, as early as 1847, had introduced the use of chlorine water as an application before and during labor, in his wards at the Vienna

Hospital, and thereby brought down the mortality to a comparatively low figure. Especially after Listerism had begun its triumphant march throughout the civilized world, did antiseptic measures attract attention in obstetrics; and as early as 1870, Stasburg, of Copenhagen, had employed carbolic acid in this connection. For the past eight years he himself had used this agent for washing instruments and the hands, and for making vaginal injections twice a day during the first week after confinement. So pleased had he been with its effects that, when he was appointed to the Maternity at the Charity Hospital, he had introduced its use there; but he had found out by a sad experience that this was not sufficient to prevent the danger of infection. In private practice it was comparatively easy, as a rule, to avoid this; but the lying-in hospital afforded the only crucial test of the efficacy of any means proposed for the accomplishment of this purpose.

The Maternity on Blackwell's Island was not an independent lying-in institution, but simply an adjunct of Charity Hospital. There were usually about twenty women waiting to be confined, and the pavilions in use are quite inadequate for the number of patients. When infection first occurred in them, the patients were transferred to the general hospital, where the condition of affairs soon became worse than it had been in the pavilions, and the women had to be moved back. In 1875 there had been 517 confinements at the Maternity Hospital, with 15 deaths, a percentage of 2.67. In 1876 there were 536 confinements, with 20 deaths, a percentage of 3.78. In 1877 there were 480 confinements, with 32 deaths, a percentage of 6.67. In 1878 there were 225 confinements, with 7 deaths, a percentage of 3.11. In 1879 there were 254 confinements, with 11 deaths, a percentage of 4.40. In 1880 there were 149 confinements, with 8 deaths, a percentage of 5.37. In 1881 there were 382 confinements with 9 deaths, a percentage of 2.36. In 1882 there were 439 confinements, with 14 deaths, a percentage of 3.25. While none of these deaths were attributable to other causes, there could be no doubt that the great majority of them were due to hospitalism. In the first three months of 1883, when he himself had been the attending accoucheur, there were 108 confinements, and of these patients 11 had died. During the six months of his term of service, from the first of October till the last of March, there were 192 confinements Out of these, 46 of the women, or about one in four were seriously ill, and 39, or about one in five, suffered from inflammatory puerperal disease.

When he came on duty again, the 1st of October, 1883, the condition of the hospital was no better, nine patients having died during the previous month. In the mean while the bichloride of mercury had come prominently into notice as an antiseptic, and he now determined to give it an extended trial. He did not depend on this alone, however, but adopted several other means of preventing infection in addition. In the first place, he divided his service into two departments, one for the well and one for the sick, and also employed rapid alternation in the use of the wards. Each patient was allowed to remain in the pavilion where she was confined for eight days after labor, and was then transferred to the convalescent ward. The doors between the different wards were kept locked, all chinks were carefully filled up, and the doors to the water-closets provided with springs. As soon as a ward was vacated, it was fumigated with burning sulphur, twenty pounds of sulphur being used for the large wards and fifteen for the small ones. Every article of furniture was then washed with a solution of bichloride of mercury (1 to 1000), and fresh bed-clothes and new straw for the beds provided. In all the wards large demijohns of the above solution were kept. For the hands, it was undiluted, or with a small quantity of warm water added to it in cold weather. For use about the patients' persons, the solution was diluted one-half, and in case of post-partum hemorrhage, it was employed very hot. At the commencement of labor, the patient was given an enema and a bath, after which at least two quarts of water containing the bichloride of mercury were injected into the vagina by means of the fountain-syringe. A glass reservoir was used, with a long rubber tube leading from it, to which was attached a straight glass tube. When it was necessary to use a intrauterine injection, a curved glass tube was used instead. In cases of tedious labor, the vaginal injection was repeated every three hours. Both physicians and nurses were required to wash their hands with soap and water, employing a large, stiff nail-brush, and, before touching the patient, to let the hand rest for a minute in a solution of the bichloride. As few examinations as possible were to be made by either physician or nurse, and the former was especially charged not to put his fingers into the os uteri. No emollient was used, except when operations were performed, when glycerine was used in connection with bichloride solutions. It was preferred to carbolized oil, as the glycerine itself was possessed of antiseptic qualities.

When the head appeared at the vulva it was covered with lint, and after the expulsion of the child the genitals were kept carefully covered with the same. The placenta was then expressed by Crédé's method. Intrauterine injections were employed only in cases where it had been necessary to introduce the hand or instruments into the uterus. He never allowed any part of the placenta or membranes to remain in the uterus, and he considered the introduction of even the whole hand (if done with proper care), much preferable to running the risk of hemorrhage or septicæmia by not removing any portion of them retained. The curved glass tube, used for intrauterine injections, was fifteen inches in length, and contained a large opening at the extremity, in addition to eight holes at the side. It differed from Dr. Chamberlain's tube in being of smaller calibre (one-fourth of an inch in diameter), and in having an opening at the end, as well as a greater number of apertures at the side. The advantage of having it of smaller calibre, was that it could be used in cases of abortion where the os uteri was not very largely dilated, as well as at a comparatively late stage of the ordinary puerperal period, when the os had become contracted. The open end permitted the injection to impinge directly upon the fundus, while the numerous holes at the side, all being within a distance of four inches from the extremity, insured the thorough washing of the uterine walls by antiseptic fluid. When the intrauterine tube was used directly after confinement, it was held in position by the fingers, but if at a later period, and signs of inflammation had developed, he was in the habit of first introducing into the vagina a Cusco's speculum, which brought the parts into view, and through which the tube was passed into the uterus. At the Maternity Hospital on Blackwell's Island, diphtheritic exudation was a very frequent result of puerperal injection, and the patches in the vagina could thus be readily observed.

After this digression, Dr. Garrigues returned to the consideration of a supposed case of normal labor. As soon as the placenta was delivered the vulva was covered by the nurse with a piece of lint eight by six inches, doubled on itself lengthwise, so as to make it when folded three inches in width. Over this was placed a piece of oiled muslin nine by five inches, and over this again a large pad of oakum. The whole dressing was then covered with a piece of muslin eighteen inches square, the edges of which were folded over so as to form a kind of boat; the ends of the boat being finally fastened to the binder in front and behind by means of safety-pins. This dressing was put on with the same care that would be used in that of a wound after a capital operation, and it was renewed four times in each twenty-four hours, twice by the day-nurse and twice by the night-nurse. Before changing it the nurse was always required to bathe her hands in the antiseptic fluid. When such a dressing as this was properly employed it rendered all vaginal injections unnecessary, and thus, he believed, one of the greatest dangers of septic infection was avoided.

For, at least, eight days no visitors whatever were allowed to see the patient, and this rule included even clergymen, unless the woman was in a precarious state. Formerly he had found it necessary to exclude from the wards medical men from outside also; but since the introduction of his present plan of treatment, he thought there was but little risk in admitting physicians, and he trusted, therefore, that in the future such clinical facilities could be afforded in this institution as are now felt to be one of the chief wants in medical training in the city of New York.

All the physicians and nurses connected with the lying-in ward were forbidden to enter either Charity Hospital or the dead house. At present he employed carbolic acid only in the case of instruments, as the solution of bichloride of mercury was found to corrode metallic instruments, and also to become weakened thereby. In one or two cases, slight eruptions had been caused by the wash of bichloride of mercury, but in no instance had the use of the drug been abandoned. Some of the nurses complained at first of its making the hands sore, but the trouble was at once relieved by the application of glycerine. Under the present *regime* the lochia were kept sweet, and the wards had entirely lost the unpleasant odor which was formerly so characteristic a feature of them. The vulvar dressing was kept up as long as the patient remained in bed. If there was any case of protracted non puerperal disease, it was removed at as early a date as possible to the wards of the Charity Hospital.

As to the results obtained, he continued, out of ninety-seven cases of confinement since the first of October, not one had proved fatal, and only six of the patients had been at all ill. Of these, two suffered from perimetritis, three from metritis, and one from eclampsia. The latter was the only one who was at all seriously sick, yet some of the labors had been quite severe—two cases of version and one craniotomy being included in their number. In two cases only had there been any rise of temperature; whereas formerly this had been noticed in from one-third to two-thirds of all the cases. The physicians and nurses were now no longer over-worked as formerly, while the patients were bright and cheerful, instead of being despondent. For the good results noticed he was greatly indebted both to the house-surgeon and the head nurse, who had carried out all the details of the plan adopted with great care. The bichloride had great advantages over carbolic acid and other disinfectants. In the first place, it was a much more reliable antiseptic; and, secondly, while free from odor itself, it was an excellent deodorizer. It affected the skin of the hands much less severely, and was also much cheaper. In fact, the whole treatment had been proved to be very economical, for the cost of the materials used was very trifling when compared with that of the immense quantities of quinine, morphia, and whiskey formerly consumed in the wards.

In private practice he thought some slight modifications might be made in the treatment. It would be sufficient to change the vulvar dressing three times a day. When intrauterine injections were necessary a tin tube would be preferable to a glass one, as it was flexible, and this was an advantage in case of abortion.

It might be offered as an objection to this paper that the time in which the plan of treatment had been carried out was too short to prove anything; but he thought the change in the condition of the patients and of the wards was so sudden and so marked that it could be attributed to this cause alone. If the same careful attention were paid to details, he believed that the same good results could be continued indefinitely in the future. Finally, the reports from other hospitals in which similar plans had been adopted, corresponded in the results shown. The secret of success he considered to depend mainly upon (1) the use of the bichloride of mercury as an antiseptic, and (2) the exclusion of the air by the vulvar pad.

Dr. Murray remarked that the paper was of special interest to him, as he had been Dr. Garrigues's immediate predecessor at the Maternity Hospital. In the three months of his service, 96 women had been confined, and out of these no less than 14 had died, although four of the deaths are not attributable to puerperal disease, the exact puerperal mortality was, therefore, 8 out of 96. The fever which he had noticed prevailing was very similar to that which was met with in the lying-in wards of Bellevue Hosptal six years ago. Puerperal peritonitis was seldom seen, but there was a good deal of puerperal diphtheritis. The exudation would commence at the vulva and then extend up through the vagina, but seldom entered the cavity of the uterus. If the disease was protracted for a fortnight, however, it was very likely to involve the uterus. The symptoms are not very marked at the onset of the attack, and the temperature was not often above 100° for the first few days. After that it became more or less intermittent.

If the vulva were exposed at an early period of the disease, one could watch a slight blush come over any excoriations that might be present. Within twenty-four or forty-eight hours (though sometimes a slightly longer period) this would be succeeded by an ashen hue, and the diphtheritic exudation would be sure to be formed. With this immediately ensued typhoid symptoms, and in some cases the patients became semi-comatose. Various kinds of treatment were employed, and carbolic acid yielded fairly good results, although the fever was by no means controlled.

In a certain ward almost every case was attacked with puerperal diphtheria, and though it was disinfected as thoroughly as possible, the same result was noticed afterward. When Dr. Garrigues came on duty a new ward was given him, which had not been used for a year, and he thought that this circumstance might possibly have had something to do with the absence of mortality which he had reported. Thus, in Charity Hospital upon the establishment of the Maternity, it had been generally found that when a new ward was occupied, which had not been in use for some time, there was a great improvement for a week or so. Still, while this might have had some effect, he questioned whether the remarkable results which Dr. Garrigues had spoken of would have been obtained without the strict attention to details of treatment which he had carried out so faithfully. It would be very difficult to do the same in private practice, he thought, yet the material part of the plan might be adopted, and in case there were any lesion of continuity iodoform or a solution of the bichloride of mercury could be applied.

When carbolic acid was applied locally it almost invariably produced a marked tenderness of the part, which was afterwards followed by lack of sensibility. Yet when the slight slough which it occasioned had separated, he had seen a diphtheritic deposit appear and spread to all the points with which the acid had come in contact. Even when the parts had been actually cauterized this had been the case. The difference between a hospital like the Maternity and private practice was so great that to an outsider the strict precautions recommended would seem almost unneccessary.

Dr. W. Gill Wylie said that about six months ago he had read a paper before the County Medical Society on the same general topic, and he was glad to find that Dr. Garrigues did not contradict anything that he had said on that occasion, but only added confirmation to the statements that he had made. He was a thorough believer in antiseptic midwifery, and had commenced to practise it when an interne of Bellevue Hospital in 1871. During his term of service in the lying-in ward he had attended thirty-six confinements, and the only death that occurred was the result of convulsions. Since then he had employed antiseptics in every case which he had had in private practice. It was his plan to wash out the vagina with a solution of carbolic acid (one to thirty, or one to fifty), and to carbolize all the bed-linen. He insisted on having two sets of blankets, and at least thirty-six napkins. He had never had a single case of puerperal fever, and had never even seen any rise in temperature during the first few days after delivery, except in one case, where there was a dry labor, and it was necessary to use forceps.

The only instances of increased temperature which he had met with were in cases of mastitis after the eighth day. He would now use the bichloride of mercury. He could not agree with Dr. Murray in the opinion that there was not much necessity for preventing infection in private practice. A physician might have a long series of cases without any fever, but unless precautions were taken, it was liable to occur sooner or later.

Dr. Gillette remarked that he had been connected with the maternity service of Charity Hospital for twelve years, and he thought that there could be no question as to the importance of all the suggestions which had been made in the paper of the evening, though there might, perhaps, be some discussion in regard to some of the methods proposed. As being the latest germicide. the bichloride of mercury was now highly lauded, and all must bow down to it; though he was not convinced that it was more valuable than some other agents. He had not, however, as yet used it himself. As regards Dr. Garrigues's dressing for the urethra, theoretically it was excellent; but he did not see how it could be of any benefit practically, since it could not be kept in absolute contact with the parts, and hence there was abundant opportunity for the entrance of any germs which might be in the air.

He trusted that the good results obtained by the Doctor would be permanent, but at the same time he thought he ought not to be too sanguine. He was sorry that he had not commenced his account of the Maternity with the year 1875, or just after the obstetric patients were removed from Bellevue to Charity Hospital, in consequence of the fact that puerperal fever had been epidemic in the wards of the former for years, and all efforts to break it up had failed. Finally, the mortality had become so great that this step was resolved upon, and forty patients were transferred to Charity Hospital.

At that time, Dr. Gillette said, he was in sole control of the lying-in wards there, and although the women were saturated with hospital influences, under the effect of extraordinary cleanliness only one case of puerperal fever occurred among them. Nothing was then known of Listerism, and nothing was done in the way of antiseptic treatment except the adoption of carbolic acid baths. During the year six hundred and thirteen confinements occurred, and among the whole number only two cases of puerperal septicæmia were met with. Cleanliness he considered the real secret of success, and he thought the fact that Dr. Garrigues commenced his service in a new ward had no little to do with the good results which he had obtained.

Dr. Alexander Hunter said that he found himself quite in accord with the author of the paper in his views. In regard to the vulvar compress employed, however, he agreed with Dr. Gillette. If the space to be covered were two or three inches in width, he could see how it might be of service, but as in reality the thighs of the patient were ordinarily in direct contact with each other, he did not think it possible for the compress to exclude germs. He then spoke of the superior advantages, in his opinion, of the metallic tube of Dr. Lyman, of Boston, for intrauterine injections, when these were required. He also preferred the Davidson syringe, with its intermittent strain, to the fountain syringe recommended by Dr. Garrigues. In private practice he would be quite willing to dispense with the pad and depend on vaginal injections, together with the partial saturation with solution of bichloride of mercury of the napkin usually laid between the thighs.

Dr. Baruch spoke in unqualified disapproval of all antiseptic injections after normal labor, and proceeded to give his own experience with them. During the last twenty years he had attended some nine hundred cases of confinement, and among them had met every sort of complication. In the whole number there had been but one death preceded by febrile symptoms, and in this he believed that no septic influence was concerned. His experience with prophylactic vaginal injections was comparatively limited, but it had been sufficient to cause him to resolve to give the method a wide berth in the future. It was by the paper of Dr. Wylie, to which he had referred, that he had been induced to make trial of them, and in the next cases which he attended, he made use of an injection of a three per cent. solution of carbolic acid, night and morning. Yet in six cases, which were all faithfully syringed, he met with four which were undoubtedly of septic character.

Dr. Baruch then went on to say that there was now quite a reaction against the use of prophylactic injections in Germany, and quoted from Fehling, of Stuttgardt, and other authors. He thought the objections to their use well founded. In the first place, he held the opinion that the puerperal woman ought to be kept perfectly quiet, and this was impossible when injections were made every few hours. Secondly, it was impossible to make them without giving rise to a certain amount of pain and nervous disturbance. Thirdly, there are very few nurses who know how to give an injection properly. In the fourth place, the injections were liable to displace clots, and thus give rise to hemorrhage, or else open avenues for infection. Finally, they might also loosen adhesions. He believed that simple cleanliness before, during, and after labor, was all that was necessary, as a rule, and that vaginal injections should never be used except in cases where there was danger. In Germany, iodoform pencils, made up with glycerine and starch, had recently been used with excellent results, and their adoption here (two or three only being required in the whole course of the puerperal period), might, perhaps, open a satisfactory way out of the dilemma in which we were placed by the advocates of injections.

Dr. Garrigues then brought the discussion to a close. In regard to the suggestion that the success which he had met with might be attributable in a great measure to the new ward in which he began his service, he said that while it was true that there was one new ward, there were two others which had been in constant use, and each of the three was used for the lying-in-women in rapid alternation. In one of these wards there had been some particularly bad cases, and one of them had ended in erysipelas. He agreed with Dr. Wylie as to the necessity of taking every precaution even in private practice here in New York, where the skilful obstetricians met with cases of puerperal fever. In regard to the vulvar dressing, he said that it had been designed with special reference to the parts to which it was to be applied, its width being really just the distance between the thighs, and it had seemed to him to serve a very admirable purpose when properly adjusted. Dr. Gillette had not understood him correctly, for it was in the year 1875 that he had commenced to give the statistics of the lying-in department of Charity Hospital, and it was from Dr. Gillette's own report that he had quoted the figures of that year—five hundred and seventy confinements and fifteen deaths; which was certainly a great improvement over the previous mortality at Bellevue.

(Dr. Gillette had left the hall before the time of Dr. Garrigues's closing remarks.)

As a rule, he was strongly opposed to intrauterine injections by way of prophylaxis, but after labors in which the hand or instruments had been introduced into the uterus, or where there was a dead child (one which had been dead some time), he thought they were advisable. Vaginal injections he did not think so dangerous, especially in private practice; but with the compress which he had described they became superfluous. One of the great advantages of the use of the latter was, that the nurse had very little to do with the genitals. Tarnier, of Paris, was the first to use bichloride of mercury in obstetric practice, in June, 1882.

COLLEGE OF PHYSICIANS OF PHILADELPHIA.

Stated Meeting, December 5, 1883.

THE PRESIDENT, ALFRED STILLÉ, M.D., IN THE CHAIR.

DR. CHARLES W. DULLES, presented some

CRITICISMS ON THE SPECIFIC THEORY OF HYDROPHOBIA.

The theories as to the nature of hydrophobia, he said, are contradictory and illogical; the teachings as to its treatment are without the slightest hope of success. In regard to both, the ablest men who have discussed it occasionally or systematically are in irreconcilable opposition While some hold to certain modes of communication, others strenuously deny them. While some admit its spontaneous origin, others will not admit it for a moment. While some think the virus is to be found in the saliva, the blood, the bronchial mucus, the milk, the flesh of rabid animals, others limit it to the first of these alone. In regard to the period of incubation the widest divergence of opinion exists. The range is from one day to forty years, and no one seems to have been able to fix a limit to either its shortness or its length. Equal contradiction meets the gaze when one turns to the matter of treatment. From the throwing into a fish-pond, as practised by Celsus, to the inhalation of oxygen, as recently practised by Drs. Schmidt and Zebeden, there is a variety of methods which demonstrates how utterly every attempt to find a specific has lacked the guidance of any accurate idea as to the nature of the disorder. To almost any statement of men whose names are highly respected in medicine, may be opposed the most positive and contradictory statements of others equally respected.

The prepossession of a theory which, at the outset, demands a certain surrender of the judgment will impair the freedom of the judgment at every subsequent step. Such, it seems to Dr. Dulles, is the condition in which every believer in the specific nature of hydrophobia stands. The assumption of a specific virus which, and which alone, is the originator of the disease in any individual compels its adherents to bend their judgment to accept the belief that there is a virus which behaves in a way contradictory to that of every other virus about which we have any positive knowledge.

One might suppose that such a contradiction would lead observers to be constantly on the look-out to find some other way of explaining the phenomena of hydrophobia, and that everything that was presented as evidence in support of it would be subjected to the most rigid scrutiny. But the literature of the subject shows that the very opposite is the case. The *post hoc propter hoc* argument is the one which rules here. A careful perusal of a large number of recorded cases leaves the impression that they have not been studied with any idea that they might be something else than what they appeared to be. Though it is no secret that the dread of water is a symptom of a great variety of affections, one finds over and over again the ablest men resting a diagnosis on this which is acknowledged by most systematic writers to be the least reliable of its signs. Another thing which has struck Dr. Dulles in examining the records of cases is the readiness with which reporters, aware of the objection, so often raised, of the effect of mental influence, accept the statements of friends or the silence of patients in regard to it as evidence that it does not exist.

Another curious thing, to be observed in the literature of hydrophobia, is the way in which the madness of the dog is often—one might say usually—deduced from the diagnosis of hydrophobia in the man; instead of the diagnosis of hydrophobia being made to rest upon reliable evidence that the dog was really mad. It is uncommon to find any proof whatever that a dog to which hydrophobia is attributed was rabid, this being, with rare exceptions, a pure assumption. The one phenomenon of a dread of water usually determines the conviction of the physician that he has a case of hydrophobia before him, and settles his opinion of any dog that may ever have bitten the patient, and cannot now be accounted for. Nay, more, this mode of reasoning has led certain writers to the assertion that there may be a passing state in dogs in which they may communicate to a human being hydrophobia, but themselves recover. Thus is the struggle to support the specific theory kept up when circumstances seem to be most adverse to it.

Dr. Dulles finds in the recorded cases—with very rare exceptions—that, when once hydrophobia is suspected, every phenomenon that occurs during life, every lesion that is found post mortem, is unhesitatingly set down as a feature of this disorder; and the idea does not seem to be entertained that many of them are grounds of suspicion that some other disorder is present. In this way, all lines of distinction between hydrophobia and disorders which simulate it are erased; and it remains for every medical man who is called to a patient who has a dread of water, accompanied with exaltation of reflex excitability, to inquire for a bite or scratch of a dog or cat; if one cannot be drawn out, to assume that it has been received and forgotten; then to make a diagnosis of hydrophobia, after which it is only necessary for the patient to die, to make a complete record. If to this be added a careful microscopical examination of the state of the brain and spinal cord, the observer will have an exact counterpart of the process by which the famous conclusions of certain investigators—often quoted by those who have not taken the pains to go to the evidence upon which they are founded—were arrived at.

Concerning the pathological lesions of hydrophobia, he said that they all tend to confirm the opinion that as yet no gross or microscopical lesion has been discovered which can be regarded as pathognomonic of rabies or hydrophobia.

In closing, he said, "I have now been engaged for nearly two years in a laborious study of the evidences upon which the general belief in regard to hydrophobia rests, and I have been gradually led to certain convictions different from those with which I started, and which I feel it my duty to make public. One of these is that hydrophobia is not a specific, inoculable disease, derived from the bite of a similarly affected animal. Another is that if we wish to have an accurate, scientific knowledge of what too often actually takes place, and is usually called hydrophobia, we must begin the study of it unprejudiced by the views heretofore generally entertained in regard to it, and with canons of criticism very different from those heretofore deemed sufficient.

"I know that these convictions are not novel, and that they have been stated and defended with arguments before. I know, too, that they have heretofore failed to secure the assent of the greatest men, who in every generation have adorned the profession of medicine. None the less, however, do I believe them to be true, and that the time will come when they will not be —as they have been in the past—characterized as too absurd to be discussed, or decried as too dangerous to be tolerated."

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, December 20, 1883.

The President, Fordyce Barker, M.D., LL.D., in the Chair.

Dr. Charles Heitzman read a paper entitled

A REPORT ON THE PROGRESS OF BIOLOGY IN EUROPE.

He commenced by saying, that when in the years 1872 and 1873 he enunciated his new views, doing away with the universally accepted doctrine, and substituting a different structure, both for single elements and the whole animal body, he did not expect an immediate approval by the entire scientific world. In order to make out satisfactorily this newly described structure, both an unusually well trained eye and unusually good lenses were required.

One of his very first claims, he said, had been in regard to protoplasm, which had always before been regarded as structureless, but which he had found to have in reality a well-marked reticulated structure. He had claimed that this network building up the nucleus and the nucleoli was the living matter. The second proof to him was that all new formation started from the points of intersection in the living matter. In consequence of the novelty of these views, he had been very anxious to learn what the opinion of the best microscopists in Europe was in regard to them. Many, he found, had adopted them, but there were some exceptions, such as Klein, of London, who had objected to his assertion that the contained substance was liquid, while the whole was ensheathed by a continuous membrane of living matter.

Many years ago Beale, as was well known, claimed that the nucleus alone consisted of germinal matter. To-day, he continued, we saw that the nucleus was nothing more than the reticulum in more compact form. The reticulum was especially prominent in mucous elements, but in every instance the very best lenses were required in order discover it.

Having referred to the objections of Spina, of Prague, he went on to say that in 1872 he had announced, contrary to the views of the advocates of the cell doctrine, that the so-called intercellular substance was not destitute of life, but endowed with the same life as the ensheathed elements. He had demonstrated this first in cartilage, and in order to do so had employed unusual agents, such as nitrate of silver and chloride of gold. On this was based a new view of the structure of the whole animal body. If the so-called cells were of the same structure as the intermediate or basis structure, the whole being was the same uninterruptedly from the crown of the head to the sole of the foot. The facts on which this theory was based were now acknowledged by many observers.

Spina, of Prague, had demonstrated, by his observations of the omentum of the frog, the undulating motion in the basis substance, and in his last publication he had definitely announced that the time had now arrived to give up the cell doctrine. Stricker, in the last volume of his *Pathology*, gave a chapter to the explanation of all the facts bearing on the matter, in which he agreed with himself, and gave him full credit for his discoveries; distinctly admitting that there was no difference, as regards life and the power of reproduction, between the reticulum and the cells proper.

Both Recklinghausen and Stricker now denied the wandering corpuscles of Cohnheim. From his own researches he had seen enough to convince him that there were in reality no migrating corpuscles. If, therefore, his views are correct, the whole subject of the pathology of inflammation would have to be altered. Stricker had contended for twelve years against Cohnheim's teachings, and in 1873 he had called attention to the point that pus never produces new tissue.

Then passing on to the subject of tuberculosis, he said that experiments had been made in Vienna which fully confirmed his own views on the subject. In 1873 he had stated that from the examination of the lungs of three hundred persons who had died of tuberculosis, he believed it to be a strictly constitutional disease, and later he had declared that the whole trouble could be explained on the ground that it occurred only when there was already a lack of living matter for the reproduction of blood corpuscles. In tubercle there are no bloodvessels whatever. It seemed to him that the growth which Koch called bacillus merely found a favorable place for development in those affected with tuberculosis. He himself had observed that the mucus from the nose of a perfectly healthy individual, when allowed to stand for a few days, swarmed with the tuberculous bacillus. When he was in Stricker's laboratory in Vienna, there was not the slightest doubt that the bacillus was not the cause, but a product of tuberculosis. But this view, he acknowledged, was held in Vienna alone. In Berlin all were fully convinced that the bacillus produced tuberculosis; and the same was also true in regard to London. At present, therefore, the question was one which did not as yet permit of a conclusive settlement.

In conclusion, he said that he had reason to be pleased with the results which he had observed in Europe.

Dr. William H. Welsh stated that he was at variance with Dr. Heitzman in regard to almost every point upon which he had touched. In regard to the structure of protoplasm, he thought that Frohman was clearly entitled to priority. It was true that he had not described its distinctly reticulated character with the same fulness as Heitzman, but he had first pointed out the existence of fibrillæ. In regard to the character of the nucleus, in the next place, he could not at all agree with Dr. Heitzman. To him, as to most observers, it appeared to be of an entirely different nature from the surrounding structure. But the essential point of Heitzman's theory was the structure of epithelial tissue. This was a question that was still *sub judice*, and he thought that the general verdict of microscopists in regard to the new doctrine at the present day would be, "not proven." Heitzman and Stricker stood almost entirely alone in their peculiar views as yet. Finally, he took issue with Dr. Heitzman in regard to the subjects of tuberculosis and inflammation.

Drs. Elsberg and others then spoke, and the discussion was brought to a close by Dr. Heitzman, after which the Academy adjourned.

NEWS ITEMS.

BERLIN.

(From our Special Correspondent.)

A Second Cholera Report from Koch.—A second report of the Cholera Commission, dated Suez, 10th of November, mainly confirms the former statements. The last post-mortem examination, made in Alexandria, furnished the same bacilli in the intestinal walls as were before noted, but the inoculation-experiments, although modified and multiplied in every way, were equally of no result whatever.

The Commission then left Alexandria for Cairo, Damietta, and Suez. At all these places important inquiries were made about the origin of the last epidemic, the results of which, although seemingly quite positive, are spoken of with due reserve. Of the greatest epidemiological interest was an excursion on board the Egyptian steamer "Damanhur," bound, with hospital equipment, for the quarantine harbor at Tor. Five hundred pilgrims, coming from Djedda, reached this place the day after the arrival of the Commission. Although the ship-surgeon declared them all healthy, a certain number proved ill from choleraic symptoms, and were immediately sent to the quarantine hospital. Returning from a trip to El Wedj some days later, the Commission found that another ship had arrived also with some sick pilgrims, and that the cholera had broken out in both camps, three pilgrims from the first, and one from the second ship having died. A thorough disinfection followed this excursion.

During their sojourn in Egypt, Dr. Koch and his assistants have attentively studied the water-supply and filtration, the influence of the level of the Nile upon the course of the epidemic, the methods of interment, the pollution of the soil by cesspools, the meteorological conditions, etc.

Valuable researches were also made on dysentery, on the prevalence of tuberculosis in Egypt, and on some parasitic diseases (Distoma hamatobium, Anchylostoma duodenale, Filaria sanguinis).

Egyptian Ophthalmia.—The examination by the Commission of fifty cases of Egyptian eye-disease gave evidence that two different processes are confounded under this name. The one, of a more malignant character, is caused by a species of bacteria, similar to, and perhaps identical with, the micrococci of gonorrhœa. The other form, less serious, is characterized by the presence of very small bacilli in the interior of the pus cells.

The members of the Commission express themselves very much indebted to the Khedive for having granted them the opportunity to visit the quarantine harbors.

CINCINNATI.

(From our Special Correspondent.)

The Holiday Vacation.—Our medical colleges have closed for a vacation of two weeks. The societies, also, will hold no sessions until after the holidays.

A New Hospital for Children will be opened on New Year's Day. It is to be known as the Episcopal Hospital for Children, and will be under the supervision of a board of managers consisting of ladies from the Episcopal churches of the city. Dr. William Carson will take charge of the medical cases, and Dr. N. P. Dandridge, of the surgical. The building appropriated for use as a hospital was formerly a residence, and is located in East Walnut Hills, a delightful place for it, but so far removed from the more densely populated parts of the city that its usefulness, especially to the poor, will necessarily be limited.

The Children's Hospital that was established a few months ago, and to which reference was made at the time in The Medical News, is doing all that was anticipated of it, and it has been filled almost to the limit of its capacity ever since it was opened.

Scurvy in the County Jail.—Several cases of scurvy have occurred of late in the Hamilton County Jail, in this city. Aside from the clinical interest arising from the appearance of a disease so rare in this part of the world, the cases are arousing still greater interest because of the ill-treatment of the prisoners, which their occurrence implies. The chief diet of the prisoners has been soup, salt meats, and corn-bread, with almost no vegetables. These articles, the prisoners say, were prepared so as to be palatable, but were so deficient in quantity as to leave them in constant hunger.

The Ohio State Sanitary Association will hold its first meeting in Columbus, February 14th and 15th. It is anticipated that some action will be taken toward securing the appointment of a State Board of Health.

BOSTON.

(From our Special Correspondent.)

Hospital for Incurables.—Another charity whose inauguration was also mentioned in The News at this time last year, is the Hospital for Incurables. This institution, whose scope and work thus far are very similar to those of the Philadelphia Hospital for Incurables, was established by a lady whose life for many years has been wholly and incessantly devoted to work among the poor—Miss Cordelia Harmon—and who lived only six months after having thus nobly crowned her unselfish life. Resources, she had absolutely none. Nearly the entire amount by which the hospital thus far has been supported was raised by Miss Harmon alone. She engaged and furnished the house during the rare intervals of leisure in her busy life, and since the hospital was opened it has, in a small way, been a success. Sixteen patients, all of them women, have been received. But the necessities of the public are so pressing that a meeting was called this week to disscuss the feasibility of enlarging and developing this vigorous nucleus. A preliminary committee was appointed, with authority to form a new organization, consisting of managers, and visiting committee, and other lay officers. Since Miss Harmon's death the administration of the charity has rested wholly upon one or two individuals, who are responsible to nobody. All this will be changed, the hospital will be incorporated, and a call made for funds in such amount as will at once give the institution a strong basis and permanent status. The need of such a refuge on a large scale is sadly apparent in Boston. The City and Massachusetts General Hospitals, by their charters, are not allowed to give admittance to chronic cases. During the past five years the first of these hospitals has refused admittance to more than *thirteen hundred* "incurables." The Massachusetts General Hospital does not so strictly classify cases refused, but does record a yearly average of five hundred persons who could not be admitted because in condition of chronic disease.

The public need of a hospital for incurables in this city has been publicly recognized by the Trustees of the Massachusetts General Hospital, who, in their report for 1881, published in 1882, express their sense of this need, and also their willingness to receive funds toward the establishment of a hospital. This position of the trustees has heretofore been somewhat of a stumbling block in the way of the friends of the Harmon Hospital, for they found that the public were waiting to see what the Massachusetts General Hospital intended to do for incurables, and, therefore, in many cases, refused to contribute to the younger hospital. They naturally preferred to help incurables through the older institution. Becoming aware of this, and considering the obstacle to their own success a serious one, the workers for the little hospital for incurables now in operation, appealed to the Trustees of the Massachusetts General Hospital, asking their protection for the infant hospital. After due consideration, pending which the matter was referred to a special committee, the Trustees formally declined to accept the younger hospital, and for the following reasons:

At Somerville, the Massachusetts General Hospital has two hundred insane patients in a locality which formerly was one of great beauty and extreme quietude. Progress has encircled this place with railroads and factories of various dimensions, which have succeeded in converting this peaceful retreat into a most unhygienic pandemonium. The trustees of the hospital, therefore, feel it a matter of duty to move their insane department to their lands in Belmont, in which town their Convalescent Home is now in operation. To do this will involve a large outlay. There was a period during which the Somerville property, if it had been converted into cash, would have gone far toward meeting the cost of new buildings at Belmont. As it is, however, the Somerville real estate has largely depreciated in value, and consequently nothing can be done for the insane patients of this hospital until more funds have been raised. For this reason the trustees feel that while this prior claim upon their treasury exists, they cannot appeal to the public for funds on behalf of the generally incurable. If they ask at all, it must be for the insane. For years to come then they can give no thought to the care of incurables. The day may come when they can see their way to doing so, but they have left the hospital for incurables to do its best independently of their protection. It is hoped that this decision may become generally known, for it would thus both directly and indirectly be a help to the new hospital. The public would soon learn that incurables were to be cared for by only one institution and their money would flow that way.

The subject of further accommodations for consumptives (for whom there is at present inadequate provision) is also being agitated. Many, however, feel that it would be a mistake to multiply the number of small institutions. The proper course would be a generous contribution to the hospital for incurables, say half a million of dollars. This would make it perfectly easy to provide for consumptives as well as for general cases.

Egyptian Rags.—Surgeon-General John B. Hamilton, of the Marine-Hospital Service, has made arrangements, through the State Department, for the thorough disinfection of all Egyptian rags stored in Alexandria, and bound for the United States. This disinfection is to be performed before the rags are shipped, and will consist in steaming them, and subjecting them to such other disinfectants as may be found necessary to purify them.

Medical Legislation in New York.—We are informed that, at the ensuing meeting of the State Assembly of New York, a bill is to be introduced at the request of the Buffalo Medical Society, providing for a State Medical Board which shall have the sole power to issue licenses to physicians to practise in the State. The Board is to consist of six physicians, two homœopathic practitioners, and one eclectic member. It is now stated that the irregulars, while favoring the general purposes of the measure, are already preparing to oppose the bill unless more equitable representation is granted their school.

Large Damages for Libel.—Last year Dr. McLean, Demonstrator of Anatomy in the Medical Department of the State University, and a well-known surgeon, was charged with criminal relations with a lady patient from Canada, who sought his advice, the publication being made in *The Evening News*, an afternoon paper of Detroit. Dr. McLean sued the newspaper for libel, which it undertook to justify, but the jury rendered a verdict of $20,000 damages. The case was appealed to the Supreme Court, which last week affirmed the judgment of the Court below.

New Medical Baronets.—The Queen has conferred the honor of a baronetcy on Mr. Joseph Lister, F.R.S., F.R.C.S., and Mr. William Bowman, F.R.S., the eminent ophthalmologist.

Prof. Owen.—Prof. Owen's state of health and his advancing years have necessitated his resigning his appointment as Superintendent of the Natural History Departments of the British Museum, which he has held with so much distinction for more than a quarter of a century. Prof. Owen's services to science are well known. In the questions which now perplex and divide biologists, he has maintained the position of a conservative naturalist of the pre-Darwinian epoch, and been regarded as somewhat behind the age. But all his contemporaries will acknowledge, and the most eminent of them most readily, that his place is among the foremost of those who have illustrated science and advanced its pursuit in England.

International Congress at Rome.—The European powers have signified their acceptance of the invitation to meet at Rome for the purpose of holding a Sanitary Congress.

Professor Pajot.—By a decree of November 17, M. Pajot, Professor of Midwifery, has been transferred at his own request to the Chair of Clinical Obstetrics, recently made vacant by the death of Prof. Depaul.

German Liberalism.—A French journal, *L'Hygiène Pratique*, has been recently interdicted in Germany in the following words: "This journal, founded in 1882, and edited by a committee of savants and vulgarians, such as MM. Pietra Santa, Camille Flammarion, Louis Figuier, W. de Fonvielle, Henri de Parville, Félix Hément, Dr. E. Monin, Dr. Ed. Barré, etc., is applied solely to the popularizing of sanitary science without treating at all of questions of policy." This action, says a French journal, is only to be explained by the inconceivable hatred for every thing that is French.

ORIGIN OF THR WORD "CHARLATAN."—It is generally admitted that the word "charlatan" is derived from the Italian word *Ciarlare*, to chatter, to prate. It appears that up to the 16th and 17th centuries the word was pronounced "chiarlatan." A German journal gives its etymology differently: a Paris physician, Latan, went through the town in a chariot containing his drugs, and in which he examined his patients. This caused the expression "Voila le Char de Latan," which was subsequently corrupted into "charlatan."

VITAL STATISTICS OF ENGLAND.—The quarterly return of marriages, births, and deaths in England, ending September, 1883, shows the resident population of the United Kingdom to be 35,639,060 persons; that of England and Wales being 26,770,744, of Scotland 3,825,744, and of Ireland 5,042,572. Total births in the United Kingdom 271,892 children, deaths 148,827, and marriages 119,428. Birth-rate, 30.3; death-rate, 16.6; marriage-rate 13.4. The annual death rate from diarrhœal diseases as compared with continental cities is given as follows: In twenty-eight large English towns, 2.1 per 1000; Breslau, 8.2; Munich, 8.4; Brooklyn, 8.7; Berlin, 11.3.

PHOTOGRAPHY IN HOSPITALS.—A photographic studio has now been attached to most of the French hospitals, for photographing the sick persons at different times. The rapid dry-plate process is employed. An electrically operated camera, devised by Prof. Charcot, of the Saltpêtrière, is very useful in taking, in rapid succession, a series of views.—*Med. Times and Gazette*, Dec. 1, 1883.

HEALTH IN MICHIGAN.—Reports to the State Board of Health for the week ending December 15, 1883, indicate that puerperal fever has increased, and that intermittent fever, influenza, remittent fever, rheumatism, and inflammation of bowels, have decreased in area of prevalence.

Including reports by regular observers and others, diphtheria was reported present during the week ending December 15th, and since at twenty places; scarlet fever at eighteen places; and measles at twelve places.

NOTES AND QUERIES.

THE METRIC SYSTEM.

To the Editor of THE MEDICAL NEWS.

SIR: In reading a letter of Dr. Prentiss in THE MEDICAL NEWS, on the use of the metric system of weights and measures in prescribing, one cannot fail to perceive what perfect exactness ought to ensue from its adoption, if grains, drachms, scruples, etc. could be suddenly annihilated and erased from the tablet of our professional memory. Alas for the "if"! As Touchstone says, "There's great virtue in an if." The metric system at present does not give that boasted exactness which it ought; and for it to be attained, the old system must be wiped out utterly, the whole mass of medical literature revised; in fact, we must forget that there ever were such things in existence as grains, scruples, etc. Until such a state of things does come to pass, which is highly improbable, the metric system fails to be an exact one in prescribing, and is only an approximate one. In the District of Columbia there are but few druggists who have and use the metric weights and measures. That they all pride themselves on being able to translate or convert one system into the other is true, and it is just here lies the error which makes the metric system an approximate one instead of an exact one.

Take the first prescription of Dr. Prentiss:

R.—Morphiæ Sulph.	1 06
Hydrat. Chloral.	6 00
Syr. Aurant Cort.	25 00
Aquæ,	*ad* 100

In looking over ten tables, giving the equivalent of a grain in centigrammes, I find seven different values, the lowest, 0.05; the highest, 0.07; and for the ounce, four values, the lowest, 30, the highest, 32 grammes.

Now in the prescription above, the druggist must work back the centigrammes into grains, if he have not the weights, which he generally does not. In fact, it is a question if three druggists would produce the same result. One might get less than a grain if he takes .07 — 1 grain; a second, a grain if he takes .06 — 1 grain; and a third, more than a grain if he use .05 gm. as equivalent for a grain. The amount in either case would be an approximate one; the difference small—not enough to do harm, but possibly enough to prevent good. The physician is in the same condition of perplexity if he wishes to write for a grain in the metric system. From one table of comparative equivalents he will find his grain = .05; in a second, .06; and in a third, .07. By the time the physician has settled upon his equivalent, and then the druggist upon his, it will take some time to find out the unknown quantity in the prescription. These are well worn and old objections, but I think they still remain opposed to the reputed exactness of the metric system. In fact, upon the blank form of the doctor's, the statement 1 grain or 1 minim = .06, as explanation of how the metric system may be utilized, is not exact, but a close approximation.

C. F.

To the Editor of THE MEDICAL NEWS.

SIR: In your issue of Nov. 24th, I notice an answer by Dr. Prentiss to a protest against the use of the metric system in prescribing. I think he neglects some of the beauties and simplicities of the metric system, and venture to criticise the critic.

I think his prescription looks better in this shape:

R.—Morphiæ Sulph.		10
Olei Menth. Pip.		50
Acid. Hydrocyan. Dil.	1	
Chloroformi,	3	
Tr Cannab. Indic.	20	
Tr. Capsici,	20	
Glycerini,	20	
Alcohol,	*ad* 100	

M. S. 10 cc. every four hours, etc.

Medicine glasses graduated to five, ten, and twenty cubic centimetres could be used, and should be used when active and dangerous remedies are prescribed.

Even if dessertspoonfuls are ordered, there can be more "rounding off" in the prescription of Dr. Prentiss; for instance, 3 50 and 25, instead of 3.60 and 24. This would be easier for the druggist, and more in the spirit of the metric system. When this system is used, it is certainly simpler to order five, ten, or twenty doses, of five, ten, or twenty cubic centimetres each, than ordering eight, twelve, or sixteen doses. The amounts are more easily ascertained, and it is more "metric."

Again, in writing for a five per cent. solution of carbolic acid, I would write:

R.—Acid. Carbolici,	5 grammes,
Aquæ,	95 "

Not 100 grammes of water, as Dr. Prentiss directs.

As long as the use of the metric system is not compulsory, its use in prescribing will, I think, remain very limited.

Respectfully,

E. F. TIEDEMANN, M.D.

O'FALLON, ILL., Dec. 3, 1883.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*
